LUXURY IN THE BRITISH HOUSE OF PARLIAMENT. — An editorial of the London *Daily Telegraph* furnishes the following: "Now that Roman luxury, invading the once austere precincts of Parliament, has added baths for the use of members to the Palace of Westminster, a result which might fairly have been predicted has duly followed. The speaker's secretary has received a communication from a professional 'masseuse,' who suggests, enclosing her card, that arrangements should be made to provide members with facilities for obtaining the treatment of massage, which would, she says, be found 'a great recuperative agent to the nervous system after a great mental strain following on a long debate.'"

EUROPEAN BACTERIOLOGISTS VERY BUSY. — A Berlin correspondent writes as follows to the New York *Sun:* "This is no time for young bacteriologists to come to Europe for instruction. The men foremost

in that field of science are too busy with their investigations to give lectures. A young bacteriologist who has been hanging around the University of Berlin for a couple of months, catching up any scrap of information that his professors might be good enough to let drop, and looking through microscopes in the hope of discovering something that he didn't know before, went off to Paris to see if he could find some one there who would stop his investigations long enough to give him instruction. He found even a worse state of affairs there. The scientific men of to-day who are making investigations in bacteriology are as feverish as were the prospectors for gold in California half a century ago."

Two Simple Expedients. — Dr. Cocksedge, of Wales, places the following "tips" at the disposal of his brethren (*Medical Press*): If you have a fatiguingly deaf patient to talk to, place the ear-pieces of your binaural stethoscope in the patient's ears, and talk into the chest-piece, and you have an excellent ear-trumpet. If you leave your spectacles at home, being old and a presbyopic, make a hole with a pin in the corner of your visiting card, and you can read your clinical thermometer or anything else.

Intravenous Saline Infusions. — At a recent meeting of the New York Surgical Society, reported in the *Annals of Surgery*, Dr. Dawbarn stated his opinion that the amount of fluid usually recommended for intravenous infusion in hemorrhage was ridiculously small. A smaller amount than a quart will seldom be of much use, and in bad cases this should be repeated several hours later, as indicated. It is a bad rule to replace the blood lost at an operation only by an equal amount of salt water. The inward bleeding from shock, especially into the patient's own veins should not be forgotten. The chief advantage of infusion is the effect of the bulk of the fluid, which makes possible effective action of the heart.

Antitoxin in Ocular Diphtheria. — Dastot (*Annales d'Oculistique*, January, 1895), apropos of a second case of ocular diphtheria successfully treated by antitoxin, writes as follows: "It is superfluous to dwell longer on the important rôle played by sero-therapy in the treatment of ocular diphtheria. Thanks to the injections of antitoxin, we are henceforth in a fair way to check the invading progress of pseudo-membranous exudates. Better still, the last two stages of the malady may be suppressed, with all the dangers that accompany them. In short, with this new treatment, when the false membrane has once disappeared the disease itself is conquered. If treatment is begun at the proper time it will not be forty-eight hours before all the menacing symptoms have disappeared, and the physician will be gratified by the rapid and complete recovery."

The Newest Thing in Medical Titles. — The British nurses who are seeking to obtain official recognition and registration on the same lines as medical practitioners, are meeting half-way the legislation for that purpose which they so much desire by adopting a distinctive title, says the *Medical Press*. M.R.B.N.A. is the affix which they append to their names, and it is to be interpreted as Member of the Royal British Nurses' Association. The day is soon coming when clinical reports will read something as follows: A case of —— reported by A. Jones Smith, M.A., M.D. (Oxon.), F.R.C.P., and B. Jenks Robinson, M.A., M.D. (Cantab.), F.R.C.S., in which the successful result was largely due to the faithful and untiring efforts of the nurse, Miss Sarah J. Gamp, M.R.B.N.A., etc.

Abuse of Medical Charity. — A remedy for the abuse of medical charity is offered by a "Young Subscriber" in a letter to the *Medical Record*. He suggests that the victim of such abuse "the next time, and whenever he has need of a consultation or has a patient to send to a specialist, avoid the man who daily robs him by indiscriminate dispensary work and pick out instead one who regards the rights of his fellows. There are men at the heads of dispensary classes throughout the city enjoying large special practices who boast that they have no care for the financial standing of their dispensary cases so long as they furnish the required material for clinical purposes; and as for the complaining doctors they say, 'let them go and be blanked.' So long as they can do this and keep the support of the general practitioner they will hold the same views. The moment they find it affecting their pockets they may at least cease to pride themselves upon their dirty treatment of their professional brethren. Let the non-dispensary men look to their rights and they will soon have less wrongs."

### BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — During the week ending at noon, March 20, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 70, scarlet fever 56, measles 92, typhoid fever 4.

A New Hospital for Contagious Diseases at Brookline, Mass. — A hospital for contagious diseases has been built by the Brookline Board of Health at an expense of $5,000. The hospital stands on high ground, and has plenty of open space about it. The buildings are of wood, single-story, pavilion style, each having three small wards, with a hallway through the middle of the building, a kitchen, cellar and attic, and can together accommodate from twenty-five to thirty patients and attendants. The walls are plastered with Windsor cement, to permit of easy and thorough cleansing, and all the rooms except the kitchen have open fireplaces. The smaller building is for diphtheria patients and the other for scarlet fever. There is also provided a probationary ward.

Antitoxin in Connecticut. — The Secretary of the State Board of Health of Connecticut announces that a bill has been submitted to the legislature looking to the protection of the public, from imposition by the sale of spurious or inefficient antitoxin products,

that may be offered by unscrupulous dealers. It is the purpose of the bill to provide some guarantee for the quality of whatever may be found in our markets.

NEW YORK.

CORONERS IN NEW YORK. — The select committee of the Medico-Legal Society of New York to whom was referred the Senate Bill No. 81, "An Act to amend title four hundred and ten of the Law of 1882, entitled an Act to consolidate into one Act and to declare the Special and Local Laws affecting Public Interests in the City of New York," so far as the same relates to coroners, have reported to the legislature as follows: (1) That they approve of the bill, and recommend its passage; (2) That they recommend that the coroner so to be hereafter chosen should be a counsellor-at-law of at least ten years' practice; (3) That they recommend that the medical examiners shall be skilled in medico-legal science and selected with regard to their professional fitness and without reference to political considerations; (4) That they recommend that line 20, section 1779, of the proposed bill be amended by changing the words "Police Justice" to the words "Justice of the Supreme Court," as the office of Coroner in their judgment under the law should rank with that of a Justice of the Supreme Court.

MEDICAL EXAMINATION BY PROXY.—During the past week the examination was held by the Board of Regents of the University of the State of New York of such first-year students of medicine as had not been graduated from a registered college or satisfactorily completed not less than a three years' academic course in a registered academy or high school. This is in accordance with the new law regarding the conferring of the degree of bachelor or doctor of medicine, and the studies comprised in the examination are: arithmetic, elementary English, geography, spelling, United States history, English composition, and physics. On March 13th it was discovered that two of the applicants had appeared under assumed names; one representing a student of Bellevue Hospital Medical College and the other a student of the College of Physicians and Surgeons. It is said that those concerned in the fraud will be black-listed in all the medical colleges of the State and that they may perhaps be criminally prosecuted by the Medical Society of the County of New York.

A TETANUS ANTITOXIN.—At a meeting of the Medico-Legal Society held March 13th, Dr. Paul Gibier, of the New York Pasteur Institute, read a paper in which he claimed to have discovered an antitoxin, prepared from the cultivation of the bacilli of this disease, which had proved successful in both the cure and prevention of traumatic tetanus. He exhibited specimens of the bacilli of tetanus under the microscope, and expressed the opinion that these germs were indigenous in all parts of the world inhabited by man or beast. The horse, he stated, more than any other animal, even man, was susceptible to this disease, and this could readily be accounted for from the fact that the filth of the stable offered the most favorable conditions for the development and multiplication of the tetanus bacilli.

PROGRESS OF THE TENEMENT-HOUSE COMMISSION'S BILLS.—It is gratifying to learn that one of the bills drawn up by the Tenement-House Commission appointed by Governor Flower has been passed by the legislature, and that the others, after some amendments by the committees to which they were referred, have been favorably reported in both branches of that body. The one already passed provides for the payment of the remaining moneys due on the three small parks in the tenement-house districts recently set apart under the Small Parks Act of 1887. Among the other bills is one providing for playgrounds about the public-school buildings. Another is for the better protection of tenement houses against fire, and the enforcement of stricter measures for the protection of their inmates from disease. A fourth bill provides for additional small parks during the next three years in the most crowded parts of the city.

## Miscellany.

### DOGS, WOMEN, MEN, HUMANITY.

PROF. W. W. KEEN, of Philadelphia, recently wanted a dog, from which to exsect a nerve for the purpose of grafting it into a gap in the sciatic of a patient, in the Jefferson College Hospital. He sent to the city pound for a dog for this purpose, but his request was refused by Mrs. Caroline Earle White, the president of the woman's branch of the S. P. C. A., which society it appears, has charge of the pound. The operation had to be postponed. A correspondence followed between Mrs. White and Dr. Keen, which is published in full in the Philadelphia *Record* of March 14th. We cannot forbear giving a short extract from one of Mrs. White's letters, and the whole of Professor Keen's reply.

Mrs. White to Professor Keen:

"In answer to your note I will say that although I should always approve of sacrificing a dog's life in order to save that of a man, unless the latter was a curse to the world and the former a boon and a blessing (which is sometimes the case), I think that I am justified in refusing to give you one of the dogs at our pound for an experiment which may prove of benefit to one of your patients, or may not, the latter being the most likely alternative."

Professor Keen to Mrs. White:

"Aside from myself there are three parties who are to be considered in this matter. First, the dog; second, the man, and third, mankind.

"First, the dog; I stated to you that the dog would not suffer; that he would be treated with the same care as the man, and that after the operation I should continue the anesthetic until the dog was dead. Yet you refuse me the dog because, forsooth, somebody else may be cruel to some other dog.

"Secondly, the man. This man knows what I am going to do, and is anxious to have it done. His leg is paralyzed. If by an ordinary surgical procedure I can re-establish the continuity of the nerve, I may be able to cure his paralysis. In that case I should not have recourse to the dog.

If, on the contrary, the gap between the two ends of the nerve is so great that I cannot bring them together, either the man must be condemned to paralysis for life or some other means must be tried to re-establish the nerve and so restore to him a useful leg. This might be done by the process of nerve grafting.

"Yet you refuse me a dog on the ground that it is an 'experiment.' Granting that it is, it is at the most, a perfectly harmless experiment, for it would not be more painful than any ordinary operation; and even if it absolutely fails, it leaves the patient not a whit the worse off. If it succeeds, it will be the greatest possible service to him.

"Thirdly, mankind. The only way in which surgery can make any progress is by testing new methods of treatment which have at least a reasonable possibility of success. Just such persistence and continued trials have encircled the globe with ocean cables. But you assume the rôle of a judge, who decides that such a new method of treatment shall not be tested. You, who I presume would admit that you know nothing of surgery, put your judgment against that of one who has spent thirty-five years in the earnest study, active practice and continuous teaching of surgery. You will excuse me if I think you are not a competent judge.

"If you had your way there would be no Pasteur Institutes in any part of the world to save so many lives from hydrophobia; there would be no antitoxin treatment of diphtheria, which already has borne such wonderful results; there would be no inoculation against cholera, which in the hands of Haffkine bids fair to rescue thousands of lives; there would be no cerebral surgery, since you would not allow us to investigate the functions of the brain; there would be little or no antiseptic surgery, the greatest stride forward of this century.

"In your misguided zeal for dogs you are guilty, in my opinion, of cruelty to this man, and cruelty to all mankind, because you thwart scientific progress under the guise of love for animals. You would condemn to the torture and disabilities of accident and disease, people who have happily been rescued by the more humane scientists in my profession.

"You will pardon me if I write earnestly. It is because I feel deeply the injury you are trying to inflict upon the human race. Happily, the common sense of the community does not allow you to have your way, as they prefer the devotion of my own profession to the welfare of mankind, to your devotion to dogs in preference to men."

## THE TRIUMPH OF M. PÉAN.

The session of the Académie de Médecine of Paris held January 15th, was made remarkable by the presentation of a patient by M. Péan.

This patient had had a carcinoma of the larynx, and to relieve it, it was necessary for M. Péan to make entire extirpation of the larynx, the superior portion of the esophagus and the inferior portion of the pharynx. Not only did the patient support the mutilation, but by means of a prothetic apparatus constructed by M. Michalës, under the direction of M. Péan, the organs were replaced so that the patient could breathe, eat and drink. Not only that, but the apparatus allowed the patient to make articulate sounds, so that speech could be understood. It is two years since the patient was operated upon, and the crowning glory of the operation has been the phenomenal, nay, the brilliant success of the artificial larynx. In former times the saving of the life of a patient so afflicted would in itself have been a triumph of surgery, but to replace lost parts with apparatus of such delicacy and usefulness seems to represent an art almost superhuman.—*Journal of the American Medical Association.*

## ACTINOMYCOSIS IN FRANCE.

Poncet, at the meeting of the French Academy of Medicine, of January 22d, reported that he had seen at Lyons during the past year six cases of actinomycosis: one involving the lungs; one the upper jaw, with extension to the base of the skull (ending in meningitis); one the larynx, attended by deep cervical lymphangitis; the three others presenting the common form, actinomycosis of the face and jaw. The first two cases had a fatal termination, and in the third the same result was expected.

Poncet thinks that, considering the fact that without taking special pains to that end, he had seen six cases within so short a time, actinomycosis is common in France as in other countries, Brandenburg and Austria excepted. Although up to the present time only twenty-two cases have been reported in France, he thinks that errors in diagnosis have in all probability resulted in many patients who were in reality suffering from this disease being treated for syphilis. The efficacy of iodide of potassium in the treatment of actinomycosis probably renders this mistake a frequent one. In many acute cases in which there is lymphangitis about the lower jaw, the disease is regarded as resulting from the development of a wisdom tooth; in other more chronic cases, a carcinoma of the tongue, the jaw, or the floor of the mouth is simulated. Microscopic examination and culture of the fungus can alone establish the diagnosis; if careful examinations were made in all suppurative processes, reported cases of actinomycosis would markedly increase in number.

## THERAPEUTIC NOTES.

Disinfection of Catheters. — Dr. John Ward Cousins, in the *British Medical Journal*, January 19, 1895, recommends a steam apparatus for the disinfection of metallic and other catheters. It is well known that boiling is not a good way to cleanse soft catheters, and that the insides of metallic catheters cannot be satisfactorily cleaned by the ordinary method. Dr. Cousins's apparatus consists of a boiler having a capacity of about three pints and capable of bearing a pressure of eighty pounds to the square inch. It can be heated by a spirit or gas jet in about fifteen minutes. The steam pipe is connected with a circular tube fitted with projecting terminals, and these are adapted to hold a complete set of catheters. An old-fashioned spray apparatus can have the circular tube attached to them if required. After the steaming a polishing stilette is introduced and the instrument carefully dried.

How to Compute the Dose for Children.[1] — Dr. P. Bolognini contends that the formulæ in general use for computing the doses of remedies suitable for different ages are unsatisfactory. He has computed the average weight of children for each month of the first year, and for each year thereafter up to the eighteenth, and upon this basis has formulated the following rules: (1) From birth to the end of the first year: let $d$ stand for dose and $m$ for the age of the infant in months. Then the fraction of the adult dose will be represented by $d = \frac{1}{20 - m}$. (2) For a child from two to eighteen years of age the formula is $d = \frac{2 + a}{25}$; $d$ = dose, and $a$ = age of the child in years.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 9, 1895.

| Cities. | Estimated population. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | | Infectious diseases. | Acute lung disease. | Diarrheal Diseases. | Diphtheria and croup. | Scarlet fever. |
| New York | 1,956,000 | 864 | 332 | 11.64 | 23.76 | 1.32 | 4.68 | 1.80 |
| Chicago | 1,600,000 | — | — | — | — | — | — | — |
| Philadelphia | 1,139,457 | — | — | — | — | — | — | — |
| Brooklyn | 1,043,000 | 418 | 153 | 15.12 | 24.00 | .96 | 9.60 | 1 44 |
| St. Louis | 540,800 | — | — | — | — | — | — | — |
| Boston | 501,107 | 235 | 71 | 6.45 | 21.50 | .86 | 3.01 | 1.29 |
| Baltimore | 500,000 | — | — | — | — | — | — | — |
| Washington | 265,000 | 126 | 33 | 3.16 | 20.54 | .79 | .79 | — |
| Cincinnati | 325,000 | 123 | 29 | 3.24 | 27.54 | 1.62 | .81 | — |
| Cleveland | 325,000 | 109 | 37 | 6.44 | 18.40 | — | .92 | 2.76 |
| Pittsburg | 272,000 | 102 | 38 | 6.86 | 27.44 | — | 2.94 | 3.92 |
| Milwaukee | 265,000 | — | — | — | — | — | — | — |
| Nashville | 87,784 | 36 | 7 | 5.56 | 19.46 | — | 2.94 | 2.94 |
| Charleston | 65,165 | 36 | 12 | 2.78 | 16.68 | — | — | — |
| Portland | 40,000 | — | — | — | — | — | — | — |
| Worcester | 100,410 | 34 | 7 | 5.88 | 26.46 | — | 2.94 | — |
| Fall River | 92,233 | 49 | 25 | 8.16 | 40.80 | 4.16 | 2.04 | 2.04 |
| Lowell | 90,613 | 29 | 8 | 7.14 | 28.56 | — | 3.57 | — |
| Cambridge | 79,607 | 34 | 7 | 2.94 | 14.70 | — | — | — |
| Lynn | 65,123 | 28 | 5 | 7.14 | 17.85 | — | 3.57 | — |
| Springfield | 50,384 | 27 | 6 | 11.11 | 37.00 | — | — | 3.70 |
| Lawrence | 49,966 | 20 | 7 | 10.0 | 35.00 | — | — | — |
| New Bedford | 47,141 | 24 | 7 | 8.32 | 20.80 | 4.16 | 4.16 | — |

| Fitchburg | 29,383 | 7 | 4 | — | — | — | — | — |
| Newton | 28,837 | 17 | 1 | — | 35.28 | — | — | — |
| Gloucester | 27,293 | — | — | — | — | — | — | — |
| Taunton | 26,954 | 18 | — | — | — | — | — | — |
| Waltham | 22,058 | 7 | 3 | — | 42.84 | — | — | — |
| Quincy | 19,642 | 8 | 5 | — | 25.00 | — | — | — |
| Pittsfield | 18,802 | 4 | 1 | — | 75.00 | — | — | — |
| Everett | 16,585 | — | — | — | — | — | — | — |
| Northam | 16,331 | 5 | 2 | — | 20.00 | — | — | — |
| Newburyport | 14,073 | 6 | 1 | — | 30.00 | — | — | — |
| Amesbury | 10,920 | — | — | — | — | — | — | — |

Deaths reported 2,556: under five years of age 852; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 234, acute lung diseases 596, consumption 308, diphtheria and croup 100, scarlet fever 37, diarrheal diseases 26, measles 20, typhoid fever 18, whooping-cough 14, cerebro-spinal meningitis 11, erysipelas 8.

From measles New York 13, Brooklyn 3, Providence 2, Boston and Springfield 1 each. From typhoid fever Cleveland and Pittsburg 3 each, New York 2, Boston, Washington, Cincinnati, Charleston, Worcester, Lowell, Cambridge, Springfield and Clinton 1 each. From whooping-cough Brooklyn 7, New York 6, Boston 1. From cerebro-spinal meningitis New York 5, Holyoke 3, Lawrence 2, Lynn 1. From erysipelas New York 5, Brooklyn 2, Providence 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530, for the week ending March 2d, the death-rate was 32.9. Deaths reported 6,683: acute diseases of the respiratory organs (London) 1,449, whooping-cough 113, measles 61, diphtheria 47, diarrhea 36, fever 35, scarlet fever 30, small-pox (London and Liverpool 1 each) 2.

The death-rates ranged from 15.1 in Derby to 55.5 in Liverpool; Birkenhead 27.7, Birmingham 23.1, Bradford 25.3, Brighton 32.3, Cardiff 34.5, Halifax 43.4, Leeds 23.7, Leicester 19.1, London 38.5, Manchester 28.7, Nottingham 49.2, Plymouth 39.2, Preston 36.1, Salford 30.5, Swansea 28.5, West Ham 28.6.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 8, 1895, TO MARCH 15, 1895.

Leave of absence for one month, to take effect about March 10, 1895, is granted MAJOR CHARLES L. HEIZMAN, surgeon, U. S. A., Fort Douglas, Utah.

The leave of absence for seven days granted CAPTAIN PAUL CLENDENIN, assistant surgeon, is extended twenty-one days.

The attending surgeon at Boston, Mass, will attend the sick at Fort Warren, Mass., during the absence of CAPTAIN CLENDENIN.

FIRST-LIEUT. GEORGE D. DESHON, assistant surgeon, is relieved from duty at Fort Logan, Colorado, and ordered to duty at Fort Douglas, Utah.

CAPTAIN FREEMAN V. WALKER, assistant surgeon, is granted leave of absence for one month, to take effect upon his relief from duty at Fort Trumbull, Conn.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 16, 1895.

L. L. YOUNG, assistant surgeon, detached from the Naval Hospital, Norfolk, Va., and wait orders.

AMMEN FARENHOLT, assistant surgeon, ordered to the U. S. S. "Baltimore."

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING MARCH 15, 1895.

GODFREY, JOHN, surgeon. Detailed as chairman board for physical examination of candidates, Revenue Cutter Service. March 6, 1895.

IRWIN, FAIRFAX, surgeon. To inspect Cape Charles Quarantine Station. March 9, 1895.

MEAD, F. W., surgeon. Detailed as chairman board for physical examination of candidates, Revenue Cutter Service. March 6, 1895.

GLENNAN, A. H., passed assistant surgeon. To report at Bureau for temporary duty. March 12, 1895.

GARDNER, C. H., assistant surgeon. To proceed to Angel Island Quarantine Station for temporary duty. March 4, 1895. Detailed as recorder for board for physical examination of candidates, Revenue Cutter Service. March 6, 1895.

STEWART, W. J. S., assistant surgeon. Detailed as recorder board for physical examination of candidates, Revenue Cutter Service. March 6, 1895.

OAKLEY, J. H., assistant surgeon. Detailed for duty on Revenue Steamer "Rush." March 13, 1895.

CUMMING, H. S., assistant surgeon. To proceed to Boston, Mass., for temporary duty. March 6, 1895.

## SOCIETY NOTICE.

NORFOLK DISTRICT MEDICAL SOCIETY.—The Fellows of the Norfolk District Medical Society resident in Dorchester and vicinity, will entertain the Society at the Old Dorchester Club House, on Tuesday, March 26, 1895, at 7.45 P. M.

Communication: "The Relation of the Massachusetts Medical Society to the Medical Profession in Massachusetts," W. S. Everett, M.D.

It is expected that some of the officers of the Massachusetts Medical Society will be present and take part in the discussion.

Collation at 9.30 P. M.

The Club House is located on Pleasant Street near Stoughton Street. The Field's Corner or Ashmont cars pass the door.

J. C. D. PIGEON, M.D., *Secretary.*

## BOOKS AND PAMPHLETS RECEIVED.

A Practical Theory and Treatment of Pulmonary Tuberculosis. By Frank S. Parsons, M.D., Philadelphia.

A Review of Six Interesting Pathologic Cases. By E. R. Axtell, M.D., of Denver, Col. Reprint. 1895.

## A REPORT ON THE BACTERIOLOGICAL INVESTIGATIONS OF AUTOPSIES.[1]

BY J. H. WRIGHT, M.D.,
*Assistant in Pathology, Harvard Medical School;*
AND WM. R. STOKES, M.D.,
*Resident Assistant Pathologist, Boston City Hospital.*

(Continued from No. 12, p. 275.)

### ACUTE ENDOCARDITIS.

The evidence in favor of the bacterial origin of acute endocarditis is both experimental and pathological.

The possibility of inducing an experimental acute endocarditis, due to bacteria, was first suggested by Rosenbach, in 1878, who showed that by injuring the heart-valves of an animal by means of a sound passed into the carotid, in certain cases vegetations were produced on the valve in which micro-organisms could be demonstrated. These micro-organisms were carried into the circulation accidentally by the operation, and Rosenbach considered that a certain proportion of the heart-lesions resulting were due to their presence and was independent of the mechanical injury produced by the sound. These experiments of Rosenbach opened the way for the later work of Wyssokowitsch and Orth in 1885, who proved that by the injection of the pyogenes cocci into the circulation of animals, after previous mechanical injury to the valves of the heart by Rosenbach's method, a true acute endocarditis could be induced. These investigators maintained that the previous lesion of the valves was necessary, for the mere injection of the pyogenic cocci into the circulation was not followed by the appearance of valvular vegetations, nor did such vegetations appear after the mechanical injury of the valves, if no bacteria were introduced into the blood. The experimental production of acute endocarditis has also been studied by Netter, Ribbert, Fränkel and Sänger, Prudden, Weichselbaum, Stern and Hirschler, and Viti. The combined results of the work of these writers has shown that true endocarditis can readily be produced in animals by the intravenous injection of any of a number of species of bacteria, provided that there is some previous lesion of the heart-valves, although the necessity of this previous lesion is denied by Netter and Ribbert.

The pathological evidence of the infectious nature of acute endocarditis is also convincing. In 1885 Wyssokowitsch reported finding the staphylococcus pyogenes aureus in a case of ulcerative endocarditis, but failed to find any bacteria in 11 cases of the verrucose form. In the same year Weichselbaum published the results of his study of one case of the verrucose form and three cases of the ulcerative form, in all of which he found either the staphylococcus pyogenes aureus or the streptococcus, or both. The first extensive study, however, of the etiology of acute endocarditis in man, is that of Fränkel and Sänger, published in 1886. These investigators studied 11 cases of the verrucose form and one case of the ulcerative form, and found in nine cases bacteria in the cardiac lesions, the staphylococcus pyogenes aureus being present in six. This publication was important because it was a strong confirmation of the view, which is now generally held, that all forms of acute endocarditis are to be regarded as of infectious origin. An important work also is that of Netter, who observed the micrococcus lanceolatus in seven or nine cases of acute endocarditis associated with acute lobar pneumonia.

Weichselbaum has, however, contributed more to our knowledge of this disease than any other single investigator. From a study of 15 cases of ulcerative endocarditis, 13 cases of verrucose endocarditis and one case of endocarditis of the left auricle, Weichselbaum concluded that there is no essential difference between the various forms of endocarditis, either histologically or bacteriologically; that no one species of bacteria are concerned in the production of the disease; that in cases in which no bacteria are found, the bacteria have died or there is some defect in the method of examination for their presence; and that chronic endocarditis is the result of the acute form of the disease. Of the 29 cases of Weichselbaum, the micrococcus lanceolatus was found in seven (six of the ulcerative form and one of the verrucose form); the streptococcus in six (four ulcerative and two verrucose); the staphylococcus pyogenes aureus in two (verrucose); and in six cases various unusual bacteria. In eight cases the examination for the presence of bacteria was negative.

Other observations of bacteria in acute endocarditis are those of Banti (20 cases), Viti (eight cases), Girode (six cases), Senger, Lanceraux, Stern and Hirschler, Meyer, Vinay, Steinberg, Malvolz, Tombolan[2] and Fava, Perret and Rodet, Gilbert and Lion, Paulus, Lanceraux and Besançon, Oulmont and Barbier, Lafitte, Josser and Roux, Barbacci, Glusincki, Leyden, Howard and Councilman. The cases studied by these writers prove conclusively that a great variety of bacteria are to be found associated with the acute forms of the disease, in which not only the ordinary pyogenic cocci, the micrococcus lanceolatus and other less known species may be present, but also the gonococcus, (Councilman and others) and the bacillus diphtheriæ (Howard) as well.

In 10 cases of acute endocarditis examinations of the valvular vegetations or ulcerating tissue of the heart have been made; and in seven of the 10 cases the micrococcus lanceolatus has been found, in one case accompanied by the bacillus diphtheriæ. Of the three remaining cases in which the micrococcus lanceolatus was not found, the staphylococcus pyogenes aureus was present in one, the streptococcus and the staphylococcus pyogenes aureus in the second, and unknown bacteria in the third case. In all, 19 cases of acute endocarditis, six or seven of which were of the ulcerative form, have been studied with reference to the occurrence of bacteria in the internal organs. The micrococcus lanceolatus has been found in the heart-blood or in some or all of the parenchymatous viscera in seven cases. Combining the results of these cultures with the results of the examination of the heart-lesions, mentioned above, it may be said that evidence of the association of the micrococcus lanceolatus with acute endocarditis has been obtained in nine out of the 19 cases. Of the remaining cases, in two there was a well-marked general infection with the staphylococcus pyogenes aureus; in two others, both in puerperal females, a general infection with the streptococcus; and in six no definite conclusion was to be drawn from the results of the cultures. The staphylococcus pyogenes aureus was also present with the

[1] This paper will appear in the Boston City Hospital Reports, Sixth Series.

streptococcus in the blood of the liver as well as in the valvular vegetation in one of these puerpural cases. It is worthy of note that in a third puerperal case, with acute endocarditis, the micrococcus lanceolatus was found in the blood of the heart and in the embolic pneumonia, while the streptococcus was found in the uterus and kidney.

### GENERAL INFECTIONS WITH THE MICROCOCCUS LANCEOLATUS.

In addition to the foregoing cases of general infection with the micrococcus lanceolatus in acute lobar pneumonia and acute endocarditis, a number of other cases have been met with in which this organism has been found in some or all of the large viscera. These cases are essentially as follows:

CASE I. Acute fibrinous pericarditis with effusion. Acute fibrinous pleuritis, acute splenic tumor. Acute degeneration of liver and kidneys. Micrococcus lanceolatus in pericardium, lung, liver and kidney. Spleen sterile.

CASE II. Ulcus ventriculi; abscess of adjacent fat tissue with perforation into peritoneal cavity. Fibrinous peritonitis and pleuritis. Micrococcus lanceolatus in fibrinous exudate on peritoneum and pleura, in spleen, kidney and wall of heart. Bacillus coli communis in liver and in some of the other organs also.

CASE III. Hysterectomy. Occlusion of ureters by ligature, leakage of urine into peritoneal cavity, congestion of lungs, acute splenic tumor. Micrococcus lanceolatus in peritoneum and spleen. Blood of heart negative. Various bacteria were also present in peritoneum.

CASE IV. Acute adenitis of inguinal and peritoneal lymph-glands, acute splenic tumor, edema and congestion of lungs. No infection-atrium demonstrated. Micrococcus lanceolatus in inguinal lymph-gland, kidney and liver. Spleen and femoral lymph-gland sterile. Bacillus coli communis in liver.

CASE V. Fracture of base of skull, extending through the petrous portion of the left temporal bone. Acute purulent otitis media (left), purulent leptomeningitis, thrombosis of left lateral sinus, acute splenic tumor, acute degeneration of liver and kidneys. The otitis was apparently subsequent to the fracture. Micrococcus lanceolatus in pus of internal ear and of meninges, blood of heart, liver, spleen, kidney and lung. Staphylococcus pyogenes aureus also in lung. As elsewhere pointed out, the infection-atrium in this case was most probably the internal ear.

CASE VI. Subacute diffuse nephritis (large white kidney), anasarca, ascites, hydrothorax, subacute peritonitis. Micrococcus lanceolatus in peritoneal exudate, spleen, kidney, liver and blood of heart.

CASE VII. Disseminated general sarcomatosis. Broncho-pneumonia. Micrococcus lanceolatus in broncho-pneumonia, liver, kidney, and blood of heart. Staphylococcus pyogenes aureus also in kidney. Spleen sterile.

CASE VIII. Child, aged two and one half days. Acute pneumonia of both lungs. Hemorrhages beneath dura and peritoneum. Micrococcus lanceolatus by cover-slips (direct examination) in lung, liver, spleen, kidney and blood of heart. There was no evidence of infection from mother.

Additional cases of general infection with the micrococcus lanceolatus are considered under puerperal infection, diphtheria and scarlet fever.

### MISCELLANEOUS GENERAL INFECTIONS WITH THE STREPTOCOCCUS.

In this group we have collected a variety of cases in which the bacteriological examination showed more or less of a general invasion of the viscera by the streptococcus. Some of these cases have been of a surgical character, but a number of others have been cases in which there was little or no reason for suspecting any pyogenic infection, either clinically or at the autopsy. With the exception of a single case, none of the cases with general infection with the streptococcus in diphtheria and scarlet fever are included in this group, but are considered elsewhere in connection with these diseases. The exceptional case was one of diphtheria and scarlet fever in which the streptococcus septicemia was apparently of surgical origin, and on that account it is included here.

CASE I. General arterio-sclerosis, hypertrophy and dilatation of the heart, thrombosis of right auricular appendix, multiple emboli of lungs with infarction, arterio-sclerotic kidney and liver, edema, ascites and hydrothorax. Streptococcus in liver, kidney, spleen, infarction of lung and blood of heart.

CASE II. Disseminated tuberculosis of lungs. Tuberculosis of epididymus, seminal vesicles and kidney, acute splenic tumor. Streptococcus in spleen and lungs; in lung, also, bacillus diphtheriæ and staphylococcus pyogenes aureus. Kidney and liver sterile.

CASE III. General hematogenous miliary tuberculosis. Primary tubercular ulcer of intestine, tuberculosis of mesenteric glands and thoracic duct. Streptococcus in spleen, liver, kidney, lung, blood of heart and in superficial vein.

CASE IV. Cancer of rectum. Streptococcus in kidney, lung and blood of heart.

CASE V. Subcutaneous injections of bouillon cultures of the streptococcus derived from erysipelas, in a case of sarcoma of the thigh. Death after about ten days. At the autopsy there was found edema and congestion of the lungs, hemorrhages in parietal and visceral pleuræ, enlargement and congestion of the inguinal glands on the side of the tumor, and of the posterior mesenteric and gastro-hepatic lymph-glands. Streptococcus in tumor, inguinal gland, spleen, liver and blood of heart. Bacillus pyocyaneus in tumor.

CASE VI. Broncho-pneumonia, purulent bronchitis, mucopurulent cystitis. Streptococcus in spleen, liver, kidney and blood of heart.

CASE VII. Operation for congenital hernia, followed by abscess formation. Diphtheria. This case is included among the diphtheria cases. Streptococcus in liver, spleen, lung and kidney. Bacillus diphtheriæ in throat, lung and spleen. It seems probable that in this case the infection-atrium for the streptococcus was the operation wound.

CASE VIII. Empyema, thoracentesis, croupous pneumonia, acute splenic tumor, fatty degeneration of liver, chronic diffuse nephritis. Larynx and trachea not examined. No suspicion of diphtheria. Streptococcus in kidney, spleen, liver, lung and blood of heart. Bacillus diphtheriæ and staphylococcus pyogenes aureus also in lung.

CASE IX. Operation for tuberculosis of hip-joint. Acute peri- and endocarditis. Chronic endocarditis with general chronic passive congestion. Steptococcus in operation wound, liver, spleen, kidney and heart-

muscle. Staphylococcus pyogenes aureus also in the operation wound.

CASE X. Ulcers and cellulitis of leg, purulent arthritis of knee. Broncho-pneumonia. Fatty degeneration of liver. Acute splenic tumor. Acute degeneration of kidney. Diphtheritic ulceration of large intestine. Streptococcus in knee-joint, kidney, spleen, blood of heart, broncho-pneumonia, and possibly in liver. It is possible that there was a general poly-infection to a certain extent with the streptococcus and the micrococcus lanceolatus, but this was not determined accurately.

CASE XI. Operation wound, removal of vermiform appendix, acute purulent peritonitis, broncho-pneumonia, acute parenchymatous degeneration of liver and kidneys. Streptococcus in peritoneal pus, liver and kidney.

### PUERPERAL INFECTION.

The present state of our knowledge on the subject of puerperal infection has been recently reviewed by Williams, who concludes "that various, very diverse micro-organisms, especially the streptococcus and the staphylococcus," may be concerned in this condition, but "that most of the fatal cases of puerperal disease have been due to infection with the streptococcus." Among the first observations of the occurrence of the streptococcus in puerperal infection was that of Orth, in 1873, who described and figured a spherical organism, growing in chains in the purulent exudation of puerperal peritonitis. The first to cultivate this organism from autopsies on puerperal cases was Pasteur, in 1880, and since that time its frequent occurrence in puerperal infection has been demonstrated by Winkel, Pfannenstiel, Czerniewski, and others.

In this group of cases we have included all those cases of infection which seemed to have been of puerperal origin. It will be noted that some of them are well-marked poly-infections.

CASE I. Typical diphtheritic endometritis and vaginitis, abscesses in lungs, acute fibrinous pleuritis, acute splenic tumor. Streptococcus in pus of uterine lymphatics, blood of heart and spleen. Streptococcus, staphylococcus pyogenes aureus and micrococcus lanceolatus in lung (abscesses).

CASE II. Diphtheritic endometritis and vaginitis, abscesses in lung, acute pleuritis and parotiditis, acute splenic tumor. Criminal abortion at third month. Staphylococcus pyogenes aureus in parotid gland, blood of heart and lung; in the lung, also streptococcus. Liver and spleen sterile. Various unknown bacteria in uterus.

CASE III. Fever after childbirth, with intense jaundice. Acute nephritis. Streptococcus in liver, spleen, kidney and blood of heart.

CASE IV. Abortion and septic endometritis. Streptococcus in uterus, pus of Fallopian tube, and in spleen. Liver and kidney negative.

CASE V. Puerperal fever. Streptococcus in uterus, thrombosed uterine vein and kidney. Other organs not examined.

CASE VI. Acute puerperal diphtheritic vaginitis, thrombosis of vaginal veins and uterine lymph-vessels, purulent peritonitis, acute pleuritis, congestion and edema of lungs, acute parenchymatous degeneration of liver and kidney. Congenital defect in intra-ventricular septum, patency of foramen ovale, hypoplasia of aorta; chronic passive congestion of lungs. Streptococcus in abdominal pus, pleural exudate and blood of heart. Staphylococcus pyogenes aureus in spleen. Bacillus coli communis in uterine lymph-sinus, vaginal veins, kidney and in some other situations.

CASE VII. Hemorrhagic pericarditis, uterine hemorrhage, abortion in progress. Bacillus coli communis in body of uterus, kidney, blood of heart and spleen. Liver sterile. Pericardium negative.

CASE VIII. Puerperal septicemia, partially retained placenta, acute splenic tumor, acute parenchymatous degeneration of liver and kidneys. Streptococcus in kidney. Bacillus coli communis in uterus, liver, spleen, kidney and blood of heart.

CASE IX. Croupous pneumonia following childbirth. Streptococcus in uterus and kidney. Micrococcus lanceolatus in lung and pleural exduate. Bacillus coli communis in all organs.

CASE X. Hypertrophy of uterus after early abortion. Endometritis, acute endocarditis, hemorrhagic infarction of lungs with embolic pneumonia, acute splenic tumor. Micrococcus lanceolatus in blood of heart and lung. Streptococcus in uterus and kidney. Bacillus coli communis in liver and in other organs.

CASE XI. Acute endometritis. Post-partum hypertrophy of uterus, acute endocarditis, septic infarction of spleen and kidneys, embolism of branches of superior mesenteric artery, subacute nephritis, slight chronic passive congestion of lung, liver and spleen. Streptococcus in endometrium, liver, kidney, spleen infarction. Streptococcus and staphylococcus pyogenes aureus in heart-lesion and blood of liver vein. Spleen sterile.

CASE XII. Clinical diagnosis: puerperal eclampsia. Post-partum hypertrophy of uterus, laceration of cervix with hemorrhage into ligamentum latum. Hydrothorax, hydro-pericardium, edema of lungs, acute splenic tumor. Micrococcus lanceolatus in endometrium, liver, lung, spleen and kidney.

The streptococcus has been found in one or more of the internal organs in nine of these twelve cases. This result is in harmony with the generally accepted view that this organism is by far the most common cause of puerperal infection.

### ERYSIPELAS.

CASE I. Erysipelas of face, pulmonary apoplexy, acute splenic tumor. Old tuberculosis of apices of lungs, scattered foci of tuberculosis in the upper lobe of right lung, acute tubercular pleuritis left side. Streptococcus in tissue of face. Staphylococcus pyogenes aureus also in tissue of face and in spleen, kidney and lung and blood of heart. Liver negative.

CASE II. Erysipelas of face and neck. Acute nephritis. Cultures failed to demonstrate any specific infection.

CASE III. Erysipelas of face and scalp, congestion of lungs, acute splenic tumor. Steptococcus and other organisms in scalp. Liver and spleen sterile. Various bacteria in blood of heart and lateral sinus. Staphylococcus pyogenes aureus in lung.

CASE IV. Erysipelas of face and scalp. Diffuse visceral syphilis. Streptococcus in blood of heart, spleen and lung. Bacillus coli communis in kidney.

CASE V. Erysipelas of face. Contusion of forehead and buttock. Fatty degeneration and purulent infiltration of muscles of buttock. Streptococcus in muscles of buttock, spleen, kidney, liver, lung and blood of heart.

CASE VI. Erysipelas of leg; small ulcer on pos-

terior surface of leg. Inguinal glands on affected side enlarged and reddened, and in the adjacent tissue small purulent foci. Hypostatic congestion of lungs, acute splenic tumor. Streptococcus in the deep subcutaneous tissue of leg and inguinal gland. Micrococcus lanceolatus in lung. Bacillus coli communis in kidney and blood of heart.

CASE VII. Erysipelas of leg. Broncho-pneumonia. Tissues of leg and inguinal gland sterile. Streptococcus in liver. Staphylococcus pyogenes aureus in lung, kidney and spleen. Blood of heart sterile.

It will be seen that the streptococcus has been found associated with six of these cases, while in two there was a general infection with the staphylococcus pyogenes aureus in addition. We consider the general infection with the latter organism as a secondary one, following on the erysipelas, which was induced by the streptococcus. The failure to demonstrate the streptococcus in the local lesion in one of the cases in which that was examined, is not surprising, as it is well known that it does not long survive in the tissue after it has produced its effects.

We have examined four cases of extensive superficial burns which we will consider in one group. The bacteriological results are as follows:

CASE I. Streptococcus in spleen, kidney and blood of heart. Liver and mesenteric gland sterile.

CASE II. Streptococcus in suppurating tracheal gland, liver, spleen and kidney.

CASE III. Bacillus coli communis in spleen, kidney and lung. Liver and blood of heart sterile.

CASE IV. Various unknown bacteria found in the various organs.

## A CASE OF ACTINOMYCOSIS.[1]

BY F. B. MALLORY, M.D.,
*Instructor in Pathology in Harvard Medical School.*

ACTINOMYCOSIS is a sufficiently rare disease in this part of the world to render a case coming to autopsy at the Boston City Hospital of enough importance to be reported. Unfortunately the nature of the disease was not recognized either clinically or at the post-mortem examination, so that many queries which were raised later could not be definitely settled owing to a lack of investigation at the proper time.

The patient, a native of Denmark, came from the West several months before his death. Further than that nothing is known of his previous history. He entered the Massachusetts General Hospital on the 2d of June, 1894. His temperature was then 99.1° F., his pulse 120 and his respiration 28. He complained of gradual failure of breath and of the development of a cough. About two weeks before entrance he had noticed a lump in his epigastrium.

"*Physical Examination.* — A weak, emaciated man with anxious expression. Heart-sounds heard loudly in chest, anemic murmur. Nothing found in lungs except dulness in upper left front. Liver dulness one-half inch below ribs. Skin on left epigastrium, over an area of several square inches, reddened and tense. Abdominal wall thickened all around and dull on percussion. Abscess opened and considerable foul material looking like broken-down tuberculous tissue escaped. Packed with iodoform gauze and poulticed. The wound was dressed daily, but remained thoroughly indolent, so that on June 14th the patient was etherized and the granulations curetted, the curette laying bare the cartilage of the left ribs and the abdominal fascia. No dead bone was found."

No further notes were made on the case, but the patient left the hospital soon after the first of July.

On the 23d of August he was admitted to the Boston City Hospital. He was then "dull in mind" and "talked very thick," so that his words could not be understood. No history concerning him could be obtained.

"*Physical Examination.* — Poorly nourished and emaciated. Heart-sounds weak and rapid. Apex in mammary line, one and three-fourths inches below nipple. Râles and bronchial breathing over the apices of both lungs, front and back. Percussion subtympanitic on the left side. About one and one-half inches below xiphoid and running parallel with the costal border, is a wound about two inches long, which discharges foul-smelling, purulent, whitish fluid. Between the tenth and eleventh ribs, about three inches to outer side of wound spoken of above, is a small round wound discharging a similar fluid. On the left forearm over the pronator muscles, on the left shoulder-cap over the deltoid, and on the dorsum of the right forearm above the wrist, are fluctuant tumors, each the size of an egg. Plaster swathes were applied to the abdominal wounds and bandages to the tumors on the arms."

During the following three days the patient remained dull, and failed in strength. The pulse became weak and more rapid, and death occurred on the fourth day after entrance.

The temperature of the patient on the day of admission was 102° F. On the next day it was 104°, falling to normal by evening. The following morning it was 96.2°, and remained subnormal until death. The pulse was 100 on entrance, and rose gradually to 120. The respirations fell from 42 to 30.

At the autopsy no connection was found between the sinuses in the epigastrium and the thoracic or peritoneal cavity. The organs only of the case were seen by the pathologist to the hospital. The following is his description of them:

"Both lungs firmly adherent to costal pleura by old adhesions. Left lung denser than normal; does not contract on removal from thorax; the density most marked in the upper lobe. In the apex a circumscribed cavity with smooth walls filled with caseo-purulent contents; elsewhere in upper lobe there is slaty-gray consolidation with caseation. There are also small foci of a reddish color, consolidated, from which pus can be squeezed. In the lower lobe there is much cicatricial tissue and areas of broncho-pneumonia. In the right lung there is perfect cicatrization of lower lobe with slight dilatation of bronchi. From this an abundance of pus can be squeezed, leaving very smooth cavities. In the upper lobe considerable edema and numerous reddish foci of purulent infiltration.

"In both of the lungs there is a great deal of cicatricial tissue. Large vessels and bronchi at base free.

"Liver of ordinary size and strongly adherent to diaphragm. In the left lobe of the liver the capsule is greatly thickened, cicatricial; and apparently the entire lobe is converted into a mass of necrotic tissue infiltrated with pus. The tissue, on section, of a whitish color (no trace of liver substance apparent), and intimately united with the thickened cicatricial capsule.

[1] Read before the Boston Society for Medical Improvement, December 17, 1894.

The right lobe of dark-red color, congested, free from abscess.

"Kidneys large, cortex hyperemic, markings normal. In both there are several circumscribed abscesses from size of a pea to a cherry. The abscesses contain pus of rather firm consistency, and a small amount of necrotic tissue. The pus is apparently infiltrated in the necrotic tissue. The pus from all these abscesses is thick and yellowish.

"In the right side of the brain, in the frontal region, at a point about corresponding to the middle of the first frontal convolution and extending down into the region of the second, there is a sharply circumscribed abscess filled with thick, greenish pus.

"Anatomical diagnosis. Tuberculosis, bronchopneumonia and secondary abscesses of lungs, with interstitial pneumonia. Perihepatitis and abscess of liver. Abscesses of kidneys, abscess of brain."

At both hospitals the case was regarded clinically as tubercular.

Cultures showed many colon bacilli in the heart's blood and in the abscesses in the lungs and liver. Many colonies of the staphylococcus pyogenes aureus were present in the cultures from the abscesses of the brain, lungs and over the deltoid. A few were found in the blood and in the abscess of the liver. A culture from an abscess of the kidney remained sterile. Cover-slip preparations from some of the abscesses were reported to contain cocci and delicate bacilli.

Fortunately the abscesses of the brain and kidneys with the surrounding tissue, and considerable portions of the lungs and liver were hardened in alcohol for microscopic purposes. Examination later showed the pathological processes to be due largely or entirely to actinomyces.

The first case of actinomycosis in man was observed by Langenbeck in 1845; but it was not until 1878 that the case, together with the original drawings, was published by J. Israel. There is also no doubt Lebert saw the organism in man in 1857 and pictured it accurately. It was not, however, until 1878 that J. Israel described a case of actinomycosis thoroughly, and showed the relation of the peculiar organism to the pathological lesions.

Actinomyces were discovered in the tongue of a cow by Hahn in 1870, and in 1877 Ballinger showed them to be present constantly in certain tumor-masses about the jaws and in the tongues of cattle. The organism was studied botanically by Harz and termed "actinomycosis bovis," or ray fungus. The identity of actinomyces in man and cattle was demonstrated by Ponfick in 1882. Since then the occurrence of the disease in man has been established by numerous observations all over the world.

In the lesions produced the actinomyces grow in characteristic colonies, which are often large enough to be recognized by the naked eye. They measure 0.18 mm. to 0.6 mm. in diameter. Occasionally they are conglomerate, and may measure as much as 2 mm., or even more, in diameter. To the naked eye the single colonies appear spherical, oval or slightly curved; the larger colonies are more irregular. According to Bostrœm, whose monograph on this subject has become a classic, the largest colonies are found where the tissue shows the greatest inflammatory reaction.

When the growth of the colonies is not interfered with, they develop, according to him, a certain typical structure which is shaped like a hollow ball with an opening at some point, out of which streams into the surrounding tissue a network of fibres which he calls the root. The mantle of the hollow ball consists of a basement layer composed of a very thick tangle of filaments which branch dichotomously, and of collections of small round bodies. The centre of the ball consists of a few branching irregularly-arranged threads. From the basement layer arise, first, small bush-like masses of threads but little branched; later, however, they are larger and the threads show numerous branches. On the outside lies the layer of the clubs.

The colonies are distinguished by color which depends on their age. The younger colonies appear gray and gelatinous like bits of mucus, and consist of only a loose tangle of branching filaments. In the next stage they are denser but still small and look grayish white or opaque white. The denser the network of threads, the whiter and more opaque the colonies become, until finally the color passes into yellow or even brown. The clubs have a metallic lustre which may become yellowish-green or bright green if they are large and numerous.

The examination of cover-slip preparations from actively growing colonies shows often a great variety of forms so that one is inclined to suspect a mixed infection due to several organisms. Side by side will be found coccus-like bodies, short and long bacilli, and single and branched threads, of which some stain uniformly while others consist of longer or shorter joints each of which corresponds to a coccus or to a bacillus. Besides these there are the transparent club-shaped bodies in which can be found bacilli and cocci similar to those in the threads.

All these different forms are now pretty generally looked upon as belonging to one and the same organism, which is classed among the polymorphous bacteria. On account of the branching, Bostrœm places it in the class Cladothrix.

The club-shaped formations have always excited the greatest interest and form one of the most characteristic features of this bacterium. According to Bostrœm whose views are now generally accepted, these clubs are due to a peculiar degeneration of the membrane or sheath of the organism. This degeneration may occur along the course of the filaments but is found especially at the ends. The filaments can often be traced directly into them. The swollen, degenerated sheaths get denser with age; they often crack and form curious, irregular and branching figures.

Cultures of actinomyces have been obtained by Bostrœm and by a number of other investigators. Inasmuch, however, as only those obtained by M. Wolff and J. Israel produced typical lesions when introduced into animals, it seems best to consider only their results in that direction. They succeeded in growing pure cultures from two separate cases in man, from a retro-maxillary tumor and from the lung. They found that the most important characteristics of the growth on agar were that the organism was anerobic (although not strictly so), that it showed a marked inclination to form small knots which rarely appeared before the third to the fifth day and that these knots had a tendency to remain separate even after months. The surface growth was remarkably dry, non-elevated, and sent roots into the culture medium beneath. The older colonies were not infrequently of a pale-yellow color. Microscopically the commonest form of the

growth on agar was found to be a short, straight or curved rod of which the length and breadth varied considerably. In some cultures very short thick rods were present; in others they were long, and thin or thick with often one end swollen. Occasionally threads were found which were usually wavy or spiral.

In the cultures in eggs, although rods were present, a tangle of threads was the commonest form. The filaments were straight, wavy or spiral and often dichotomously divided. The filaments on the periphery of the tangled masses showed a more or less radiating pattern. The single threads were not of the same thickness; some were slender, others thick. Many of the threads could be differentiated into rows of longer or shorter rods, or into round bodies like cocci. Wolff and Israel do not agree with Bostrœm in regarding the small round bodies which look like cocci as spores, for the reason that they stain readily by Gram, a property which other spores do not possess, and they suggest that these apparent cocci may be due to division of the short rods.

No club-shaped formations could be found in the cultures. The swollen ends of the rods often seen stained intensely with Gram, and could not therefore be due to degeneration of the sheath, for the degenerated bodies formed in this way stain only with diffuse stains.

Wolff and Israel introduced portions of their cultures into the peritoneal cavities of guinea-pigs and rabbits, and produced small tumors from the size of a millet-seed to a plum in which were found typical colonies of actinomyces with club-shaped bodies around the periphery. The larger tumors were nodular, of a pink color speckled with yellow, and showed on section a connective-tissue capsule from which extended many anastomosing septa between the soft, dough-like masses in which the colonies were situated.

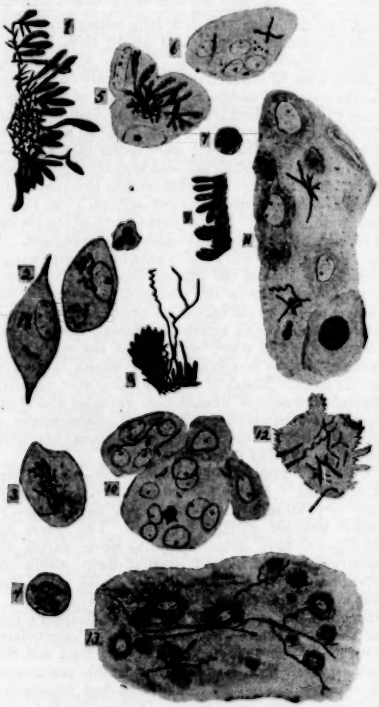
There remains still to speak of the pathological lesion produced by actinomyces. This could best be studied by introducing pure cultures of the organism into animals and killing them after different periods of time. Then the direct effect of the polymorphous bacterium on the surrounding tissues could be accurately determined. This work, however, still remains to be done.

In cattle, according to Thoma, actinomyces, as a rule, give rise to circumscribed tumors in which the colonies are surrounded usually by a circular area of young, newly-formed connective tissue very rich in lymphoid and epithelioid cells. These areas, rich in cells, with the organism in the centre, are surrounded by more or less strong, at times very extensive bands of dense fibrillar scar tissue. These tumors may resemble sarcomas. In other cases the newly-formed tissue undergoes a mucous, pus-like softening. There arise then more or less richly branched canals or fistulæ filled with mucus and purulent fluids which may permeate the organs extensively. The walls of these fistulous canals are formed by the degenerating masses of the very cellular, newly-formed tissue. This latter form of the disease is much more common in man than is the formation of tumors.

The microscopic examination of the case cited at the beginning of this paper proved extremely interesting. The denser portions of the lungs and the whole of the abscess-like mass in the liver consisted of fibrous tissue riddled with pockets of various sizes, filled with pus in which were many colonies of actinomyces. The more normal portions of the lungs showed numerous areas of broncho-pneumonia caused by the actinomyces, colonies of which were often found in the bronchi and bronchioles. The epithelium was usually stripped from the walls, and the bronchus and adjoining alveoli were filled with polynuclear leucocytes. Often only the masses of cartilage could be found to mark the site of a bronchus.

In the abscesses in the brain and kidneys the disease showed a much more acute process than elsewhere. There was little formation of connective tissue beyond the young connective-tissue cells in the walls of the softened areas.

Through the kindness of Dr. A. K. Stone I was able to compare the character of the lesions produced in this case and the appearance of the colonies with those in a case of bovine actinomycosis. In the latter the softened areas were rather small and the production of young connective tissue abundant. The colonies were large, irregular and showed a great many clubs all around the periphery. Even in the very small colonies the swollen sheaths around the ends of the filaments could often be demonstrated. In the human actinomycosis the areas of softening were much larger, the zone of young connective tissue thin or even in places lacking, and large colonies rather the exception. On the other hand, the production of clubs was much less marked, while the filaments often radiated out in every direction from the colonies. These filaments were found everywhere between the leucocytes, and were characterized by their wavy, spiral course, their frequently jointed appearance and their branching. Small actively growing colonies were very abundant.



It would seem as though, in the study of the peculiar and characteristic colonies formed by actinomyces in tissues, the presence of the organism in any other form had been for the most part lost sight of. Bostrœm speaks of finding rod-shaped forms in pus cells and suggests that they may in that way be carried to the neighboring tissues and thus infect them. Thoma calls attention to the wavy, spiral threads extending out from the colonies and thinks that they may cause infection of the surrounding parts.

Careful study of the walls of the softened areas present both in the human and in the bovine actinomycosis threw much light on this subject. In many of the young connective-tissue cells of the bovine actinomycosis rod-shaped forms were found singly and in clumps, lying in the protoplasm outside of the nucleus. They were frequently beaded and showed much resemblance to the bacilli of tuberculosis and leprosy in cells. Some of them seemed to degenerate and die off. Others developed into small colonies with branching filaments and gradually extended to the adjoining cells. The nuclei seemed to withdraw as far as possible from the approaching organism. Finally, the cells underwent necrosis and the nuclei disappeared. As the colonies enlarged the necrosis extended and polynuclear leucocytes began to make their appearance.

The rods were also found occasionally in the denser fibrous tissue outside of the young connective-tissue cells. In the areas of softening the same form was often found in numbers in and between the leucocytes and other cells. Branching filaments were rare.

In the human actinomycosis the process was much more rapid. There was less young connective tissue and it broke down quickly. The actinomyces showed

much less tendency to form colonies. Instead they grew luxuriantly in loose filamentous tangles and as clumps of bacilli and possibly of cocci. In the young connective tissue were frequently giant cells which also contained the organism as rods and threads. In the brain rod and filamentous forms were found in and between the cells outside of the area of softening. In the softened areas rods and wavy, spiral-branching filaments were found in great numbers in and between the cells, and small, loosely-woven colonies were very numerous.

Explanation of Figures in Plate.

Figs. 1 to 5 are from a case of bovine actinomycosis.
Figs. 6 to 13, from the case reported in the paper.
Fig. 2 shows the rod forms in the young connective-tissue cells around an area of softening.
Figs. 3 and 5 show the development of a young colony in the epithelioid cells of the young connective tissue.
Fig. 4, a leucocyte containing rod forms.
Fig. 1, the edge of a young colony showing the swollen sheaths around the ends of the filaments. The same condition is seen in Figures 3 and 5.
Figs. 6 and 10, giant cells from the wall of the abscess of the brain with rods and filaments.
Fig. 11, brain tissue just outside of the wall of the abscess showing branching filaments and two degenerating rods.
Fig. 9, edge of a colony in the liver showing the filaments extending out beyond the clubs.
Fig. 7, leucocyte from lung filled with rods.
Fig. 13, branching filaments and small clumps of bacilli and perhaps of cocci in softened area of liver.
Fig. 8, small mass of clubs, some of which are fissured, left after death of colony; from liver.
Fig. 12, section through surface of old colony of liver showing a fused mass of clubs and a few degenerating rods and filaments.
The drawings were all made with a Zeiss one-twelfth oil immersion and No. 4 ocular.

As a colony gets larger the centre undergoes necrosis and in this way arise the hollow-ball formations which Bostrœm regards as the highest structural development of a colony. The fact that there is often an opening through the mantle is probably due also to degeneration of the filaments at one or more points, especially on a side near another colony where the supply of nourishment would undoubtedly be less.

For staining actinomyces no method equals Gram or its modifications. The nuclei of the cells should first be stained with lithium or alum carmine. Then every form of the organism except the clubs stands out in sharpest contrast to the rest of the tissue. It is important that the tissues be thoroughly imbedded in celloidin so that the softened areas and the colonies will not drop out of the sections. If the Gram or Gram-Günther method be employed, the sections after being decolorized and dehydrated in 95 per cent. alcohol can be cleared in oil of bergamot. After mounting on the slide every trace of the oil should be removed by xylol before adding the xylol balsam. Personally I prefer Weigert's modification, because by staining on the slide the section can usually be kept flatter.

For staining the clubs in connection with the filaments in sections, the following method will be found to give quite constant results. It is Weigert's stain followed by a saturated solution of fuchsine in aniline oil:

(1) Aniline oil gentian violet, at least ten minutes.
(2) Iodine solution, 1-2-100 one to two minutes.
(3) Fuchsine (saturated solution in aniline oil), two to five minutes or more.
(4) Aniline oil. Change several times; watch the process of decolorization with low power; when sufficient, wash off the aniline oil with xylol.
(5) Xylol balsam.

The section should be dried with filter paper between each step. The nuclei will appear sharper if the sections are first lightly stained with alum cochineal, which gives the best contrast. The filaments within the swollen sheaths can be best seen in the young colonies of bovine actinomycosis.

Infection in man with actinomyces occurs in four ways: by the mouth and pharynx, by the respiratory tract, by the gastro-intestinal tract, and much more rarely through the skin. In a number of cases, both in man and in cattle, the source of the infection has been demonstrated to be some portion of an ear of grain on the surface of which the actinomyces could be shown to be present.

The case here reported would seem to have been infected through the respiratory tract. From there the process extended to the left lobe of the liver. The other organs and probably the arms were infected through the blood. Although not demonstrated, it is probable that the process extended from the lungs to the abdominal wall, and that in this manner the abscess in the epigastrium arose, for it is characteristic of actinomycosis of the lungs that it has a tendency to extend to the chest wall and then to appear beneath the skin.

Actinomycosis of the brain is quite a rare lesion. Martin has just published, from Chiari's laboratory, two cases which he studied there. He was able to find record of but four others.

It has been claimed that there are a great many varieties of actinomyces. Gasperini enumerates eighteen. This is a question which together with several

other disputed points in regard to actinomycosis will have to be left to the future to decide.

## TWO CASES OF ACTINOMYCOSIS HOMINIS, WITH REMARKS FROM A CLINICAL STANDPOINT.[1]

BY HOWARD A. LOTHROP, A.M., M.D.

THE rarity of reported cases of actinomycosis in this country, due in a measure to unfamiliarity with the disease, has led me to report two cases observed in Vienna, and to make a few remarks as regards its clinical history and treatment.

CASE I was that of a man about thirty years of age, and a farmer by occupation. His family history was negative, and he stated that he had always enjoyed good health until the onset of his present illness. Somewhat over a year ago a cough set in, which became more or less troublesome and was so obstinate that he sought medical advice. He was pale and had lost considerable weight, and, in spite of treatment the lung symptoms increased, so that he was led to believe that his case was one of pulmonary tuberculosis, and that he had not long to live.

He states that six months later an abscess appeared somewhat below and to the inner side of the right nipple; this ruptured of itself, and some weeks later two smaller ones appeared near this. Meanwhile the patient continued to lose weight and strength, while there was daily considerable expectoration and free discharge of pus from these sinuses. At periods he was confined to his bed, and was subject to chills and fever especially during the last month. Sharp pains referred to the right chest had been the cause of great suffering particularly before the abscess formation. No abdominal symptoms.

*Condition on Entering Hospital.*— Patient well developed, but extremely emaciated and very anemic. Inspection of thorax showed a limitation of respiratory motion on the right side as compared with the left, as well as a considerable degree of retraction. In the right para-sternal line, about one inch below the nipple, was the opening of a sinus; while about an inch to the outer side of this opening were two smaller ones. Pus escaped from all of them. Right apex dull on percussion, and this area of dulness extended down along the sternum to merge with that of the heart and liver. Vocal fremitus and voice sounds increased over this area. Fine moist râles to be heard over whole right lung, while at the apex the signs were suggestive of cavity formation, and the expiratory murmur was prolonged. Over the left lung was an occasional râle, but examination was otherwise negative. Heart sounds normal. Abdomen retracted, slight epigastric tenderness. Respiration 26; pulse 86; temperature 100° F.

Although repeated examinations failed to reveal tubercle bacilli in the sputum, nevertheless the case was considered one of pulmonary tuberculosis with empyema.

[1] Read before the Harvard '87 Medical Club, February 12, 1895.

The further history of this case until death, two weeks later, presented nothing remarkable.

*Autopsy*, twelve hours after death. Rigor mortis present. In the chest were openings of three sinuses, as described above, which admitted large probes for several inches and out of which exuded pus which was very slimy and tenacious in character. Careful examination of this pus with the naked eye revealed numerous small sulphur-colored bodies smaller than the head of a pin; and the suspicion of this being a case of actinomycosis was verified later with the microscope. On opening the chest, the heart was found to be normal, the left lung collapsed, but the right one remained firmly held on all sides by thick, fibrous, pleuritic adhesions. Section of right lung showed areas of brancho-pneumonia scattered throughout the upper and middle lobes, and many of the bronchi filled with a purulent secretion, while these lobes anteriorly were firm, elastic and honeycombed with sinuses and cavities, none of which were larger than a walnut. The same characteristic pus was seen throughout these lobes. The anterior mediastinum was involved in the process; the costal cartilages and sternum about the sinuses were eroded. The adjacent parts of the pericardium and diaphragm were considerably indurated. In the left lung there was nothing abnormal except a slight secretion in some of the smaller bronchi. No excess of peritoneal fluid in the abdomen. Liver and diaphragm united by old fibrous adhesions anteriorly. In the left kidney was a metastatic abscess, size of a pea, containing pus in which were found the actinomyces bodies. Mucous membranes of the mouth intact; no carious teeth. Result of autopsy otherwise negative. Careful microscopic examination revealed the tissue changes and bacterial developments characteristic of actinomycosis, a description which does not come within the scope of this paper.

CASE II. Female, aged nineteen years, employed at housework. Family history negative. Had never been very strong, but remembered having had no serious sickness during childhood. Two years ago she began to have abdominal pain, worse during the menstrual period, located at first deep within the pelvis, but later it became more indefinite and diffuse over whole lower abdomen. Soon there appeared a tender area on the left side just above Poupart's ligament which developed into an abscess. Patient stated that she had considerable fever at this time and was confined to her bed; also that considerable pus escaped on opening this abscess, and there had remained a discharging sinus ever since. During the last year her menses had been very scanty and irregular; the urine had been very turbid and foul while emaciation and loss of strength had steadily progressed. She had never had any cough and her bowels had been easily regulated. She had been confined to her bed for the last four months.

On entering the hospital, her condition was as follows: She complained of some pain in the lower abdomen, and of frequent micturition with considerable vesical tenesmus. There was loss of appetite, and patient was too weak to help herself in any way. There was considerable diarrhea, but no mucus or pus was found in the stools. No symptoms referable to the thorax.

On inspection she was seen to be fairly developed, but very poorly nourished and anemic in the extreme. The chest presented nothing abnormal. The abdomen

was not distended. On a line about one-third of the distance from the centre of Poupart's ligament to the umbilicus, was the opening of a sinus from which there was a profuse discharge of pus, tenacious and slimy in character, and close inspection revealed the presence of the minute sulphur-colored bodies characteristic of actinomycosis. This region was tender; the skin edematous, red and indurated. Percussion and deep palpation revealed a tumor about the size of a large cocoanut corresponding to the left ovarian region. Vaginal examination showed that all the pelvic organs were glued together in one firm, resistant mass. The urine contained a few hyaline and granular casts, otherwise was that seen in a case of chronic purulent cystitis. Actinomyces colonies were found in the urine.

Patient died two days after entrance.

*Autopsy*, sixteen hours after death. Rigor mortis present. Extreme emaciation. Heart and lungs presented nothing abnormal. The abdomen was somewhat prominent; sinus on the left, as noted above. A small amount of turbid fluid escaped on opening the cavity. Corresponding to the tumor described above, the intestines, omentum, left ovary, uterus and bladder were glued together in one mass by fibrous and fibrinous adhesions. Many small abscesses were scattered throughout this mass, connected by small, tortuous sinuses, some of which led to the opening in the abdominal wall, others to the opening into the bladder. The left ovary was about twice the normal size, indurated and honeycombed with minute abscesses and sinuses. Right ovary normal on section. Both tubes filled with pus, some of which had escaped into the uterus, which was otherwise normal. Bladder wall near entrance of left ureter perforated and thickened so as nearly to occlude this ureter. Liver, kidneys and spleen showed the reaction for amyloid degeneration. Pyelonephritis of both kidneys, with pyonephrosis on the left. Careful examination of intestinal mucous membrane revealed in the sigmoid flexure an indurated pigmented scar about one-half an inch in diameter, and this was considered to be the primary source of infection. Some retroperitoneal glands hypertrophied. Buccal mucous membrane and teeth in good condition. The diagnosis of actinomycosis was verified later by careful microscopic examinations and culture experiments.

## HISTORY.

The occurence of actinomycosis is undoubtedly more frequent than statistics would lead us to infer, as shown by the number of cases diagnosed for the first time on the autopsy table. Being a disease of comparatively recent discovery, failure of the clinician to make a diagnosis may be due either to omission in differentiating the possibilities suggested by any given case, or to unfamiliarity with the disease in question. Consequently, as the histological and developmental phases have been carefully presented in a recent article by Dr. F. B. Mallory, a few remarks from a clinical standpoint may not be amiss.

In 1879 actinomycosis had been discovered in man, and found to be identical with bovine actinomycosis. In 1886 there were about seventy-five well authenticated and published cases, and at the present time there are reports of about four hundred and seventy-five. This would suggest that the disease was on the increase, but the more probable explanation is that the profession is more alert to make such a diagnosis according as opportunity presents.

As yet, notwithstanding most careful and scientific investigations, the etiology, morphology and exact tissue changes are still somewhat obscure. It is most probable, however, that actinomycosis is caused by one of the higher orders of bacteria resembling cladothrix and that in nature its habitat is to be found on certain cereals. That the disease is contagious and due to a specific germ, is proved by the fact that these germs have been isolated, made to flourish in culture media, and have been inoculated from beast to beast, and from man to beast. Most of the recorded cases come from Germany, Austria and Russia; but neither age nor occupation seems to be of value as regards occurrence. Males are about three times as liable as females to become victims.

## CLINICAL HISTORY AND DIAGNOSIS.

Actinomycosis in essentially a chronic disease, but the clinical pictures are at extreme variance according to the seat of origin and the presence or absence of the cocci of septic infection. The actinomyces colonies of themselves do not lead to pus formation. When once a colony is established in any given organ, it spreads either by direct extension (contact), or by means of the blood system, never by lymph-channels, for in non-septic cases the lymph-glands remain normal. When sepsis has become a complication in any given case, than the corresponding glands swell, but, nevertheless, are free from actinomyces colonies unless the diseased parts and the glands are in direct contact. In uncomplicated cases the subjective symptoms are generally trivial; the entrance of pyogenic organisms, however, may be of serious moment and lead to most disastrous results.

As regards certain general considerations applicable to all cases, a careful inspection of the pus is the most important, for by this means alone most cases can be recognized, and this should be a routine procedure in all cases of chronic suppuration. In actinomycosis the pus is more translucent, slimy and tenacious, varying according to the degree of septic infection. A small amount should be spread in a thin layer over any dark colored surface, with the idea of searching for small yellow bodies about half the size of the head of a pin. Some are quite translucent and very pale, others opaque and sulphur-colored. If such bodies are present their nature should be determined by the microscope. Given a suspicious case where none of the colonies can be detected with the naked eye, the microscope should invariably be resorted to. It is beyond the scope of this paper to deal with the histological appearances and requisite staining processes.

The appearance of an abscess is very often the first symptom to which our attention is called. If sinuses have formed the clinician can hardly fail to observe the relatively large amount of induration. Rather than one large abscess cavity, we more often find a series of small abscesses connected by tortuous sinuses. The pus from these small, freshly-opened abscesses is particularly characteristic.

In order to understand more fully the diversity of symptoms and appearances produced by actinomyces invasion, we shall consider separately the four primary sources of infection:

I. Head, including face, neck, tongue, teeth and gums.

II. Lungs.
III. Intestinal tract.
IV. Skin.

I. Head. More than 60 per cent. of the recorded cases come under this class. The germ may find its primary nidus in the pulp of a carious tooth, the tartar at its base, in any abrasion of the buccal mucous membrane, or even on the tongue. Its presence may escape detection until we are called upon to open an abscess pointing externally, commonly about the inferior maxilla. It may spread to any part of the face and neck, or seek deep regions and find its way into the cranial cavity. In many cases bone tissue may be eroded and occasionally necrosed.

A list of diseases for eliminative diagnosis may be of service in suggesting the variety of pathological appearances which could be brought about by actinomyces invasion.

(1) Malignant disease.
(2) Primary syphilitic lesions.
(3) Gummata.
(4) Simple periostitis (cocci infection) and necrosis of facial bones.
(5) Dentigerous cysts.
(6) Epulis.
(7) Tubercular processes.
(8) Actinomycosis.
(9) Ulcerative stomatitis (non specific).

II. Lungs. Here the germs are inspired, either directly from the exterior or from colonies already established somewhere in the buccal cavity. The early symptoms are apt to be very obscure and baffle the skill of the most careful and experienced diagnostician. There is generally the history of cough, but only in the later stages do we find a sputum containing colonies, and even this may fail. Most of these cases run a course very similiar to fatal cases of pulmonary tuberculosis, complicated or not by empyema. Actinomycosis, however, shows a great tendency to invade the mediastina and reach the surface of the body; and sooner or later we find an abscess formation, commonly on either side of the sternum and near its lower costal attachments. Unless there has been a characteristic sputum, this may be the first opportunity to establish a diagnosis. Areas of consolidation and fluid accumulation give the usual signs on auscultation and percussion. Occasionally a case may run its course without lung symptoms, and an abscess formation is the first intimation we have of disease; this would seem to be the most hopeful class of lung actinomycosis, there being two recoveries on record.

DIFFERENTIAL DIAGNOSIS.

1. Pulmonary tuberculosis.
2. Empyema.
3. Broncho-pneumonia.
4. Fibroid phthisis.
5. Chronic pleurisy.
6. Pulmonary syphilis.
7. Ecchinococcus.
8. Gummata in chest wall and mediastinum.
9. Caries rib, — simple, tubercular, syphilitic.
10. Malignant disease.
11. Retro-mammary abscess.
12. Abscess pulmonum.
13. Actinomycosis.

III. Intestinal tract. Includes approximately 20 per cent. of all cases. Germ probably enters with the ingesta. Nature of clinical symptoms open to great variation, as suggested by the table for differental diagnosis. For the sake of classification, we may consider the two following fairly well-marked groups of cases:

(*a*) Where the lesions are confined to the pelvic organs and retro-peritoneal tissues, and give rise to obscure symptoms according to their exact location, and finally reach the surface at a late period, after the patient's general condition has been seriously impaired. The diagnosis in these cases must often be a matter of conjecture until too late to hope for recovery.

(*b*) Where there may be no symptoms attributable to any of the abdominal viscera and our attention is first attracted to an area in the abdominal wall which may be red, swollen, indurated, tender and painful. This may develop into an abscess if left to itself, but after the first discharge of pus there remains the characteristic induration, tortuous sinuses and recurrent small abscess formations. These cases have been permanently relieved by total excision, before abscess formation, with the idea that they were malignant tumors, some calling for partial resection of intestine.

Extensive septic infection in abdominal actinomycosis is often a serious complication, and such cases are liable to run a very acute course.

DIFFERENTIAL DIAGNOSIS.

1. Malignant disease in abdominal wall.
2. Gummata.
3. Chronic pelvic inflammatory processes.
4. Inflammation and tumors about the cecum and appendix. — Tubercular, syphilitic, malignant, streptococcus or staphylococcus invasion; concretions and foreign bodies in appendix.
5. Actinomycosis.
6. Chronic tubercular peritonitis.
7. Perinephritis abscesses.
8. Chronic suppurative affections about the liver.
9. All abdominal fistulæ, not readily accounted for, should lead to a careful inspection of the discharge.

IV. Skin. Primary actinomycosis of the skin has been but recently discovered, and is characterized by a chronic ulcerative process. Pus is generally characteristic, and the diagnosis is readily made if the actinomyces colonies are looked for.

DIFFERENTIAL DIAGNOSIS.

1. Syphilis.
2. Cutaneous tuberculosis (scrofuloderma, lupus, tuberculosis of skin).
3. Epithelioma.
4. Actinomycosis.

PROGNOSIS.

Until recently actinomycosis has been looked upon as a very serious disease, but the latest statistics from large clinics are very encouraging. If the lesions are superficial and accessible to surgical treatment, we have much to hope for; if the lesions are deep seated and situated where interference means serious risk to life, then the prognosis is not encouraging, and up to the present time such cases end their miserable existence as victims of a long, wasting disease.

Of the head cases more than 50 per cent. recover; but two lung cases are reported as having recovered, it being six years since their wounds were healed and no recurrence has taken place. Abdominal cases are hopeful where the pathological process is confined to the abdominal wall or near it, but it is a very serious matter when the retro-peritoneal tissues and organs become involved.

Skin cases ought invariably to recover if treatment has not been too long deferred.

TREATMENT.

*A. Prophylactic.*

(1) Legislation which would lead to the extermination of bovine actinomycosis.

(2) Avoiding uncooked cereals in suspicious localities.

(3) Suitable precautions during the treatment of existing cases.

(4) Proper care of teeth and mouth.

*B. Curative.*

Many cases tend to recover if left alone, as shown by scars and the study of tissue changes where the lesions are superficial. The colonies thrive best when removed from oxygen, as shown by laboratory experiments, thus we can understand why deep-seated lesions make such rapid progress and so often terminate fatally. This fact can be taken advantage of in the treatment, as will be mentioned below.

(1) Internal medication. Only very recently has this mode of treatment received serious consideration. From several reliable sources come reports of the almost specific value of the iodide of potash, administered in doses of thirty to forty grains three times a day. Its use cannot be considered harmful, and all such cases should have the benefit of a trial. It is our only refuge in cases unsuitable for surgical treatment.

(2) External medication. The important antiseptic solutions used to-day will destroy the colonies with which they come in contact; the most valuable for irrigation and washes are corrosive sublimate, carbolic acid and peroxide of hydrogen. Iodoform gauze packings are very efficient as well as applications of solid nitrate of silver.

(3) Operative procedures. These are far less bold than formerly. Excisions of the maxillæ are now rarely necessary. We are guided by the fact that the actinomyces colonies thrive far less luxuriantly when exposed to oxygen. All abscesses should be freely opened and their walls thoroughly curetted. Pockets for pus should be obliterated and sinuses carefully followed up and laid open. General principles, applicable to all cases of septic infection, should be resorted to according to indications. Daily irrigations with antiseptics above mentioned should be used, suspicious spots touched with silver nitrate from time to time, and then iodoform dressings applied.

If possible, small isolated foci should be excised, and, if thoroughly done, there need be no fear of recurrence. In lung and deep abdominal cases, surgical methods are of less avail, and one is forced to rely upon the iodide of potash, with the hope that recent claims as regards the value of this drug in actinomycosis will reach our expectations.

## Clinical Department.

### ACTINOMYCOSIS OF THE ABDOMINAL WALL.

BY S. J. MIXTER, M.D.

The patient was an old man, between sixty and seventy, who had never had anything to do with cattle. He came to the hospital on account of a little bunch just below the umbilicus directly in the median line, which gave him some pain. I etherized him, and started to remove this mass which I thought might be malignant, perhaps of the abdominal wall or perhaps starting from the urachus. It was in the position where you sometimes find the abscesses or tumors starting from the urachus or umbilicus. There seemed to be no clearly defined outline, and finally I went through the abdominal wall on all sides, cutting clear round through the peritoneum expecting it would then be free. I found, however, omentum and intestine attached to it. These were drawn out through the wound, everything freed from the abdominal wall, and the mass was gradually dissected away from the intestine, going down to its submucous coat. Thinking it might be malignant I was intending to excise the intestinal loop. Just then Dr. Whitney came in, having examined the supposed pus, and said it was actinomycosis; so the wounded intestine was folded in by stitches beyond the torn edges, and the wound was united, the whole thing being thoroughly removed as far as could be seen. The fish-bones were not found for some days or weeks afterwards, but at the time of the operation, before I had separated it from the intestine, I cut into it to see if this mass were inflammatory or malignant and found this pus. I said at the time that this was very much like a skewer abscess in the dog. I have seen quite a number of times abscesses which formed in dogs from swallowing the wooden skewers that come in meat. These get into the stomach or intestine and perforate their walls which become adherent to the abdominal parietes, and an abscess forms on the outside, bursts, and the pus and skewer are discharged. It was practically such a process here, because these fish-bones were right in this mass and were the cause of the trouble. They must, I suppose, have carried the infection.

It will be interesting to follow this patient, and see if it is a cure. There was no sign of anything in any other part of the body, and the mass was not very large and was removed with very wide border. The umbilicus was removed; and I should say the incision was something like four or five inches long when sewed up, and part of the rectus muscle on each side having been excised it took a good deal of force to bring the edges of the wound together. It united perfectly, and he had no further symptoms.

The specimen removed consisted of an irregularly oval mass of fibrous-looking tissue to which the umbilicus and skin were adherent on one side and a little fatty tissue on the other. The section exposed a pale, slightly dull surface in which were several small cavities containing a little puriform fluid in which were

numerous minute opaque granules. Imbedded in the tissue were two spindle-shaped fish-bones the size of a hair-pin and about three-fourths of an inch in length.

Microscopic examination of the granules showed them to be made up of masses of minute clubbed and branching bodies radiating from the centre. These were in every way similar to the polymorphous bacillus found in the disease of actinomycosis. The mass was made of rather elongated, and in places round cells, recalling more the structure of a sarcoma than the simple fibrous tissue found surrounding ordinary inflammatory processes.

In this case there is no doubt but that the perforation of the wall of the intestine by the bone was the primary lesion and in the track of this that the actinomycosis had developed.

## DOES ETHERIZATION EVER CAUSE ACUTE LOBAR PNEUMONIA?[1]

BY W. H. PRESCOTT, M.D.

A CASE of pneumonia following an etherization made for the purpose of diagnosis, and occurring in the service of Dr. W. N. Bullard was the cause of this inquiry.

The dangers of and sequelæ to etherization are of sufficient importance to justify any research.

I have been able to find no reference to ether as a cause of pneumonia. I mean the exciting cause; for most authorities agree that acute lobar pneumonia is due to the pneumococcus, although some cases have been attributed to the bacillus of Friedlander and other organisms.

Scattered through the mass of papers yearly written, or in the proceedings of the societies, there are probably many cases where a pneumonia has complicated to a greater or less degree the recovery from an etherization; but it would be impossible to collect all the cases from such sources. I have found, or had sent to me, the record of four; three being in gynecological cases, and one being after etherization for the extraction of a tooth. There is nothing of importance in these records, as they are limited to the fact that during the convalescence the patients had an attack of pneumonia.

There are many cases of broncho-pneumonia and inhalation-pneumonia and cases with pulmonary symptoms, no definite diagnosis being possible, as among the drunkards who have been etherized for the purpose of dressing a compound fracture; but these, while interesting, do not bear upon the subject. A number of physicians, whom I have asked about this matter, have thought they remembered cases of pneumonia, but upon looking them up have found them to be cases of broncho-pneumonia or of inhalation-pneumonia.

In looking up the subject I have been permitted to examine the records of the Massachusetts General Hospital, the Boston City Hospital, the Carney Hospital and the Free Hospital for Women; and I wish to express my obligations to the officers and staffs of these institutions.

At the Free Hospital for Women there was only one case which was suspicious, but there was nothing in the records (there was no autopsy) which would point to the case as being one of acute lobar pneumonia. Dr. F. H. Davenport, under whose care the patient was, and who was kind enough to call my attention to it, said he thought it was a case of pneumonia, although he never could find any physical signs to bear out his opinion. The facts were these: C. H., age forty-three, married, was etherized November 10th (after having been in the hospital six weeks), and colporrhaphy and perineorrhaphy performed. That night the temperature was 105.2°, and nothing was found at any time to explain the condition. Death occurred November 16th, both operation wounds being in good condition.

At the City Hospital I could find no account of a case, although I searched through all the autopsy records (and many of the clinical records) previous to January, 1893. (Dr. Abner Post told me he remembered one case, but I could not find it in the records.)

In looking through the records at the Massachusetts General Hospital, I was aided very much by the excellent paper by Townsend and Coolidge. At this hospital I found one case (Case II), although about the same time there were a number of cases with severe bronchitis.

In the records of the Carney Hospital I found one case (Case I), and another case with severe bronchitis.[1]

Dr. E. W. Cushing has kindly given me notes of the only case occurring in his practice, both private and hospital.

I have no means of accurately judging of the number of etherizations during the time covered by my researches, but there were probably more than forty thousand.

CASE I. B. C., forty, a widow, native of Ireland. Entered the Carney Hospital January 29, 1891, in the service of Dr. Bullard. Family history negative. Well up to one year ago, except for rheumatism nine years ago. Catamenia began at fifteen, and has always been regular until a year ago. During the last year she has been very irregular, and has not menstruated at all for four months. Married fifteen years; no children; no miscarriages. Had frequent micturition at first of her present sickness, but at present had no trouble. Feet swell some at night. Constipation. Appetite fair. Heart and lungs negative. Hepatic dulness diminished. Abdomen distended, somewhat tense, rather dull over central portion, normal in flanks, no fluid detected. Vaginal examination unsatisfactory, but reveals nothing abnormal.

February 8th. Abdomen no longer tender. Large swelling felt, occupying front part of abdomen; somewhat movable, suggesting a pregnant uterus. Fetal heart not distinctly heard; some movement apparently seen and felt in first part of examination. There was a prominence in left epigastric region, which disappeared.

February 10th. Examined again to-day. Not as suggestive of pregnancy. Tumor can be distinctly felt, and is a firm, somewhat irregularly rounded mass, freely movable. Some tenderness in left hypochondrium.

February 14th. Examination under ether. Drs. Gavin, Bullard, Johnson and Conant present. Tumor found occupying a large part of the abdomen; firm, somewhat irregular, quite freely movable. Uterus of about normal size. Vagina and cervix soft and velvety. Result of consultation: operation for removal of tumor advised.

February 16th. Patient refused operation. Last evening was taken with a severe chill. Cough, bloody

[1] Read before the Boston Society for Medical Improvement, December 10, 1894.

[1] Dr. W. N. Bullard has told me since this paper was prepared that this case was also one of pneumonia, but the records confirmed nothing to make such a diagnosis probable.

sputa, and pain in right lower back; considerable dyspnea and some cyanosis. Dulness in right back below angle of scapula; bronchial breathing; few subcrepitant râles.

February 20th. Has been in about the same condition since last entry until last night about twelve, when during a coughing spell there was a gush of water from the vagina, and since then she has been having pains at intervals in lower abdomen. Presentation, breech. Baby born at 2.45 P. M., apparently an eight months' fetus. After much labor the baby was made to breathe, and lived about five hours. At 9 P. M. patient comfortable and apparently in good condition.

February 21st. At 2 A. M. the patient was found unconscious, with dyspnea and cyanosis; pulse not very rapid but feeble. In spite of stimulation, she sank, and died about 6 A. M.

The autopsy showed the right lung, with exception of the very apex, completely solidified.

In this case the symptoms just preceding death would suggest pulmonary embolism as the immediate cause of death, but there is no mention of any having been found.

CASE II. B. C., fifty-three, widow. Admitted to the Massachusetts General Hospital, October 7, 1891, in the service of Drs. Porter and Cabot, and gave the following history: No catamenia for seven years. Has had nine children, being badly torn at the time of her first labor. Discharge from the vagina since last spring, not much before. No bearing down; much backache; some smarting in the vagina. Is now quite weak and has been in bed most of the time during the four weeks preceding entrance.

Examination showed marked irritation of the vagina, with some glairy discharge; cervix lacerated bilateraly; sides of os eroded to a distance of one-half inch beyond the cervical canal; perineum ruptured almost through the sphincter. Temperature 99.6°, pulse 106, respiration 21. Urine pale, specific gravity 1.015; albumin absent.

Corrosive sublimate douche (1 to 10,000) morning and night, cervix painted every other day with glycerite of tannin.

November 6th. Has been doing very well, and the os is looking so well that it is not necessary to operate upon it. Ether. Edges, sides and base of perineum dissected away with scissors as far as the loose tissue, and then brought together with five wire and two catgut sutures.

November 10th. Patient complains of some considerable pain in lower right chest, and on examination by Dr. W. W. Gannett is found to have pneumonia of the right lower lobe. No cough; no expectoration.

November 15th. Patient's local condition about the same.

November 17th. Stitches out. Perineum in good condition.

November 24th. Patient evidently much worse, although the pneumonia is resolving. Heart shows systolic murmur. It is a question whether the heart trouble is new or old.

November 25th. Patient has been slowly failing for the last twenty-four hours; and, in spite of stimulation, she died at 1.20. No autopsy.

CASE III occurred at the private hospital of Dr. E. W. Cushing.

A. B., sixty, was operated upon two days after severe exposure, during which there was a slight chill. Three days after operation her temperature arose to 105°, and she had an attack of acute lobar pneumonia, which complicated her convalescence, but she eventually recovered.

It seems fair, in conclusion, to say, considering the large number of etherizations and the small number of pneumonias reported, that ether rarely acts as the exciting cause of acute lobar pneumonia, and that the few cases found may have been simple coincidences, as Dr. Cushing's case evidently was.

## Medical Progress.

### REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D.

#### ADENO-CARCINOMA OF THE SKIN, ORIGINATING IN THE COIL-GLANDS.

AN example of this rare affection is reported by Dr. Fordyce in the *Journal of Cutaneous and Genito-Urinary Diseases* for February, 1895. He begins by speaking of the different forms assumed by epithelioma of the skin histologically and of the different forms of epithelial cells represented. The tubular form of skin cancer which includes rodent ulcer, may be derived from the epidermis, from the outer root sheath of the hair follicles, and possibly from the glands of the skin. It is to be noted that clinically identical epitheliomata may have various points of origin. Fordyce has examined small benign "pearly" tumors of the face, which are found to be due to epithelial down-growths which have undergone a hyaline degeneration. Sometimes these growths may ulcerate in the centre and spread peripherally. They are much like the benign cystic epithelioma, the histology of which has been carefully studied by Dr. Fordyce.

Adenoma of the sweat-glands is a very rare affection, and few cases with this title have ever been reported. Pathologists are not agreed as to the part played by the sweat-glands in tubular epithelioma. Many have erroneously concluded that when tubular epithelial structures resembling sweat-glands were found, the growth had started from these glands. The location of these growths, away from mucous orifices, where the vascular supply and sources for irritation are less, seems to be the reason for their benign nature rather than their structure or origin. Tubular epithelioma is probably the same pathologically as rodent ulcer. Some writers consider that it arises from the sweat-glands.

The case reported by Dr. Fordyce was that of a man thirty-five years old, from the anterior surface of whose leg the tumor was excised. It was soft, lobulated, about one-half the size of a small egg, and was covered by a small open ulcer. Histologically it consisted of bands and masses of epithelial cells, which strikingly suggested a glandular structure. Cavities containing a colloid substance were found in the epithelial masses. Sweat-ducts enlarged and proliferating were seen, where the lumen and peri-glandular connective tissue were filled with epithelial cells. In the outer parts of the tumor the gland-like structure is not seen, but we have the appearances of an alveolar carcinoma. No participation of the other parts of the skin was found and there were no epidermic globes.

The difference between this tumor and the small-celled cancer which starts from the epidermis, was that in the latter the cells are larger, have no distinct basement membrane, and the tubules do not copy so closely the glandular structure. Fordyce says truly that it is often impossible when a tumor has been in part destroyed by ulceration, to say in what structures the growth started, as those very portions may have been involved in the ulceration. In this case there could be no question of the glandular structure. Karyokinesis of the glandular cells was well seen.

### PARASITES OF MOLLUSCUM CONTAGIOSUM.[1]

At the Fourth German Dermatological Congress Neisser again enunciated his well-known views of the coccidial nature of the contents of the molluscum bodies, and brought forward some new evidence. With regard to the question of psorosperms found in cancer, his own numerous investigations had afforded no sure proof of the existence of cancer parasites. Yet so many remarkable appearances have been discovered that he is stimulated to new investigation.

With regard to molluscum contagiosum, a point of great importance is that specimens hardened in alcohol, while giving a striking histological picture, do not throw light upon the question of parasites. The best specimens are obtained from fresh sections cut with the freezing microtome, best examined in common water. In such sections the transition from normal to altered epithelium is seen. Granular-looking masses sharply bounded are seen in the cells, which gradually are developed into well-defined bodies which are either still somewhat granular, or are smooth and homogeneous. The highest point of development shows a number of large cells, in which, when the nucleus is visible, bodies of variable size, glistening and homogeneous, surrounded by a distinct membrane are seen. These appearances are so striking that they cannot be passed by with the answer "degeneration." The question is asked if a similar degeneration has ever been seen in any other organ. It corresponds to none of the known forms of degeneration, colloid, hyaline, horny, or any other. It is true that the homogeneous bodies seen in these preparations, which he considers to be spores of a spore-cyst, do not fulfil all the requirements of the typical spore-cysts of other protozoa. But it must not be forgotten that the parasites develop here under quite abnormal conditions, being inclosed in epithelial cells which are undergoing a corneous degeneration.

We have, at least, a great many points of analogy between each individual stage and the known developmental stages of other sporozoa; we have the fact that these cell forms without analogy in human pathology, are found in a contagious and inoculable new formation; and that they are included in the epithelial new growths. Numerous attempts have been continually made by Neisser to obtain a further stage of development of the appearances in question, but without any definite results. The most convincing pictures were obtained from fresh sections of mollusca which had been kept in a moist chamber.

As regards the pathological histology of molluscum, the view that it is a degeneration of the sebaceous-glands has been abandoned, even Kaposi at present describing it as a benign epithelial growth. Neisser believes that it is developed from the epithelium of the rete, without any participation of the epithelium of the follicle as has been maintained, although he does not deny the *possibility* that the follicle may be the starting point.

### LOCALIZED ERYTHEMATOUS PIGMENTED ERUPTION DUE TO ANTIPYRINE.[2]

At the meeting of the Société de Dermatologie et de Syphiligraphie of March 8, 1894, Brocq offered the following communication on antipyrine eruptions:

In 1891 he was consulted by a woman of twenty-five years, who presented at her menstrual periods a reddish plaque with pretty sharply defined borders, disappearing only partially on pressure, with infiltration most marked at the centre, diminishing toward the edges, which was the seat of an acute burning sensation. After some days the redness would begin to fade, and the infiltration to diminish, but a pigmentation always remained until the next menstrual period, when the plaque reappeared as intensely as before, and in the same place. It was situated on the anterior surface of the left wrist, together with a smaller one of like nature on the side of the neck. The eruption continued to appear regularly at each menstrual period, becoming rather more marked.

Soon afterward another patient was seen, a young girl, who exhibited a like lesion on the back of the right hand, which left a pigmented spot in the intervals, and it was for this that she sought advice. Meanwhile the first patient had presented herself again, this time with an eruption of the plaque at a time when she was not menstruating, and it was then discovered that the night before this last attack she had taken a dose of antipyrine for a headache, and further inquiry revealed the fact that she was in the habit of taking a dose of antipyrine to quiet the pain, at the approach of her periods.

Other cases are cited. A woman of fifty had been affected for six months with similar plaques on the arm, shoulder, and in the lumbar region. They appeared in irregular outbreaks, and left pigmented spots. Sarcoma of the skin had been suggested by a physician, which caused great alarm. On inquiry it was found that she had never taken antipyrine, but confessed that she had frequently taken analgesine, and the appearance of the plaques coincided with the time when the drug was ingested. A man of thirty had been in the habit of taking antipyrine for severe headaches. Large oval plaques would make their appearance on the arms, back and thighs, pigmented, and leaving brown stains. Three hours after taking the antipyrine, burning and itching sensations were experienced, and the following morning the eruption would appear. In this case the effect of the drug was actually proved by trial.

Somewhat similar cases have, it is true, been recorded, but none exactly like those described here. Brocq insists particularly on the small number and circumscribed boundaries of the cutaneous eruptions, upon their pigmentation, and upon their curious tendency to recur always at the same place. The latter tendency is observed in other dermatoses, but usually in particular regions, as the ears, eyelids, genital regions, etc., while here it may occur at any part.

These eruptions are kindred to the rare bullous form that may be produced by antipyrine. A young man of twenty-three could never take the drug without

[2] Annales de Derm. et de Syph., March, 1894.

having an erythematous and bullous eruption of the prepuce and scrotum accompanied by much edema. The localization was always the same.

At the same meeting of the society Wickham showed for Professor Fournier an erythematous eruption simulating closely a syphilitic roseola. At first sight only syphilis would be thought of, although the macules were perhaps of a rather brighter red than in syphilis. No trace of syphilis could be discovered, whereas it was found that the eruption had quickly followed the ingestion of two grammes of antipyrine taken during two successive days. Fournier remarked that he had at first made a diagnosis of syphilis, but that the patient's energetic denials had forced him to a farther study of the case. Antipyrine eruptions could also closely simulate measles.

### LICHEN SCROFULOSORUM.[3]

Since the introduction of the modern methods of microscopical examination, this affection has received new attention. Jakobi, Hallopeau and Sack have declared their belief in its tuberculous character, on the ground of a similarity in its histological features with true tuberculous tissue. Lukasiewicz's observations included 43 cases of the affection, of whom 35 were men and eight were women, seen at the Vienna clinic. They were characteristic cases of the type described by Hebra, namely, small grouped or partly discrete nodules, seated mostly upon the trunk, light or dark red, tipped with a thin, fatty scale, or sometimes a diminutive pustule. In some cases the extremities also were affected. Frequently the peculiar eczema of the pubic and inguinal region was present together with acne cachecticorum of the lower extremities. In 21 cases the eruption was seated upon the trunk alone; in 11 cases on the extremities also; in one upon the lower extremities solely. In 36 of the cases there was a circinate arrangement. It was almost always possible to distinguish the individual nodules of which a plaque was composed.

The most severe cases were made to disappear in from two to eight weeks, under simple strengthening treatment, although external applications, such as cod-liver oil, zinc paste, and ichthyol were used in order to hasten the cure. Two patients suffered a relapse two months after leaving the hospital. A patient with extensive lupus of the extremities, had four attacks of lichen scrofulosorum on the trunk in three years, without any apparent effect upon the lupus. These relapses usually occurred in patients who were outside the hospital in unfavorable hygienic conditions. Most of the cases were in patients between the ages of two and twenty-five. In seven cases there was glandular enlargement, in three scrofulodermata, in six lupus. One patient died of internal tuberculosis. In eight there was a history of hereditary tuberculosis.

Pieces of skin from 12 cases were examined histologically. In the youngest papules, granulation tissue, consisting mostly of epithelioid cells, was found about the follicles. In a more advanced stage giant cells with nuclei arranged about the centre appear, and they become more numerous as the process advances. The infiltration is grouped about the vessels and lymph-spaces also. The sweat-glands are seen to be affected at all stages of the process. At first they are surrounded by a round-celled infiltration, later their place is found to be occupied by a granulation tissue consisting of epithelioid and large, round, giant cells. The latter are sharply bounded, with peripherally arranged nuclei. No evidence of necrosis was seen in any of the preparations. From these histological appearances, the process could not be considered a true tuberculosis, as there was an abundance of vascular supply, and the infiltration was arranged in bands, and never simulated the sharply-bounded, non-vascular nodules of tuberculosis. There is also an absence of cheesy degeneration and the consequent softening and ulceration in lichen scrofulosorum.

The clinical, comparatively benign course of the affection also speaks against its tuberculous nature; no known form of cutaneous tuberculosis is developed and disappears in so short a time. Tubercle bacilli were searched for in vain. Inoculation experiments upon guinea-pigs yielded no result. The writer regards this process as an inflammation which is the expression of a disturbance of nutrition. It is usually met with in tuberculous subjects, not however, in direct connection with the tuberculosis, but in consequence of the cachexia. He does not, like Richl, regard the giant cells as the result of the action of foreign bodies. They are not only found about the hair follicles, but in much greater numbers in the place of the coil-glands. He regards the epithelium of the sweat-glands as playing an important part in the formation of these giant cells.

### PIGMENTATION FROM THE USE OF ARSENIC.[4]

Hebra declared long ago that patients affected with psoriasis who had been treated with arsenic, were especially liable to pigmentation of the skin. His belief was that there was a causal connection between the arsenic medication and the discoloration of the skin. He therefore counselled leaving off the arsenic treatment on the appearance of brown stains upon the skin. Devergie and Bazin also speak of tâches arsénicales. Later, observations were published showing that pigmentation of the skin occurred after the use of arsenic for internal disorders, in cases where it could not be ascribed to the disease itself. This pigmentation has acquired the name of arsenic melanosis.

According to Förster, Haffter and Wyss, the pigmentation from arsenic begins with a yellowish-brown color on the face, trunk, or extremities, and is usually in isolated patches, which may later become confluent. By a persistent use of the drug large portions of the body can become uniformly dark brown. The mucous membranes that are visible remain free from coloration. In its localization on the skin, the pigment from the use of arsenic does not differ from that of Addison's disease. A radical difference, however, lies in the pigmentation of the mucous membranes in Addison's disease, which does not occur in arsenic melanosis. There is no evidence to show that those who have a predisposition to physiological increase of pigment, are the ones usually affected by the arsenic melanosis.

The writer then relates a case of this description, which had been under his own observation. A man of twenty-three years, was treated for psoriasis at first with a ten-per-cent. chrysarobin-traumaticin solution locally. After fourteen days, when the stain from this medication had totally disappeared, he was put upon arsenious acid internally. Two weeks later, when about three-tenths of a gramme of arsenious acid had

[3] Archiv. f. Derm. u. Syph., Heft. 1, 1894.

[4] Müller: Archiv. f. Derm. u. Syph., 1893.

been taken, numerous pigment spots began to appear on his body. They were partly in places that had been covered by psoriasis, were partly independent of these. Face, head and neck, hands and feet, were the only parts not affected by the pigmentation. A microscopical examination of a bit of skin showed the pigment present in the epithelium and in the corium. In the epithelium it was most abundant in the basal cells. It was also to be seen outside of the cells, in the form of small, brown, anastomosing lines. In the corium the greatest collection of pigment was in the papillæ, which contained eight to fifteen pigment masses each, of irregular shape. Granular bands of pigment were also seen here. Whether these pigment masses were really pigmented cells or only free clumps of coloring matter, could not be definitely determined, although it was evident that a portion of them, at least, represented cells. In accord with the investigations of other pigmented conditions, the writer was able to trace the pigmented masses from the cutis upward to the cells of the rete. As to the origin of the pigment in this melanosis, Stierling found in prolonged treatment with arsenic internally, that there was a sudden and pronounced diminution in the red corpuscles and hemoglobin of the blood. Wyss believes that the coloring matter set free from the blood is taken up by the lymph-channels and thus carried to the skin. As to the treatment of this condition, not much is to be said, except that the drug should be at once suspended. Baths and massage have been suggested, but are of doubtful efficacy. Fortunately the condition is rapidly removed by nature, so that a permanent pigmentation rarely results.

### TINCTURE OF COAL-TAR.[5]

Duhring states that the tinctures of coal-tar are not well understood pharmaceutically. The preparations that one obtains are often of no value, sometimes harmful. Experiments were therefore undertaken by Duhring and a druggist, for the purpose of obtaining a reliable preparation for external use. The formulæ for coal-tar tinctures that have been published may be divided into two groups, those made with alkalies, and those made with tincture of quillaia bark or tincture of elm bark. The object was to find a good pharmaceutical preparation, having the virtues of coal-tar, and especially a product miscible with water. Coal-tar, ten parts, in alcohol twenty-four parts, forms, when diluted, one to eight, with water, a cloudy-yellowish fluid, with an oily substance floating upon its surface. It is therefore not a homogeneous preparation, and is liable to produce a dermatitis. Caustic soda and potash will emulsify coal-tar, but strong solutions are necessary. The mixture is made cloudy by the addition of water and the coal-tar separates. Numerous formulæ were experimented with, but they were not found, on the whole, satisfactory, as there was usually a precipitate formed on the addition of water.

Le Bœuf, about 1860, first made use of tincture of quillaia with coal-tar, calling it "coal-tar saponiné." The formulæ for the preparation of the tincture of quillaia vary somewhat, but it was found that a strong tincture, one part to four of 95-per-cent. alcohol was the best. The advantage of using tincture of quillaia with the coal-tar is that a homogeneous emulsion is formed upon the addition of water in any proportion. Tincture of elm bark acts similarly, but the emulsification is not so complete. The preparation called liquor carbonis detergens, manufactured in England as a proprietary article, is probably also made with tincture of quillaia. It has the same properties as the preparation recommended below.

His conclusions are: (1) The best tincture of coal-tar is made with tincture of quillaia. (2) The strength of the tincture of quillaia should be one to four with 95-per-cent. alcohol. (3) The coal-tar, one part, should be digested with the tincture of quillaia six parts, with frequent agitation for not less than eight days, and preferably for a longer period and finally filtered. (4) The resultant product is a brown-black, clear tincture, which upon the addition of water forms a cleanly yellowish emulsion, the color and certain other characters varying with the kind of coal-tar employed. (5) The tincture is stimulating, and is usually prescribed largely diluted with from ten to sixty parts of water as a wash, and is useful where tar is indicated, as in certain forms of eczema, psoriasis, pruritus and in other inflammatory diseases of the skin. It is often more useful when employed weak than strong. (6) This preparation, which may be called "compound tincture of coal-tar," takes the place of several similarly composed proprietary preparations known as "liquor carbonis detergens" and "coal-tar saponiné."

Leistikow[6] considers that coal-tar produces more lasting effects in pruritic affections than wood-tar, oil of cade, etc. Dry eczemas of scalp, neck, abdomen, genitals and extremities, as well as prurigo and psoriasis, have been especially benefitted by its use. He cautions against its use over large surfaces on account of the danger of poisoning, or of setting up a dermatitis. It should not be used on the face. He uses this formula which he paints on with a camels' hair brush.

[6] La Semaine Médicale, No. 59, 1894.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

JOHN T. BOWEN, M.D., SECRETARY.

REGULAR Meeting, Monday, December 10, 1894, DR. C. F. FOLSOM in the chair.

DR. W. H. PRESCOTT read a paper entitled

### IS ACUTE LOBAR PNEUMONIA EVER CAUSED BY ETHERIZATION?[1]

DR. W. N. BULLARD: The first case which Dr. Prescott reported was in my service, and she was in the hospital for a very considerable time — some four or five weeks previous to examination under ether. She was examined twice under ether; and finally she was transferred to the surgical side after the second examination, with a view to operation. The surgeon considered it wiser to postpone the operation. He advised her to return in three or four months. She was to go the second or third day after the etherization, but she was suddenly attacked with high fever and retransferred to the medical side and with the result mentioned. Shortly afterwards the child was de-

[1] See page 304 of the Journal.

livered by Dr. Farlow, and the recovery from that was perfect; but the woman developed all the symptoms of acute pneumonia and died a few days later. The pneumonia must have developed in the hospital; and the question arose whether ether had anything to do with the pneumonia. One reason why I suggested this subject some time ago was because after this case I had a second one in which the lung was also consolidated, but the patient recovered fully. Very shortly after that I had a third case of lung trouble following etherization. All these cases were gynecological, and it occurred to me whether there was any more danger of pulmonary trouble in cases where there was abdominal disease than in others. Since that time I have not seen any cases of special trouble of the lungs following ether, and I should entirely agree with Dr. Prescott in the light of our present knowledge that it is extremely improbable that *acute lobar* pneumonia would be produced by etherization.

DR. G. B. SHATTUCK: In regard to Dr. Cushing's case, as I understood the report it said the patient had been exposed. That might have been regarded as an etiological factor in that case.

DR. PRESCOTT: I so regarded it. I did not get all the facts from Dr. Cushing, but he told me that two days before the operation his patient, on going to the carriage in her slippers, with nothing over her head, to say good-by to her niece, found, when she went back, the door locked, and had to go round the house, and a slight chill followed this exposure.

---

REGULAR Meeting, Monday, December 17, 1894, DR. C. F. FOLSOM in the chair.

DR. F. B. MALLORY described

A CASE OF ACTINOMYCOSIS.[2]

DR. H. L. SMITH: My interest in this subject was aroused by a young man who presented himself at the City Hospital in the summer of 1892, showing upon his face some very peculiar nodules. He had come for treatment for some other affection, and unfortunately disappeared before the diagnosis of actinomycosis, which seemed to me almost certain, could be verified. I should have had no idea as to the character of the lesions had I not seen a similar case in Vienna. I remember well the astonishment of the instructor on being told that none of the American students present had ever seen a similar case.

The case just mentioned, and two or three others, in which I suspected the presence of actinomycosis, led me to look into the matter, and I read what had been written up to that time. It appeared that nearly all the points as to the characters of the germ, which Dr. Mallory has alluded to, had been either demonstrated or foreshadowed, but a number of them were not so completely worked out as they appear to be at the present time.

The clinical features seem to be pretty well established. The diagnosis, in certain cases, appears very difficult, especially where there has been the formation of sinuses, and in that case it seems to be impossible, in many instances, to tell, clinically, whether one may not be dealing with a case of tuberculosis, or any of the other chronic forms of infective disease, especially in those cases where there is secondary pyogenic infection. But in the case of primary disease of the skin or subcutaneous tissues, especially about the face, it does not seem difficult to make the diagnosis. The nodules are quite characteristic, as will readily be seen by comparing these three lantern slides, which were made by me to illustrate a paper on this subject, read before a dental society two years ago.

To the surgeon the most important element is the question of treatment; and, so far as I can learn, this resolves itself into the question of whether it is possible or not to remove entirely the infected area. One German writer speaks in this way: "The disease should be attacked by fire and sword." In four cases, however, recovery is recorded as having resulted from treatment other than excision. One method was the use of the solid pencil of nitrate of silver, or solutions of that substance, so that it has been suggested that in some of the deeper infected areas the seat of disease might be reached by injecting the silver solution into the sinuses, and with some hope of good results.

In one case recovery followed puncture with the needle and passage of an electric current through a solution of iodide of potassium which had previously been injected into the diseased tissue. It should be said that in beginning the treatment the current had been passed without the solution, but without results. This method of breaking up chemical compounds within the tissues, by the electric current, for the purpose of getting the curative effect of an element in its most active state, at the exact spot where its power is most needed, which has been largely developed by M. Gautier, and is called, I believe, "interstitial electrolysis," opens a very promising field for further study. In the present instance the disease had involved a large area in the cheek of a young lady, and it would have been quite impossible to remove it by the knife without great disfigurement. By the method just described the resulting scar was hardly noticeable, according to the report.

DR. W. F. WHITNEY: Dr. Richardson asked me to show this fluid, which came from a cyst over the xiphoid cartilage in the median line, and I have here the reaction showing quite surely that it is of pancreatic origin. The fluid is watery, slightly turbid, when fresh practically odorless, specific gravity 1.011, very faint alkaline reaction, and contains a slight amount of albumin. The characteristic reactions for the pancreatic fluid as distinguished from other abdominal fluids are, first, its diastatic property by which it transforms starch into glucose or grape-sugar as shown by the reduction copper (the ordinary test made for sugar in the urine). Here is such a test, and you see this dark-brown discoloration which has taken place. Second the property of emulsifying fat. This can be done with olive oil, but the oil should be rendered neutral by means of oxide of magnesia and filtered carefully so that a perfectly neutral oil is obtained, and in this specimen the reaction is shown to a slight extent. Lastly, the digestive properties are next to be studied with fibrin, and you see that the greater part of the fibrin has been acted upon by this fluid. Thus the tests agree with what we know of pancreatic fluids. In regard to the formed elements they consist of a few cells with occasional fatty degenerated ones, not essentially characteristic of any particular locality.

## Recent Literature.

*Surgical Pathology and Therapeutics.* By JOHN COLLINS WARREN, M.D., Professor of Surgery in Harvard University; Surgeon to the Massachusetts General Hospital. Large octavo, pp. 832. Illustrated. Philadelphia: W. B. Saunders. 1895.

It needs a professional career of only moderate length to recall the radical changes which surgical pathology has passed through. From Bichât to Koch there has been a transition in theories and in experimentation perhaps as striking as any department of science has undergone in a century.

It is almost a truism to say that the microscope has re-made pathology. Even the ideas of Rokitansky and of Paget have been changed. The cellular structures of Virchow, the wandering cells of Cohnheim, the fermentation of Pasteur, the bacteriology of Koch, mark the stages of a sure and definite advance.

Accordingly bacteriology and the changes bacteria impose on the blood must form the leading features of any new work on surgical pathology; and they properly occupy all the primary chapters of Dr. Warren's book. Only in morbid growths do we find the cell changes described by Virchow untouched by the newer germ theories. Here, all must admit, that hitherto no causal connection has been established between a spore, a germ or a bacillus, and the occurrence of a morbid neoplasm. Misplaced cells illustrate the anatomical tissues of tumors, but fail to explain the reason of their growth; and reversion to the embryonic type must be a vagary of vital force. Vitiation of the blood by fungi; fermentation of the vital fluids by their multiplication and decay; preventive inoculation by the products of bacterial culture, all play the chief part in pathological changes.

It must not be forgotten, however, that two other great circulatory forces also exist in the currents of the lymphatics, and in the transmission of nervous power. The latter, the greatest and the least understood of all, is the primal cause which governs the expansion and the contraction of blood-vessels and lymphatics; rules the sensitiveness and the absorbent tendency to poisons; and resists their deleterious influences, through vital force.

Certain normal secretions, as the saliva, the gastric juice and the serous fluids, decompose and render innocuous poisonous germs. Nay, there is even an internecine combat of cells: some destroy germs, defeat their generation, or alter their composition. Chemico-vital forces, then, under the leadership of nervous energy, resist decay; restore health; maintain the individual in the vast and chaotic struggle for survival and supremacy. The ductless glands play an important and little understood rôle in restoring health to the blood; ciliated epithelium dusts out the air-passages; cough expels bacilli and their products; diarrhea sweeps away the ptomaines; sweat floods the surface of the body with the diluted results of decaying cells. All these are sanitary.

To favor secretion and to increase excretion are still, as they have always been, sanitary laws. Rational treatment remains but little changed, with the exception of *preventive* medicine. Antipyretics have taken the place of antiphlogistics in the treatment of inflammation, perhaps without much real gain. For fever is often sanitary in destroying hostile germs; and is merely the alarm signal of a mischief which has already occurred.

The presence of a given form of bacteria in a certain disease may be causal, coincident or consequent. The strongest argument for its being causal is in the fairly well-proved claim that the injection of the toxine of this germ aborts its growth, checks its spread, and cuts short the disease. If time shall establish as a fact that, in other diseases, these toxine products of morbid germs are as efficient as they bid fair to be in diphtheria and in rabies, then, indeed, may we congratulate mankind that a discovery has been made in treatment, as certain and as invariable, as was the vaccina of Jenner.

Here is the true road for research; here the great hope of bacterial pathology.

Meanwhile, the results of asepsis in surgery may be justly said to have proved that the prevention of the entrance of these low-grade fungi into the blood and absorbents in wounds, *pro tanto*, prevents fermentation, suppuration and putrefaction. No asepsis being perfect, the occasional failure of primary healing must depend on the susceptibility of the individual; the receptivity of the subject to small doses of the poison, insensibly received.

The practitioner, the investigator, the advanced inquirer will enjoy and profit by this conscientious and broad survey of modern pathology, in which the author has brought discoveries well down to the present moment, and presented everything new, freshly and fully. We older practitioners admire the universal seeking for truth, the balancing of theories, the endless, if sometimes contradictory, experiments, which are admirably collected and verified by the author. For our students we wish he could furnish an abstract and a condensation: for what the beginner needs is not an array of varying opinions, but a summary and digest of all.

We know of no presentation of bacteriology so painstaking and pleasing as that which occupies the first eighty pages of Dr. Warren's book. The colored illustrations and stainings are exquisite, and reflect credit on the liberality of the publisher, as they certainly do on the patient care of the investigator and author.

The writer's classical experiments and illustrations of the microscopic anatomy of repair are all to be found here.

The description of gangrene and sepsis and their chromo-lithographic plates are unusually fine. We are glad to find that we can have more hope in amputating in gangrene than former experience had justified. We confess also to a satisfaction in the author's assent to what we feel sure we have seen ourselves, that pyemia can occur without a wound (for example, in simple fractures); and that suppuration *can* occur without bacteria. In repair, we wish to call particular attention to his experimental proofs that healing by first intention takes *three weeks* to be complete. What a commentary and what a just restraint on the practice of letting laparotomies sit up short of this time. Hernia is well known to follow laparotomy; and even after Alexander's operation on the round ligaments, is now becoming not infrequent.

Fever is treated at length and thoroughly.

The chapters on erysipelas, anthrax, and especially on surgical tuberculosis, are worthy of careful reading; and the latter may be said to be exhaustive.

Bone diseases, also, are thoroughly treated in the light of modern pathology. The chapters on tumors contain the author's investigations on rodent ulcer, and on cancer.

Aseptic and antiseptic surgery are well differentiated, and their merits and proper sphere defined.

There is a valuable appendix on the toxines, on cultures, on staining and preparing, on the examination of tumors. There are two indices; a wealth of illustrations, but not one we could spare. The book is printed in fine, readable style. We congratulate, equally, the medical school with which he is connected, and the author, on a work which brings surgical pathology and therapeutics down to the present day.

"Felix qui potuit rerum cognoscere causas." Amid this sea of inquiries and generalizations, wave after wave of theory rolls in, depositing finally grains of truth, to form a solid land. D. W. C.

*An International System of Electro-therapeutics.* For Students, General Practitioners and Specialists. By Horatio R. Bigelow, M.D., and thirty-eight associate editors. Royal octavo; pp. xxxii, 1147; with 299 illustrations and four plates. Philadelphia: The F. A. Davis Co. 1894.

Even without accepting the electro-therapeutic nihilism of Möbius and Starr, we may well be pardoned for wondering whether electricity is such an important factor in the treatment of disease as to deserve a volume of such bulk. The grandiloquent preface, which tells us that "disease is a difference of potential somewhere; to establish a just equilibrium we must correct the abnormal electric conditions," naturally prejudices the reader. Nevertheless, the work contains much that is of value, and some contributions characterized by careful original work and sound sense. As is to be expected in every composite work the articles vary much in value, and some of them are distinctly the product of enthusiasts who accept electricity as a panacea. In some parts, too, the work is needlessly diffuse; there is something too much of repetition of the history of the development of electrical science, and too much space is given to a presentation of untried hypotheses, concerning which the authors express themselves incapable of pronouncing judgment. After a short article by Herdman urging the need of special education in electro-therapeutics, the scientific side of electricity is discussed, for three hundred pages, by Duff, Wesley Mills, McClure, Engelmann, and Bleyer. Of these articles Engelmann's, on faradism, easily leads. His article is a clear and able discussion of faradic electricity, enriched by much valuable original research. Brubaker writes tolerably on electro-physiology, and Robinson gives a clear, but quite inadequate article on electro-diagnosis, — a field where new and original investigation is much needed. Singularly enough in a work of this sort no diagrams of the motor points are given. Peterson contributes an admirable article on cataphoresis, which has been put upon an exact scientific basis largely by his careful research. Larat tries to prove the value of electrical treatment of intestinal occlusion, Rockwell writes of the treatment of diseases of the alimentary tract, liver and kidneys, and of gout and rheumatism, and N. S. Davis, Jr., of the treatment of thoracic diseases, in rather an unsatisfactory way. Nearly two hundred and fifty pages are devoted to the electro-therapeutics of diseases of the female pelvic organs, with articles by Massey, Grand and Famarque, Kellogg, Goelet, Tripier, Lapthorn Smith, F. H. Martin, Cole and Jarman, and Parsons. Apostoli's methods are fully described, and the virtues of electricity are set forth with somewhat undue enthusiasm, and with a disposition to attribute to ignorance the failures of men who have carefully followed Apostoli's published methods. Henrietta Johnson and Hayes discuss the electro-therapeutics of skin diseases; Sajous of diseases of the throat, and Alleman of diseases of the eye. Riggs contributes a superficial paper on diseases of the brain, giving much space to untried hypotheses. Prince contributes an excellent paper on the neuroses, based on careful work, and exhibiting a critical judgment as to the true value of electricity which is found in but few of the articles. Morton writes as an enthusiast concerning the electro-therapeutics of diseases of the spinal cord, but we fear that few neurologists have so firm a faith in the benefits of electricity as he shows. Leszynsky's article on the treatment of diseases of the peripheral nerves is clear and judicial. Byrne treats of electro-thermal surgery. Newman extols electrolysis in the treatment of urethral stricture, — a faith in which he has few followers. Walling writes of a variety of diseases, from abscess to ulcerations, in which electricity may be useful. Robinson writes of the treatment of various genito-urinary affections, McGinniss of the use of electricity in obstetrics, and Baldy of the use of electricity in pelvic inflammations. Why the electro-therapeutics of the various disorders of childhood are not sufficiently considered under the above headings we cannot say, but Mary Putnam Jacobi contributes a fifty-page article under that heading, which does little more than repeat what others have already said before.

It is perhaps inevitable that in a work of this sort, where of necessity some mention must be made of the use of electricity in every form of disease, the tendency should be to extol electricity as a panacea. This we are convinced tends to prejudice the physician against the real virtues of electricity as a therapeutic agent; for, after all, electricity, although of real value, is applicable only to a limited number of diseases. The present volume contains much that is of value, as we have said; and the physician can find in it useful information in regard to all branches of electro-therapeutics; but the work is too large, and it contains much that is needless and considerable that, to say the least, is still hypothetical. The mechanical execution of the work is poor; several of the illustrations being quite unintelligible.

*Clinical Medicine.* A Manual for the use of Students and Junior Practitioners. By Judson S. Berry, M.D. (Lond.), Senior Assistant-Physician to the Manchester Royal Infirmary, etc. With numerous illustrations and plate in colors. London: Charles Griffin & Co. Philadelphia: J. B. Lippincott & Co. 1894.

The author's aim in this manual is to assist the student and junior practitioners in the examination of medical cases. It is really a treatise on Symptomatology. Etiology and treatment are only incidentally considered. In this way the whole subject is condensed into an octavo of four hundred and seventy pages. The illustrations are numerous; some are taken from photographs or drawings of cases under the author's own care, and the rest from various sources.

*A System of Legal Medicine.* By ALLAN MCLANE HAMILTON, M.D., Consulting Physician of the Insane Asylum of New York City, etc.; and LAWRENCE GODKIN, ESQ., of the New York Bar; with a corps of Collaborators. Illustrated. Vol. II. New York: E. B. Treat. 1894.

The second and final volume of this composite work is not inferior to its predecessor; in some respects it is more attractive. It would be impossible that a book should be dull or unprofitable whose chief chapters were written by such a quartette of authors as Hamilton, Mills, Dana and Knapp. Nearly two-thirds of the text are devoted to the medico-legal relations of mental and nervous diseases; including long chapters on insanity, aphasia, traumatic neuroses and feigned diseases. Other chapters discuss abortion and infanticide (Jewett); birth, sex, pregnancy and delivery (Currier); genito-urinary and venereal diseases (Sturgis); sexual crimes (Craddock). Members of the New York Bar have contributed articles on "Expert Testimony," "The Legal Accountability of the Insane in Civil and Criminal Practice," and "The Measure of Damages in Accident Cases." Judge Baldwin, of the Connecticut Supreme Court, has a short chapter on "Marriage and Divorce," dealing solely with the legal phases of the subject.

This volume, like the first, shows the want of a well-defined plan, and suggests that the printers began their work before all the manuscript was in the editor's hands. There is a hint of hurrying in preparation which more careful editing might have eliminated. But the two volumes, taken together, constitute a treatise of which neither editor nor publisher need be ashamed and to whose general acceptability the critical reader will stand ready to testify.

*The Theory and Practice of Medicine.* By FREDERICK T. ROBERTS, M.D., F.R.C.P., etc., Professor of Materia Medica and Therapeutics and of Clinical Medicine, at University College, London, etc. Ninth Edition. Philadelphia: P. Blakiston, Son & Co. 1894.

Dr. Roberts's "Theory and Practice of Medicine" is so well known from the previous numerous editions that it requires no detailed notice. The present edition has been revised throughout, and parts of it have been rewritten. The order of subjects has in some respects been rearranged. New sections dealing with the general therapeutics of the principal systems and organs have been introduced, and should be found acceptable. The necessary consideration has been accorded to bacteriology in its general aspect and in its relation to special diseases. There never was a time when new editions of old text-books were more necessary to their keeping their place than now.

*Twentieth-Century Practice.* An International Encyclopedia of Modern Medical Science. By leading authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D. In twenty volumes. Vol. I, Diseases of the Uropoietic System. New York: William Wood & Co. 1895.

This is a bold undertaking, both on the part of the editor and the publishers. Who shall say, after the changes which the last ten or fifteen years have witnessed in medical science, what will be the modern medical science when the twentieth volume of this encyclopædia shall be issued? The editor feels that the science of medicine having been in great part recast, the time is now ripe for it to be rewritten; but with a prophetic instinct that the recasting is still in progress, he wisely reserves the consideration of the infectious diseases for the later volumes.

In the present volume of seven hundred and thirty-seven pages, with index, Dr. Francis Delafield, of New York, treats of Diseases of the Kidney; Mr. Reginald Harrison, of London, of Surgical Diseases of the Kidney, and of the Ureters; Dr. G. Frank Lydston, of Chicago, deals with Diseases of the Prostate; Mr. E. Hurry Fenwick, of London, with Diseases of the Urine; Dr. Howard A. Kelly, of Baltimore, with Diseases of the Female Bladder and Urethra.

The names of these gentlemen are a sufficient assurance of their competency to discuss the subjects assigned them. It would be an ungracious task to endeavor to point out details in which observation, theory and practice have already made some changes since these writers laid down their pens; and were such an endeavor in any measure successful it would not discredit these contributions, but would only strongly emphasize the fact that we are still in the midst of a period of intense activity in medical science and its application to medical and surgical practice.

*Atlas of Clinical Medicine.* By BYROM BRAMWELL, M.D., F.R.C.P. (Edin.), F.R.S. (Edin.), etc. Vol. III, Part I. Edinburgh: Printed by T. & A. Constable, at the University Press. 1894.

The first twenty-five pages of text of this Part I of the third volume are occupied by the well-known address on the "Thyroid Treatment of Skin Diseases" delivered by the author at the Congress of the Dermatological Society of Great Britain and Ireland in May, 1894. It is illustrated by fourteen plates. Two more plates illustrating the same subject will be issued with Part II.

The next fourteen pages of text are devoted to poliomyelitis anterior acuta, of which there are two illustrative plates. The last eight pages deal with a remarkable case of cancer of the breasts, spleen and other organs. A plate belonging with this case will be issued with the next part.

This third volume will be issued in three fasciculi.

*Landmarks in Gynecology.* By BYRON ROBINSON, M.D. Published by George S. Davis, Detroit, Mich.

These two small volumes are abstracts of some lectures delivered by Dr. Robinson at the Chicago Post-Graduate Medical School. There are six "Landmarks" which he considers of especial importance: Anatomy, Menstruation, Labor, Abortion, Gonorrhea, and Tumors, and his remarks on the diseases of women in connection with these six important subjects, make very interesting reading. He is original and suggestive, possibly at times a little fanciful, but in the main sound and practical. These books can be recommended as a pleasant variation from the ordinary text-book method of treating gynecological subjects, and will serve to while away some leisure hours very agreeably.

*Syllabus of Gynecology.* Based on the American Text-Book of Gynecology. By J. W. LONG, M.D., Philadelphia: W. B. Saunders. 1895.

An extract from the preface will best show the character of this book:

"'The Syllabus of Gynecology' has been written

with a threefold object: first, to be used as lecture notes; second, to enable the student more intelligently to follow and remember the lectures; and, finally, as a convenient reference for practitioners."

This certainly represents a good deal of painstaking labor, as it is a very full synopsis of the work mentioned above, very conveniently prepared for use; but we think there is doubt whether it will practically prove of much value, either to the lecturer, student or practitioner. Of the three it seems to us more likely to prove of value to the student.

*A Clinical Manual.* A Guide to the Practical Examination of the Excretions, Secretions, and the Blood, for the Use of Physicians and Students. By ANDREW MCFARLANE, M.D., Instructor in Neurology and Diseases of the Chest in the Albany Medical College, etc., etc. New York: G. P. Putnam's Sons. 1894.

The author's object in this little book is to give in a concise manner the methods put at the disposal of the practitioner by the recent advances in physiological chemistry and clinical microscopy for the more accurate elucidation of the problems coming daily to his attention. Part I is devoted to the urine; Part II to the stomach contents; Part III to the feces; Part IV to the blood; Part V to pathological fluids; Part VI to the pathogenic micro-organisms. The illustrations are sufficient and well selected. It is a concise and handy book and will be found useful for the purposes which it aims to meet.

*Manual of Practical Morbid Anatomy.* Being a Handbook for the Post-mortem Room. By H. D. ROLLESTON, M.A., M.D., F.R.C.P., and A. A. KANTHACK, M.D., M.R.C.P. Cambridge: At the University Press, 1894. New York: Macmillan & Co.

This small volume consists of directions as to the manner of performing autopsies, together with brief allusions to the common pathological conditions which are to be met with in the various organs. The work is unsatisfactory because it is too large for a mere manual of autopsies, and too small for a treatise on morbid anatomy. The methods of examination of the body cavities are scattered through a mass of inadequate descriptions of gross lesions which can be of little or no value to the novice.

*Diseases of the Skin.* An outline of the Principles and Practice of Dermatology. By MALCOLM MORRIS. Philadelphia: Lea Brothers.

This little book is really a good compendium of dermatology, carefully prepared and thoroughly up to date. It is astonishing to find how much the author has been able to compress into the limited space at his command. The need of such treatises is not, it is true, apparent at the present time, so many of a like nature having been put upon the market during the last few years, but it must be admitted that this one is entitled to a strong word of praise, for the care that has been taken in its compilation. At the beginning he introduces eight chromo-lithographs depicting some of the more common types of cutaneous disease, and these are pretty accurate representations of their subjects. A very fair position is taken with regard to most of the unsettled questions, and the subject of treatment is well and clearly handled.

*Syphilis in the Innocent.* By L. DUNCAN BULKLEY, M.D. New York: Bailey & Fairchild.

This essay, of nearly four hundred pages, is the result of ten years' work. Bulkley considers that the innocent occurrence of syphilis, and the modes by which it may be innocently acquired have received too little attention hitherto, and no full presentation of the subject has ever been made. This essay is essentially a compilation of the literature upon the subject, carefully gathered from a great many and diverse sources. One hundred and sixteen original personal cases of extra-genital infection are recorded, a larger number, the writer remarks, than have ever before been published by an American observer. He then devotes much space to the different methods of acquiring the disease innocently, and while little of importance that was not already known is brought out, yet many curious instances are naturally related. A table of the epidemics of syphilis that have occurred from 1577 to the present time, together with accounts of various endemic diseases which are now regarded as syphilis are appended. One hundred and forty-six pages are devoted to an analytical bibliography of syphilis insontium which should be of value for reference.

*Practical Lectures in Dermatology.* By CONDICT W. CUTLER, M.D. G. P. Putman's Sons.

Dr. Cutler was requested by the students in the Medical Department of the University of Vermont to publish his lectures on Disease of the Skin, and they are bound together in this book in the form of 15 lectures. They form a good introduction to the study of dermatology, suited to the needs of the student who has but a brief period to devote to this subject.

*Sexual Neurasthenia [Nervous Exhaustion]; its Hygiene, Symptoms and Treatment.* With a chapter on Diet for the Nervous. By GEORGE M. BEARD, A.M., M.D. Edited, with notes and additions, by A. D. ROCKWELL, A.M., M.D. Fourth edition, with formulas; 8vo, pp. xii, 294. New York: E. B. Treat. 1895.

To the fourth edition of this well-known work the editor has added a brief account of some of the forms of inordinate sexual desire which occasionally disturb neurasthenic patients, to which condition he gives the name of sexual erethism. With this exception this edition does not differ from the preceding.

*Essentials of Diseases of the Skin.* By HENRY W. STELWAGON, M.D. Saunders's Question Compends. Philadelphia: W. B. Saunders. 1894.

The third edition of Dr. Stelwagon's book has appeared, revised and enlarged, with 71 letter-press cuts and 15 half-tone illustrations. It is arranged in the form of questions and answers, and like the preceding books is intended for the use of the student of general medicine.

---

AN AID TO PRESCRIPTION WRITING. — *Doctor* (to fair patient): Put out your tongue. (Meanwhile he writes out a prescription.) There, that will do. — *Miss Chatterbox:* But, doctor, you did not even look at my tongue. — *Doctor:* No, I only wanted you to keep quiet while I wrote the prescription. — *Geillustreed Stuiversblad.*

## THE RELATION OF HEREDITY TO INSANITY AND IDIOCY.

In an interesting discussion on heredity by the Philadelphia County Medical Society, January 25th, Dr. Chapin, Medical Superintendent of the Philadelphia Hospital for the Insane, read a paper on its relation to insanity and idiocy, in which he maintained that insanity is not inherited, that is to say, that it is not directly transmissible from parent to child, in a large proportion of cases.

Referring to personal observations, an examination of 347 patients admitted during two years in the Pennsylvania Hospital showed that the probable and direct cause of insanity in 188 cases was neurasthenia or nervous exhaustion from overwork, strain or worriment, some form of general ill health, the puerperal state, septic conditions, etc.; and the element of inheritance did not appear or was not ascertained. The remainder were cases of paresis and other forms due to brain degeneration, senile failure, or organic disease, some with a history of marked heredity; of which 27, or 14 per cent. only, had a family history sufficiently marked to warrant the assumption that heredity was the probable cause of insanity.

Among Dr. Chapin's conclusions are three which we quote:

Insanity as a disease is not transmissible by inheritance, but may be acquired or evolved from a neurotic heredity as a basis.

A neurotic predisposition is transmissible by inheritance, but there is no absolute rule that it will be transmitted in any given case, or in any case.

In-breeding of neurotic temperaments is most conducive to the creation of a neurotic heredity.

Dr. Chase, Medical Superintendent of the Friends Asylum at Frankford, begins his paper with the statements that the most common cause of insanity is heredity, and that in no class of diseases is a transmission of a predisposition to ill health more potent or more evident than in insanity.

Dr. Barr, Chief Physician of the Pennsylvania Training School for Feeble-minded Children, in his paper on "The Influence of Heredity in Idiocy," regards it as a potent cause, quoting Mercier, Montaigne, Ireland, Moreau, Grabham, Shuttleworth, Beach, Langdon Down, Esquirol, Dahl and Dunlop, in support of his position. In his own experience, based on the careful examination into the family histories of 1,044 idiots, he found 397 families, or 38 per cent., with a history of insanity or imbecility, and 225, or about 21½ per cent., of various neuroses.

The authorities quoted by the readers regarded heredity as the cause of mental disease and defect in proportions of cases varying from 6 to 90 per cent. So wide divergencies of opinion can come only from different uses of terms and definitions or from greater or less accuracy and success in ascertaining facts. So great is the difficulty in obtaining exact information on these points that the Scotch Commission in Lunacy, in a supplement to their thirty-sixth report, entitled "Alleged Increasing Prevalence of Insanity in Scotland," say "We do not know of any way in which it would be possible to obtain information as to the origin of the insanity of the patients on our Register which would be of the smallest statistical or scientific value, and we have not therefore thought that any useful purpose could be served in dealing with the question from this point of view."

In the "consensus of the competent," that heredity is a remote or predisposing cause of insanity for the most part, and that the immediate or exciting causes are to a great degree preventable by avoiding injudicious marriages, by proper education of children and by sensible living, there is good reason to believe that insanity, as well as idiocy, may be controlled.

It is certainly satisfactory that the Scotch Commission can say, after most exhaustive investigations, "At present we can only repeat the conclusions arrived at in many of our former reports — a conclusion the soundness of which we do not think has been called in question by any authority in Scotland — that the facts and figures, so far as they have been already collected and studied, afford no ground for a belief that insanity is to-day more prevalent in Scotland than it was when we entered upon our functions over thirty-six years ago." The increase there, as elsewhere, has been, so far as can be seen, rather apparent than real; and this fact upholds Dr. Chapin's view, that insanity is not so directly transmissible by inheritance as has been generally supposed.

## ETIOLOGY AND TREATMENT OF ACNE.

At the meeting of the British Medical Association held at Bristol in August last, Dr. Stephen MacKenzie read a paper[1] preliminary to the discussion of this topic. A large part of his paper is devoted to the question of the relative share taken by local and by constitutional conditions in causing the disease. Grant-

[1] British Medical Journal, September 29, 1894.

ing that the pathology consists in a blocking of the ducts, followed by inflammation, the question arises as to the cause of this occlusion of the glands by the imperfectly formed products. The physiological activity of the sebaceous glands at the time of puberty is most often the starting-point of the acne, and the affection usually improves as the patient grows older. Dr. MacKenzie takes a very decided stand against the prevalent theory that constitutional disturbances play some part at least in the etiology of acne. He states that while such disturbances undoubtedly occur, they are such common troubles, that nothing at all can be argued from their association with acne, as they occur in his experience as commonly with psoriasis and scabies as with acne. He then takes up the various disorders that have been claimed to have a causal relationship with acne. Anemia is common in females with acne, but acne occurs at a time, especially in females, when anemia is often met with. The acne will not be benefited by the cure of the anemia unless the skin has local treatment also. Constipation also he puts in the same category. Irregularities of menstruation seem at first sight to have a more probable causal connection with acne than any other disorder, as the acne is so frequently aggravated at the menstrual periods. But it will be often found that this is the case where the menstruation is normal in every way. He considers it probable that there is an increased physiological activity of the sebaceous glands at the menstrual period, which would favor the increase of the acne at this time. Flushing of the skin, produced by indigestion, stimulants, changes of temperature, etc., he thinks may act as an aggravating factor, but will not produce it unless the local conditions are favorable. These local conditions he regards as of the greatest importance, while the constitutional state has little etiological significance, except in the broad sense that every debilitating condition is unfavorable to the proper performance of the functions of the glands.

Hence his conclusion that local treatment is of prime importance. Preventive treatment is regarded as very desirable, and medicated soaps are highly prized. The most useful as preventives of acne are the alkaline camphor-sulphur, Peruvian-balsam, and creolin soaps, also neutral salicylic-sulphur, and salicylic resorcin-sulphur powdered soap. In the developed disease the medicated soaps are also indicated. Puncture of the pustules he considers of great importance. Smith's method of touching each pustule with a drop of liquefied carbolic acid and then covering with collodion may be used where puncture is not consented to. Mild ointments of zinc, boracic acid, etc., at night followed by calamine lotion during the day, act well where there is much inflammation. Otherwise more stimulating ointments, as sulphur ointment, may be used at night, or sulphur in powder or suspended in eau de cologne. After the most of the trouble has been removed persistent employment of the medicated soaps is used to prevent recurrences.

Most of the speakers in the discussion that followed agreed with Dr. MacKenzie that local treatment should hold the first place, but were not all inclined to abandon constitutional measures. Dr. Radcliffe Crocker voiced the feeling of the majority of the best dermatologists when he said that attention to disorders of the alimentary canal and other derangements, *together with* local treatment offered better results than local treatment alone. Dr. Payne thought that too little stress had been laid on diet, which was certainly a factor in some instances.

## A STATE SUPPLY OF DIPHTHERIA ANTITOXIN.

It has been understood for some time that the Massachusetts Board of Health was making preparations for the production of a supply of diphtheria antitoxin. The circular printed herewith shows that the work is completed.

Dr. J. L. Goodale was placed in charge of the station established by the Board, and has been carrying on the various portions of his work since September last. The horses, five in number, were inoculated with the first dose of the toxin early in December last, and the successive doses have followed from time to time without untoward incident until an antitoxin has been obtained of satisfactory strength.

How far the supply thus obtained will go in providing for the wants of the community is, of course, an unsettled question; but it is to be hoped that the State Board will extend as far as possible its supervision over the preparation of this class of remedial agents.

COMMONWEALTH OF MASSACHUSETTS.

DIPHTHERIA ANTITOXIN.

STATE HOUSE, BOSTON, March 25, 1895.

THE investigations of Behring and Roux with reference to the value of serum-therapy in the treatment of diphtheria, and the later experience of its use in diminishing the mortality from this disease, are widely known and fully understood.

The State Board of Health, in accordance with its organic purpose as defined in the statutes, having in view the "interests of health and life among the citizens of the Commonwealth," and recognizing the value to the people of any agent which will measurably prevent the ravages of a disease capable of destroying more than a thousand of lives annually in Massachusetts and of causing suffering which cannot be expressed numerically, has prepared a supply of antitoxin, for the benefit, primarily, of such communities in this State as find it difficult or impracticable for any reason to supply themselves with the new agent from reliable sources.

Great care has been exercised in the preparation of this supply to fulfil the most exacting technical requirements for obtaining a pure and trustworthy product, and the tests of its strength have shown satisfactory results.

The Board does not propose to offer it for sale, but its gratuitous distribution will be under strict conditions designed to prevent abuse and waste and to obtain the most beneficial fruits. Each bottle is marked with a number and the date of the preparation of its contents. No antitoxin will be issued except upon a pledge that a full statement of the observed effects of its use will be returned to the Board at the termination of the case. In all instances possible a bacterial diagnosis will be insisted upon. The Board desires to emphasize the importance of using such appliances only as are adapted to the proper administration of the remedy, of remembering that experience has demonstrated that antitoxin is most useful in the earliest stages of a diph-

theritic attack, and of realizing that trained medical skill is required to administer it successfully.

A blank form for the report and a detailed statement of instructions as to methods will accompany each bottle of the antitoxin serum.

For the needs of persons living within twenty-five miles of Boston, it will be required, for the present, that personal application at the office of the Board shall be made by the attending physician in the diphtheria case, or by some person authorized by him. For the convenience of more distant parts of the State, local agencies at public hospitals or municipal health offices will probably be established by the Board in accessible centres.

The office of the Board (Room 141, State House Extension) is open each week-day, except Saturday, from 9 A. M. to 5 P. M., and on Saturday from 9 A. M. to 2 P. M.

SAM'L W. ABBOTT, *Secretary*.

## MEDICAL NOTES.

PROF. GUIDO BACELLI. — Prof. Guido Bacelli, of Rome, has been chosen an honorary member of the Harveian Society of London.

THE REGISTRATION OF MIDWIVES IN ENGLAND. — It is proposed to introduce into the British Parliament a bill for the Registration of Midwives. The bill has been drawn up by a representative committee from training schools and medical societies, with the assistance of an attorney, and is based on the suggested scheme of the midwives' registration association.

THE STORAGE OF ANTITOXIN. — Prof. Thomas R. Fraser (University of Edinburgh) writes as follows to the *British Medical Journal:* "It seems to me that much unnecessary trouble is being taken in the storage and distribution of diphtheria antitoxin. I refer to the elaborate precautions which are required so long as it continues to retain its liquid form. I would suggest that in future the liquid antitoxin should, as soon as it has been obtained, be evaporated *in vacuo* over sulphuric acid, and stored and distributed in the form of a dry powder, whose exact quantitative relationship to the liquid antitoxin or to the toxin itself could easily be ascertained and stated. There can be no doubt that in this dry form diphtheria and all other antitoxins will retain almost indefinitely their original effects. Were this plan adopted it would also be possible considerably to reduce the bulk of fluid injected under the skin."

A CONVINCING TEMPERANCE ARGUMENT. — An English temperance agitator, Miss Weston, publishes in "Ashore and Afloat," under the caption of "A Drunkard's Brain — No Joke but Awful Truth," a statement that at an inquest recently held upon a noted drunkard, on opening his skull, "the odor of alcohol that filled the room was sickening. One of the surgeons then struck a match and held it close to the head. Immediately a blue flame enveloped the whole of the exposed brain." Miss Weston seems to regard truth as a matter of slight importance compared to the virtue of total abstinence. — *Medical Record.*

CONGENITAL SPOTS A MEANS OF RACIAL IDENTIFICATION. — At a recent meeting of the American Academy of Arts and Sciences, Dr. Stephenson, U. S. N., read a paper entitled: "Congenital Spots on Annamites a Means of Racial Identification, with Remarks on Linguistics in Connection with Migration of Peoples." Reference was made, also, to the studies of the Annamese savant, Petrus Truong Vinshky of Cholon (near Saïgon, Cochin China), and to his works on linguistics, comparative philology, etc. Such investigation, as well as examination of bodily peculiarities, enables us to trace the origin and history of various peoples in their world-wanderings.

CREMATION IN GLASGOW. — A question has recently arisen in Glasgow as to the legitimacy of cremation in the absence of special instructions on the part of the deceased. The final decision was, that no society can countenance the cremation of the remains of any one who was known to disapprove of it, one of the forms to be filled containing the phrase, "and I certify that the deceased expressed to me no objection (orally or in writing) to be cremated after death."

A PATHETIC PICTURE. — The *Railway Surgeon* publishes the following letter from a physician practising in a small Southern town to a firm of instrument-makers:

February 12, 1895.

MESSRS. —— & Co. *Gentlemen:* — It is useless and a waste of postage to write me about paying you. My wife and children are on the verge of destitution. My little ones are barefoot and hungry. Our supper to-night consisted of raw turnips. It is so with us all in this section of country. A total failure of crops and a dearth of money have brought us to this terrible strait. Horses worth $100 or $150 are being turned out to die; there is nothing to feed them on. I have not *seen* a dollar for months. To send you this letter I borrow two cents from a friend. I wish I could pay you, and would do so willingly if I could, but it is entirely out of my power till these terrible times pass.

The men at the head of our government are men destitute of conscience or honor. Such distress as they have brought on the people, it seems to me, ought to move a heart of stone.

I hope you will not think hardly of me, but what I tell you are horrible facts. My dear little girls are wearing rags around their feet for shoes. You see that it is impossible for me to pay you. I have dreaded to tell you my fearful condition, hoping you would understand it by my not writing to you. When I can, I will pay you, rest assured.

I am, my dear sirs, your unhappy friend, —— ——.

P. S. The last money that I have had was from the sale of the beef I spoke about last fall. It was a fine thoroughbred Durham, and ought to have brought $40 or $50, but I got $7.35 for it. Since then I have not had one dollar.

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, March 27, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 34, scarlet fever 47, measles 125, typhoid fever 2.

THE BOSTON LYING-IN HOSPITAL. — This hospital has issued its annual report for the sixty-second year of its existence.

Since the opening of the hospital at its present situation in the year 1873, 7,226 patients have been received and treated in-doors; and in the out-patient department, since its establishment in the year 1881, 6,405 patients have been cared for under the supervision of the hospital staff. Of the total number of

patients treated in the hospital since 1873, 126 have died; but of the 4,565 cases admitted since the introduction of the antiseptic methods of treatment, all except 34 have been successfully discharged, and this has been the result, notwithstanding the difficult and complicated nature of many of the cases. In the larger part of those which resulted fatally the patients were brought to the hospital in a moribund condition. Only 15 deaths have occurred out of the whole number of out-patient cases cared for.

The number of women received and treated at the hospital, during the past year, has been 557, an increase of 56 over the number treated during the preceding year. In addition to the above the number of babies born and cared for has been 558.

The daily average of patients (mothers) in the hospital has been 23.8, being an increase over that of last year, which was 22.8. The average stay of patients in the hospital has been 15.4 days, a decrease from that of last year, which was 16.4 days.

The number of out-patients treated was 1,485, an increase of 133 over the number treated last year. The total number of patients (mothers) has therefore been 2,042, an increase of 189 over that of last year.

The total number of deaths the past year has been eight, five in the hospital and three in the out-patient department, a mortality of less than one-half of one per cent. Of the five patients who died in the hospital, four were cases of convulsions. The fifth patient died suddenly of embolism twelve hours after the birth of the child.

During the past year the total expenditures for all purposes were $17,792.40, which included an average cost for each hospital patient (mother) of $31, and an expense of $522.24 for the out-patient department.

The care of needy and deserving patients in childbirth is the primary purpose of this hospital, but it is also a centre for the obstetrical training and education of physicians and nurses.

The hospital is dependent to a large extent upon the generosity of its friends for carrying on its work. It is at present in need of a sum of $10,000 to enable it to meet its annual expenses, and has issued an appeal for contributions towards such a sum. Only to those who do not know its work is it necessary to say that no medical charity is more worthy of support.

A Polyglot Apothecary. — On the sign-board of a drug-store on Salem Street, Boston, and on the back of the prescription blanks furnished by the proprietor, he states that no less than twelve languages are spoken at his shop; namely, English, French, German, Italian, Greek, Turkish, Spanish, Russian, Hebrew, Hungarian, Roumanian and Portuguese. That an apothecary should find it necessary to advertise his ability to speak English in Boston is a curious indication of the way in which a foreign population has monopolized certain districts in the city. The changes which have taken place in the character of the population of the North End are shown by the fact that this drug-store is within a stone's throw of the Cushman School, which stands on the site of Charlotte Cushman's birthplace, on Parmenter Street.

### NEW YORK.

Commencement at the New York College of Veterinary Surgeons. — The New York College of Veterinary Surgeons and School of Comparative Medicine held its thirty-eighth annual commencement on March 18, in the Concert Hall of Madison Square Garden. Prof. James Law, of Cornell University, delivered the address, and diplomas were presented by Dr. Herman M. Biggs, President of the Board of Trustees, to thirty-one graduates.

The New Examiner in Lunacy at Bellevue Hospital. — Dr. Alexander Trautman has been appointed a public examiner in lunacy at Bellevue Hospital, in place of the late Dr. Matthew D. Field. For a number of years he was one of the resident staff at the city asylum on Ward's Island.

Proposed Legislation against Midwives. — A special meeting of the Medical Society of the County of New York was held on Saturday evening, March 16th, in response to the following call, signed by twenty members:

Whereas a number of instances have occurred in this city where reputable members of this Society have been arrested for complicity in malpractice cases without even the shadow of a reason for such action on the part of the police, therefore we request a special meeting of the Society for the purpose of ascertaining the rights and privileges of physicians who may be called to attend such cases.

On calling the meeting to order the President, Dr. E. H. Grandin, said that the position in which the medical profession had been placed by the unwarranted action of the police in several recent cases of women suffering from the effects of abortive operations, demanded action on the part of the Society. If a physician did not respond when called upon he would be called hard-hearted and unfeeling. If, on his arrival, he reported his suspicions to the police and refused to have anything to do with the case, he would render himself liable to suit for libel if his suspicions proved incorrect. If he did take hold of the case and reported it, he was, in view of recent police action, liable to arrest as an accomplice. After several resolutions had been proposed and debated at some length a resolution was adopted to the effect that the counsel of the Society be requested to prepare a legal opinion to guide members in malpractice cases. The following resolution was unanimously referred to the executive committee for action:

*Whereas*, Recent unjustifiable arrests of reputable physicians and members in good standing, of this Society, for performing their professional duties in cases of criminal operation induced by midwives, have outraged the feelings of the members of our profession and in the eyes of the public have placed the gentlemen accused in the position of criminals; and,

*Whereas*, In the vast majority of instances these criminal operations are performed by midwives, quacks and professional malpractitioners; and,

*Whereas*, In spite of the occasional spasmodic activity of the police in attempting to suppress these malefactors, the number of cases in which criminal operation is performed is by no means on the decrease; therefore, be it

*Resolved*, That a bill be drafted and presented to the Legislature through the proper channels, making it a criminal offence for any one to practice midwifery in the city of New York excepting those holding the degree of M.D.; thus legislating midwives out of existence and effectually curtailing, if not absolutely suppressing, their shameful and notorious practices.

## Miscellany.

### A PATENT MEDICINE BILL IN MINNESOTA.

IN an able editorial upon the bill now before the Minnesota Legislature, to regulate the sale of patent medicines in that State by requiring the printing of the formula of the medicine upon each package, the *North-western Lancet* states that the chief argument used by the opponents of the bill is that its passage would close several patent medicine factories, and cause a considerable loss to certain dealers having these goods on hand. The *Lancet's* answer to this objection is well stated:

"If patent medicines are harmful in themselves (and many of them are), or if they deceive and rob the people by causing them to pay high prices for compounds that are practically inert (and who can doubt it?) then their sale should be regulated, even at the expense of closing a few factories, or of entailing a loss of considerable money to the dealers in these medicines."

The objection that the bill is a piece of class legislation, intended to benefit physicians by making people come directly to them instead of first trying to cure themselves by the use of patent medicines, the *Lancet* compares to the opposition which invariably arises to the enactment of regulations for the benefit of the public health, such as compulsory vaccination, or quarantine regulations for the prevention of contagious disease:

"When any measure of this kind comes before the public the cry is always raised that it is being pushed in the interest of the medical profession, when a little common-sense would show that physicians in supporting such measures are really working against their own immediate pecuniary interests. An epidemic of small pox would enrich the medical profession a hundredfold above what comes to it from the small fee for vaccination, and a single visitation of cholera would give every physician in the community a large income while it lasted. Yet when cholera threatened these shores two years ago the medical societies were foremost in urging (not always successfully) the local authorities to take proper sanitary precautions in the way of cleanliness and quarantine, and many individual physicians gave much [unrequited] time and labor to furthering this end.

"It is the same with this patent medicine bill. The physicians in urging it are acting from disinterested motives, and if they are its chief supporters it is because they are the ones who are most in the way of seeing how crying an evil it is meant to regulate, and how much money is wasted by those who can least afford it in buying medicines that are either useless or positively harmful. But no one who knows anything of the actual practice of medicine could for a moment suppose that it has a rival in the use of patent medicines. As a matter of fact it is but rarely the case that a choice is made between buying a patent medicine and consulting a physician. The home-made ointment or liniment or 'yarb tea' is the true rival of the patent medicine. 'That tired feeling' would not be carried to the doctor even if there were not a dozen sure cures advertised in every newspaper, and the modesty that forbids consulting a physician about a 'female weakness' finds itself sympathetically drawn by Lydia's complacent gaze. No, the doctor does not fear that he will not be sought in preference to the patent medicine vender if there is anything the matter worthy of his attention, and honest medicine has no more to fear from quack remedies than it has from faith cures, astrology or any of the kindred sciences."

If the Minnesota Legislature passes this bill, it will have placed itself in advance of many Eastern States, and set an example in this matter which they would do well to follow.

### EFFECTS OF CASTRATION UPON THE ENLARGED PROSTATE.

#### UNILATERAL CASTRATION.

IN reply to a request published in various medical journals by Dr. White of Philadelphia, for information as to the effect of unilateral castration upon the prostate, E. Hurry Fenwick publishes in the *British Medical Journal* for March 9th, the results of his observations during the last ten years, upon the condition of the prostate of unilateral castration, as well as that of atrophy of the testicle or monorchism. Fenwick endorses Dr. White's statement concerning the shrinkage of the prostate after bilateral castration, and expresses the opinion that the profession and the public "owe him a real debt of gratitude for the introduction of an important addition to our means of combating certain forms of enlarged senile prostate. The results of his experience, however, do not bear out Dr. White's surmises as to the effect of unilateral castration. His notes of cases and remarks are as follows:

UNILATERAL CASTRATION.

1. Left testis removed for tuberculosis, 1889; prostate examined, 1890; left lobe equal to right, both healthy, neither atrophic.
2. Left testis removed, 1863; examined, 1889; left lobe of prostate larger than right.
3. Left testis ablated, 1887; examined, 1894; very little prostate felt, and what was detected of it was confused; no interlobular furrow appreciable.

MONORCHIDS.

4. Left testis absent; left lobe of prostate flat, slightly larger than right.
5. Left testis absent; left lobe of prostate atrophied, right lobe normal.

EXTREME ATROPHY OF TESTIS.

*A. After Inflammation.*

6. Left testis minute; both lobes of prostate equal, but flattened.
7. Left testis minute; left lobe of prostate large, right lobe atrophic.
8. Right testis minute; right lobe inflamed and cirrhotic; left lobe small.
9. Left testis very small; left lobe of prostate larger than right.
10. Right testis pea-sized; left lobe of prostate very small, half the size of right.
11. Left testis minute; both lobes of prostate equal, smooth and plump.

*B. Cause of Atrophy Unknown.*

12. Left testis very small; both lobes of prostate equal.
13. Right testis atrophic; lobes of prostate equal, flattened and cupped.
14. Left testis small; prostate of average size, left lobe slightly the larger.
15. Left testis unfeelable; prostate equal lobed.
16. Left testis small; left lobe of prostate the smaller.
17. Left testis small; prostatic lobes of equal size, but flattened.
18. Both testes retained in groin, and very small; both lobes of prostate equal; became affected by infiltrating carcinoma (primary).
19. Both testes in groin bean-sized; both lobes of prostate equal but small.
20. This case is interesting; left testis in groin very small; patient suddenly affected with gonorrheal parenchymatous prostatitis; both lobes were found equally and greatly enlarged.

"I point out with some diffidence that these cases are mostly at variance with Dr. White's surmises. At the

same time I am aware that rectal examination, however skilled, is as uncertain a guide to the activity of the prostate, as it is unreliable for estimating the amount of urinary obstruction which may be present. Moreover, none of us knows the normal shape of the prostate, for it varies with each decade and with each individual. Lastly, few seem to appreciate the fact that the prostate is often changed in rectal contour by posture, by vesical distention, and by excessive use."

### BILATERAL CASTRATION.

Fenwick also reports (in same journal, March 16th), eight cases upon which White's operation (double castration) has been performed for senile enlargement of the prostate. An interesting observation on the effect of castration upon the normal prostate was that of a man aged forty-five years, upon whom the operation was performed for extensive epithelioma, primary in the penis. Six months later the prostate was reduced to the size of a small bean. In seven of the eight cases there had been improvement, more or less marked according to the conditions present at the time of the operation. The fibrous prostate, which is tough, hard and small *per rectum*, does not diminish so quickly as the soft, elastic, fibro-myomatous gland. As to the return of voluntary micturition: in those cases in which the muscular power was still present though impaired, some return of normal micturition took place within the first week. If the atony was pronounced, however, the catheter could not be discarded. The statement applies to castration, as to all prostatic operations, that the prognosis of the return of voluntary micturition depends upon the muscular power of the bladder.

From the study of his cases Fenwick comes to the following conclusions:

(1) There is no doubt that slow shrinkage of the prostatic tissue in many of the forms of senile enlarged prostate ensues upon double castration. Further experience must, however, decide as to whether every form of prostatic growth is thus affected.

(2) It is certain that escape from catheter life after castration depends absolutely upon the health of the vesical muscle. The grade of the atony, therefore, should be most carefully estimated before any hopes of relief from catheterization are held out. To promise a confirmed catheter case that orchectomy will do away with the instrument, will merely bring discredit on the operation and disappointment to the patient. Even after prostatectomy we are unable to promise such relief if the muscle is hopelessly atonic, and we cannot do so after castration.

(3) It is possible that castration by diminishing the microbic infection from the inflamed senile prostate, will remove a constant menace to the integrity of the kidneys, for it will control the most prolific source of ascending pyelitis.

It appears to me that double castration will prove of value in the following conditions:

(1) In reducing bulky overgrowth of the lateral lobes of the prostate. It may be found that the small, tough, fibrous, median or lateral vesical outgrowths will be better removed by suprapubic prostatectomy.

(2) In controlling the distress and danger of an inflamed senile enlarged prostate.

(3) In lessening the frequency or difficulty of introducing the catheter in advanced or confirmed catheter life.

(4) In avoiding the mechanical difficulty of crushing a post-prostatic or post-trigonal stone, by levelling the base of the bladder, thus rendering the operation of litholapaxy feasible in a condition in which before it was impracticable.

(5) In reducing chronic cystitis and recurrent phosphatic calculus in cases of confirmed catheter life.

## METEOROLOGICAL RECORD,

For the week ending March 16th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer. Daily mean. | Thermometer. Daily mean. | Thermometer. Maximum. | Thermometer. Minimum. | Relative humidity. 8.00 A. M. | Relative humidity. 8.00 P. M. | Relative humidity. Deaths reported 3,012: under five years of age 975; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 303, acute lung diseases 631, consumption 349, diphtheria and croup 106, typhoid fever 33, diarrheal diseases 31, scarlet fever 30, measles 25, whooping-cough 19, cerebro-spinal meningitis 17, erysipelas 9, small-pox 3.

From scarlet fever New York 13, Philadelphia 4, Brooklyn 3, Boston and Providence 2 each, Cleveland, Nashville, Lynn, Newton, Waltham and Everett 1 each. From measles New York 18, Brooklyn 4, Cincinnati, Pittsburg and Providence 1 each. From whooping-cough New York 9, Philadelphia 5, Brooklyn 2, Washington, Somerville and Lawrence 1 each. From cerebro-spinal meningitis New York 5, Lynn 3, Brooklyn, Somerville and Worcester 2 each, Fall River, Chelsea and Fitchburg 1 each. From erysipelas New York 5, Philadelphia, Brook-

lyn, Boston and Taunton 1 each. From small-pox Philadelphia 2, Cincinnati 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530, for the week ending March 9th, the death-rate was 35.0 Deaths reported 7,117: acute diseases of the respiratory organs (London) 1,366, whooping-cough 111, measles 73, diphtheria 62, diarrhea 39, fever 30, scarlet fever 23, small-pox (Derby) 1.

The death-rates ranged from 16.1 in Derby to 48.0 in Plymouth; Birmingham 21.5, Bradford 35.7, Brighton 40.1, Cardiff 34.8, Hull 23.1, Leeds 27.4, Leicester 19.6, Liverpool 45.2, London 41.2, Manchester 32.2, Newcastle-on-Tyne 34.0, Nottingham 37.7, Oldham 34.4, Preston 35.2, West Ham 28.0.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 16, 1895, TO MARCH 22, 1895.

CAPTAIN EUCLID B. FRICK, assistant surgeon, will be relieved from duty at Fort Townsend, Washington, to take effect upon the expiration of his present leave of absence and will then report for duty at Presidio of San Francisco, Cal., relieving CAPTAIN CHAS. WILLCOX, assistant surgeon.

CAPTAIN WILLCOX, upon being thus relieved, will report for duty at the U. S. Military Academy, West Point, New York, relieving FIRST-LIEUT. FREDERICK P. REYNOLDS, assistant surgeon.

FIRST-LIEUT. REYNOLDS, on being thus relieved, will report for duty at Fort Sam Houston, Texas.

The leave of absence on surgeon's certificate of disability, granted FIRST-LIEUT. ALEXANDER S. PORTER, assistant surgeon, is extended four months, on surgeon's certificate of disability.

The leave of absence for seven days, granted MAJOR PHILIP F. HARVEY, assistant surgeon, is extended twenty-one days.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 23, 1895.

MICHAEL BRADLEY, medical director, ordered before Retiring Board, March 20, 1895.

F. A. HESLER, passed assistant surgeon, ordered to the U. S. S. "Philadelphia."

R. P. CRANDALL, passed assistant surgeon, detached from the U. S. S. "Philadelphia," ordered home and granted three months' leave of absence.

## APPOINTMENTS.

DRS. J. B. BLAKE and F. B. LUND have been appointed surgeons to out-patients at the Boston City Hospital.

## SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.— A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday evening, April 1st, at 8 o'clock.

Dr. Hamilton Osgood will read a paper on "The Treatment of Sclerosis, of Various Forms of Paralysis, of other Nervous Derangements, by Suggestion." Drs. J. J. Putnam and M. Prince will discuss the paper.

Dr. A. K. Stone will present a paper on "Prostitution; The Relation of the Experience of Europe to the Solution of the Problem in Boston." Drs. J. C. White and A. Post have been asked to take part in the discussion.

JAMES G. MUMFORD, M.D., *Secretary*.

THE WARREN CLUB. — A regular meeting of the Club will be held at 220 Clarendon Street, April 2, 1895, at 8 P. M.

Dr. W. S. Thayer: "Our Present Knowledge Concerning the Parasites of Malarial Fever."

Dr. J. E. Goldthwait: "A Case of Tendon Transplantation."

W. E. PAUL, M.D., *Secretary*.

THE SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION. — The regular monthly meeting of the Surgical section of the Suffolk District Medical Society will be held on Wednesday evening, April 3d, at 8 o'clock, at 19 Boylston Place.

"Cyst of the Finger, with Two Cases," Dr. F. M. Briggs.

"A Case of Acute Intestinal Obstruction from the Impaction of an Enterolith; Operation; Death," Dr. M. H. Richardson.

"The Treatment of Elbow-Joint Fractures by Acute Flexion, without Splints; Results with Cases," Dr. H. L. Smith.

C. L. SCUDDER, M.D., *Secretary*.

## RECENT DEATH.

SIR WILLIAM SCOVELL SAVORY, F.R.S., consulting surgeon to St. Bartholomew's Hospital, surgeon to Charité Hospital, died in London on March 4th, aged sixty-nine.

## BOOKS AND PAMPHLETS RECEIVED.

Chicago Summer School of Medicine, Chicago, Ill., Announcement, 1894.

Statistical Methods. By George W. Moorehouse, M.L. Reprint. 1894.

## ASYLUM PHYSICIANS AND COMMITMENT CERTIFICATES.[1]

BY HENRY R. STEDMAN, M.D., BOSTON.

The object of this paper is in general to collect and analyze the provisions of the commitment laws of this and foreign countries with regard to the part played therein by the qualifications required of certifying physicians, and in particular to consider how far the prevailing law on this point in the States of Massachusetts, Connecticut and Vermont falls short in respect to protection of the insane and justice to medical officers of our lunatic hospitals.

The first part of our subject is of considerable interest in itself. We shall find a variety of statutes regarding the examination of the insane for commitment, from those in which no requirement whatever as to medical testimony appears or seems to be thought necessary, to others which contain full and explicit requirements regarding the physician's professional and moral standing, his relationship to the patient and his connection with the hospitals for the insane. It will be seen also that the amount of precaution taken is, in most of the States of the Union, a fairly accurate gauge of their age and the intelligence which comes from increasing experience as to the true needs and interests of their citizens and their charges. Not less noticeable are the exceptions to this rule. For example, certain new States are found to have had wise laws regarding medical examination of the insane for commitment, even while they were territories, while on the other hand, a few old and well-governed States and foreign countries take few or no precautions in this direction. In others, which are among the most advanced communities, the antipodal extreme of overprecaution is reached in prohibiting the very physicians who are conversant with insanity from certifying. The best interests of the insane are thus overlooked and a tendency developed to a reversion in this respect to the primitive conditions of territories. It should be borne in mind, however, that we are discussing only the professional qualifications required of certifying physicians, omitting, as foreign to the purpose of this paper, the many and admirable safeguards in other directions in many of the older States and countries which go far to offset defects in the special legal provisions regarding physicians which are under consideration. We also omit reference to modifications of statutes as to requirements regarding the number of physicians, etc., in the case of emergency and voluntary patients.

For convenience in comparing States and countries we have arranged them in four groups as follows:

### I.

Seven Territories and States in the Union are without any provision for medical examination for commitment of a person to an asylum. These are Colorado, New Mexico, Wyoming, Indian Territory, in which there were no asylums at the time the laws on which this report is based were compiled between ten and fifteen years ago; also Florida, Louisiana and Mississippi. In Louisiana the superintendent of an asylum shall, however, examine all criminal lunatics committed thereto to ascertain if they are feigning. In Mississippi the patient is to be examined by six discreet persons. The trustees and superintendent of an asylum may also admit a patient if they think him insane, although no proceedings in lunacy may have been instituted. But if the sheriff is satisfied that a convict under sentence of death is insane, six physicians, or if they are not attainable six other discreet men are to examine him.

### II.

Nineteen States and territories require examination and certification for this purpose by but one physician. In Georgia and Idaho simply "one physician" is required. In Alabama and Tennessee, "one respectable physician." In Dakota, Iowa, Nebraska and Texas, "a regular practising physician." In Illinois, Kansas and Montana, a jury, one of whom shall be a physician. In Virginia and West Virginia, one; the attending physician examines, the patient's admission to the hospital being subject to the consent of an examining board of the superintendent and trustees of that hospital. Arizona, Washington, Ohio, North Carolina and Arkansas require *one or more* reputable or respectable or regular or practising or licensed practitioner to certify.

Almost all European countries also require that but one physician shall certify. France and Belgium provide in addition that he shall not be connected with the asylum to which the patient is committed. The French code also prohibits a relative of the patient from certifying.

### III.

Canada and sixteen of the United States enact that two physicians shall examine and certify in such cases. Maine, New Hampshire, Rhode Island, New Jersey, Maryland, Nevada and District of Columbia call for two "qualified," "graduated," "respectable" or "reputable" physicians; South Carolina, "two licensed practitioners"; Kentucky and Missouri, "two physicians" simply; California, "two or more graduates in medicine"; Utah, "two practitioners"; Oregon, "two or more competent physicians"; Indiana, the medical attendant of the patient and a selected examiner. Wisconsin requires "two disinterested physicians of good repute for skill and morality." Minnesota prescribes two physicians for convicts; a judge and jury — one of them a physician — for the other classes.

### IV.

Six States, besides requiring two physicians to certify, have made certain specific provisions regarding their medical education and professional experience, one or both, their residence in the State and their position as asylum physicians. They are Connecticut, Massachusetts, Michigan, New York, Pennsylvania and Vermont. Of these in their turn the statutes of Massachusetts, Michigan and Vermont also require of each certifying physician three, and those of Pennsylvania and New York require each five years of practice in the State. Of these Massachusetts and New York also forbid any but graduates of legally organized medical colleges from signing the certificate. Connecticut, Michigan and Pennsylvania make it illegal for physicians to certify if either of them be related by blood or marriage to the patient. The laws of England, Wales and Scotland, which are founded upon the longest experience and by the counsels of the

[1] Read before the New England Psychological Society, December 11, 1894.

ablest jurists and alienists, belong in this category, which represents in most respects the most thorough legislation on this point that could be desired, as well as upon lunacy matters in general.

The laws of this group are as follows:

In New York each of the certifying physicians must be of reputable character, a graduate of an incorporated medical college, a permanent resident of the State, in which he must have practised medicine three years. He shall not be superintendent, proprietor, officer or the regular professional attendant in the asylum to which the patient is committed.

The law of Pennsylvania on this point provides for two or more reputable physicians, residents of the State, who have been in practice five years. They must certify that they are not related by blood or marriage to the patient, nor in any way connected with the hospital in which it is proposed to place the patient.

The statutes of Vermont require for certification for commitment, that the two physicians shall be of unquestionable integrity and skill, residing in the same probate district as the patient, or in the same district as the asylum if the patient does not reside in the State, or if the patient be a convict such physicians may be residents of the probate district in which such place of confinement is situated. Neither physician shall be a member of one firm *nor an officer of an insane asylum in that State.*

The Massachusetts statute requires two physicians, each a graduate of a legally organized medical college and who have practised three years in the State and neither of whom is connected with any hospital or other establishment for the insane.

The law of Michigan is identical with that of New York, and that of Connecticut with that of Massachusetts. Each add, however, the clause above mentioned making relationship between patient and physician a bar to certification by the latter.

In England and Wales two medical certificates are required, one certifying physician being the usual medical attendant if practicable. Neither shall be manager of the institution to which the patient is committed, or interested in payments on account of the patient, or a regular medical attendant of the institution, the husband or wife, father or father-in-law, mother or mother-in-law, son or son-in-law, daughter or daughter-in-law, brother or brother-in-law, sister or sister-in-law, or the partner or assistant of any of the foregoing persons. Neither person signing medical certificates shall bear a similar relationship to each other and a member of the managing committee of the hospital shall not certify; nor a commissioner or authorized inspector.

In Scotland two properly qualified medical practitioners are necessary. Neither shall have immediate or pecuniary interest in the asylum in which the lunatic is placed, nor can a medical officer of any asylum certify a private patient for such asylum except in emergency cases.[2]

The laws of the group last described will, with the exception of the objectionable clause to be considered, be accepted as, in the main, the best-devised means for protecting the interests of the insane, and preventing at the same time illegal commitment of the sane by interested physicians. We have little doubt that those States in which the less numerous and severe regulations are in force regarding certifying physicians, as in Group III, or even perhaps regarding a single physician, as in Group II, are quite free from attempts at illegal commitment. Not only our belief in the integrity of physicians in general, but the fact that so few cases of this nature have come to light, seem to corroborate this view. It is, nevertheless, the part of wisdom to allay, so far as is possible, the suspicion regarding the possibility of such illegal acts which has so long possessed the public mind and which may have had its foundation in actual abuses in the early days when the general ignorance regarding insanity made such practices possible. The opportunity thus afforded interested persons, or relatives it may be, as well as physicians, of controlling the person and property of a sane person, or one not sufficiently insane to be deprived of his liberty, had much to do, especially in England where there have long been a large number of private asylums, with the imposition of the restrictions which we have detailed as well as the various other requirements of the more stringent lunacy codes. But although it is very mortifying to the alienist to feel that the unwritten law of humanity and fair-dealing is not considered binding enough in his case, he ought not to object to any reasonable provisions if they tend to encourage public confidence regarding the protection and care of the sane and the insane in this respect. It is in this spirit that asylum physicians have accepted without remonstrance even those restrictions which forbid them to certify a patient for commitment to any asylum *with which they are connected.* This requirement is, as we have seen, the law in England and Wales, Scotland, France, Belgium, New York, Pennsylvania, Vermont and Massachusetts. When, however, the laws of a State or other government forbid *all physicians who are in any way connected with an asylum certifying a patient to any and all asylums within its borders*, it is the right and duty of such physicians to protest and to use every legitimate means to amend a statute so subversive of their self-respect and of the interests of the insane.

This brings us to the second and more practical portion of our subject, the operation of the clause in the lunacy laws of Massachusetts, Connecticut and Vermont, whereby our asylum physicians and the mass of our insane are subjected to this very injustice. If we examine the provisions in all the other States and countries in the world, above given, we find that these three States alone have this unenviable distinction. The Vermont law is the least sweeping of the three. Hers is to the effect that neither certifying physician shall be an officer of *an* asylum in the State, a law which was adopted when there was but one small lunatic hospital in this, the smallest State in point of population but one — Delaware — in the country. Nevertheless, it must be said that although the Vermont law thus affects but a very few physicians, its injustice as a law is in no degree mitigated. The laws of Massachusetts and Connecticut, the former enacted in 1883 and copied by the latter in 1889, when there were eight large and several small lunatic hospitals within their borders with the usual complement of physicians, provide that no physician *connected with*

[2] The data above given were collected from Stearns's extracts from the laws of the different States and Territories of the United States which relate to the general care of the insane, 1893; Folsom's do, 1884; Tuke's Dictionary of Psychological Medicine, 1892; Reports from her Majesty's Representatives at European Courts and in the United States, etc., on same, 1885; Journal Mental Science, Vol. xxi, p. 236.

*any establishment* for the insane shall certify for commitment to a lunatic hospital. Thus, no asylum alienist, be he ever so able or upright, in whatever part of the globe he may live, is thought fit to certify that a person is insane and should be committed to a Massachusetts hospital for care and treatment. We are not the first to call attention to the matter. A few quiet protests were made by certain superintendents of lunatic hospitals in the State of Massachusetts; but there has been no actual attempt to modify the law. The public and the insane have, to be sure, great reason to be thankful to the framers of the lunacy laws of these States; but in this instance, in their zeal to protect the interests of the insane they have injured the cause of these very unfortunates by depriving such patients (outside the city of Boston, at least) from having expert opinion as to the desirability of their commitment. Moreover, the duty of certifying therefore devolves necessarily upon general physicians, many of whom shrink from giving opinions in such cases, as they recognize their necessary lack of familiarity with the disease and the possible disastrous consequences of a mistaken decision. They do not hesitate to confess comparative ignorance of the subject and their feeling of helplessness before certain patients from whom they are trying to elicit facts sufficient for proper certification. This fact was emphasized by a request made of the writer very recently by the secretary of a large district medical society that he would give its members some practical directions as to the proper methods of examining such persons and obtaining the facts necessary for their certifying them as insane persons. He asked this at the request of a number of physicians who had been often perplexed in such cases. In cases where an asylum physician also is called, their burden may be lightened by consultation, it is true, but the poor cannot afford this, and the State does not recompense the services of three physicians.

The law tends, at the same time, to lower reputable physicians in the eyes of their fellows and the people, by implying a certain distrust of the motives of all medical officers of asylums. It is a satire on Massachusetts justice that impostors and quacks should have thriven in that community until a few months ago, when the bill for regulating the practice of medicine was passed, while for the past twelve or more years its asylum physicians, men of deserved repute as able and self-sacrificing workers in a difficult field, have been restricted in a legitimate line of service and humiliated as well, by unfair legislation. We can understand, as we have said, the sentiment which seeks to prevent physicians from assisting in certification in the commitment of a person to the asylum or establishment with which he is connected. It is even no doubt a welcome protection from criticism to some superintendents, but we are at a loss to find any practical reasons based upon facts why it should be thought necessary to prevent the experienced hospital alienist from committing a patient *to any asylum in any State whatever*, whether he be connected with it or not. This restriction applies also to physicians on the boards of trustees of asylums who, although thought worthy of that honor, may not be trusted to certify for the purpose of commitment by reason of their connection with a hospital for the insane. In the same category are also eight or ten councillors of the Massachusetts Medical Society, among whom is a recent president of that body.

Other conditions which show the absurdity — we can find no other appropriate term — of this discrimination against an asylum physician as certifier for commitment, are the laws which make legal his certificate as to insanity in cases of guardianship of the property of any insane person, whether he be in his charge or not, and that which obliges him to decide as to the mental condition of voluntary patients in lunatic hospitals, as is the case in Massachusetts. Moreover, the enactment, in Massachusetts and Connecticut, which prescribes fine or imprisonment for any physician who wilfully conspires to commit any person who is not insane to a hospital or asylum in the State, demonstrates how superfluous the law is, were there no other reason for its amendment. As Dr. Fisher also forcibly puts it: "the opinion of the asylum superintendent in court may settle questions of damages of large amount or determine the disposition of large fortunes by will; the life or death of an insane criminal may depend on his judgment; but having advised so simple a thing as hospital treatment for some patient, two strange physicians must be called in, at added expense, to re-examine the person before he can be sent to a hospital for treatment."[2]

Finally, there is omitted from the statute all reference to the conditions which are imposed, as we have seen, in several of the most careful codes in this country and abroad regarding the relationship between a physician and the patient to be committed or the fact of pecuniary interest in the place of his commitment, safeguards thought by many to be eminently practical. To pass this by and insert instead the almost petty requirement of which we complain, and which is absent from all other codes, with the two minor exceptions mentioned, is another glaring inconsistency.

Enough argument has, we think, been now brought forward to justify our asylum physicians in demanding an amendment of the law so that it shall conform to that of England, for example, in forbidding certification only to physicians connected with the hospital to which the patient is committed.

Finally, we should bear in mind that the alienist has been the object of enough criticism of late, much of which we know to be unjust. Is our inactivity in tacitly allowing a statute to remain unaltered which lowers in public estimation the asylum physicians of these three States, limits their legitimate field of work and injures the cause of the insane, to be added to our other shortcomings?

## REMARKS ON TWO HUNDRED CASES OF PHTHISIS.[1]

BY GEORGE G. SEARS, M.D.,
*Physician to Out-Patients, Boston City Hospital.*

It is not my intention to go elaborately into the statistics of these cases, most of whom came under observation during my last term of service in the Out-Patient Department of the Boston City Hospital, but to use them chiefly for the discussion of a few points on which medical opinion is not yet unanimous. They comprise 93 women and 107 men, of whom almost the same proportion belongs to the first and second generation of Irish immigrants as that given by the mortality statistics of our Board of Health, 99,

[1] Read before the Clinical Section of the Suffolk District Medical Society, January 16, 1895.

[2] Thirty-second Annual Report of the Board of Directors of Public Institutions of the City of Boston, 1888.

or nearly 50 per cent., belonging to this class. One hundred and thirty-two of the patients were native Americans, of whom 62 were of Irish parentage, while the remainder were natives of a half-dozen different countries, including five Russian Jews, whose presence deserves some comment from the current ideas as to their immunity as a race; when, however, one considers their history since the enforcement of the so-called May Laws of 1882, it is not a matter of surprise that the Russian army examiner, who found no traces of phthisis among the Jewish recruits during the reign of Nicholas and Alexander II, now reject 6.5 per cent. of them for this cause, against 0.4 per cent. among all other Russians, nor that those who sought a refuge in America should occasionally succumb to a disease whose seeds in many cases were sown before they fled. Under such conditions the appearance of consumption among the chosen people cannot be considered a valid argument against the efficacy of the use of Kosher meat and strict obedience to the Mosaic law as important factors in securing the immunity with which they have been credited, but only as showing that there are limits in starvation and sanitary wretchedness to which even the Russian Jew cannot adapt himself.

Contrary to later statistics which have been given regarding the distribution of phthisis according to age, these cases show a marked decrease with advancing years after thirty has been reached, but seventeen, of whom three were women, being over fifty, while but seven were over sixty. Arranged by decades there were 2 in the first (children forming but a small proportion of the clinic), 17 in the second, 79 in the third, 49 in the fourth, 33 in the fifth, 10 in the sixth and 7 in the seventh, with 3 unplaced owing to the silence of the records on this point. It is impossible to give the relative number of phthisical patients compared with the total number in each decade which applied for treatment, but it is safe to say that the proportion given above would not be greatly altered. This is in line with the experience of the writer while a member of the Board of Pension Examining Surgeons, consumption being a very rare cause of disability among the applicants, almost all of whom are middle-aged or old men. Although the energetic pension agent has scoured the country for crippled veterans and has done his best to send before the examiners all in whom the slightest disability could be found or hoped for, yet out of over 1,500, who appeared before the board from August, 1892, to September, 1893, in eleven only, two of whom were young men recently discharged, could a diagnosis of phthisis be made after a most careful examination. In the press of work search for the tubercle bacillus was impossible, so that a certain number of cases, although they must have been few, may have been overlooked owing to the equivocal nature of the signs which are occasionally noticed in the aged. If phthisis is so common a disease in advanced life it is remarkable that so few cases were found among these men, unless the hardships of active service had previously weeded out all those with consumptive tendencies.

Arranged according to both age and sex, 69 per cent. of the women in round numbers were under thirty, while the proportion of men under thirty was almost exactly reversed, 60 per cent. being over it. This is presumably explainable by the fact that in the latter, especially of the class who appear as out-patients, exposure to cold or dust, the abuse of alcohol, etc., are influences which are operative through life, while in the former two potent factors in the causation of the disease, pregnancy and lactation, become less and less active after the age of thirty, till they finally cease. No greater susceptibility of young Irish women than of those of other nationalities could be determined.

On the two points in the natural history of the disease of greatest interest both to the profession and the community, its transmissibility by heredity and contagion, however carefully cases may be analyzed, statistics can throw but little light, and in the present state of the question may even prove misleading. The diversity of professional opinion, however, seems very largely a matter of definition. Since Koch's discovery of the tubercle bacillus some modification of what is meant by heredity in this connection has been necessary, since, although the possibility of its direct transmission from parent to offspring has been proved by six or seven well authenticated cases of prenatal tuberculosis, and suggested in a good many more, it is generally acknowledged to be a very rare event and inadequate to explain the family taint so frequently noticed. Laboratory experiments would seem to prove that the virulence of the tubercle bacillus is practically a constant quantity; and yet, although autopsies show that every third or fourth person whom one meets is somewhere tubercular, and although the bacilli themselves are so generally distributed, and often in such numbers that their actual presence can be demonstrated, only about one-seventh of all deaths result from this cause. In other words, although exposure to an ever-active germ is nearly constant, only about one-third of the population become infected, and in fully half of these the disease falls upon such infertile soil that its course is checked oftentimes before giving rise to any recognizable symptoms, while of those who die most possess sufficient resisting power to keep it localized and prevent its progress except in the most chronic manner. In comparison with many other animals, man cannot therefore be considered as especially susceptible; infection, when it occurs, being due to a lessened power of resistance in the individual, which might well be transmitted through many generations of a family and show itself in the narrow chest, the feeble muscles and transparent skin, which we associate with the phthisical habit, or in some more subtle and unrecognizable change, which Gärtner suggests may be chemical or biochemical. Even if it could be proved, as Wyssokowicz says, that the "tubercle germs could not be hereditarily transmitted, no reason could be found therein why healthy children should always come from phthisical parents. On the contrary, this result should no more be expected than that juicy fruit should grow on a gnarled and stunted tree." In the present series of cases the hereditary taint, as shown by the appearance of the disease in several members of a family, was present in 81, or about forty per cent., in some of whom it may possibly have been transmitted from one to the other by contagion, but in most the second patient had been so long away from home or so many years had elapsed between the death of the first and the development of the second case, that any connection between them seemed extremely unlikely.

In view of the many difficulties which surround the effort to prove the dependence of one case upon another, it is not surprising that careful inquiry into the details

of the histories of these patients should have failed to give any satisfactory results. Although in 22 instances, 15 women and 7 men, the second case in a family or household began to show symptoms during the lifetime of the first or shortly after his death, in only one was such a connection sufficiently marked to deserve notice. This occurred in a professional gambler, thirty-eight years old, of good family history. Three years ago he had most devotedly nursed his mistress, who was ill with the disease, through the latter months of her illness. About four weeks before her death he had a severe hemorrhage and has since suffered from cough and dyspnea with some loss of weight. At the time of examination there were well-marked signs of phthisical consolidation in the left lung with an explosion of râles after cough in the right apex.

So far as the necessity for adopting preventive measures against the spread of the disease is concerned, it is of little importance whether contagion in a particular instance can be proved or not. In the present state of our knowledge regarding the rôle which the tubercle bacillus plays in the causation of consumption, it is inconceivable that it should arise independently of some previous case in man or animal, while at the same time it is almost equally improbable that a single exposure, as in measles or scarlet fever, should be sufficient to overcome the patient. Nor is it necessary to prove the latter in order to show its contagious character, since the tubercle bacillus is able to bivouac within the body and wait for reinforcements before beginning an active campaign. A slow process of infection, an incremental infection, is thus possible, and it is not improbable that a patient finally surrenders to an army which has been recruited from many sources. Whether the contagious nature of phthisis is as great as it is sometimes claimed, or whether as Powell states, it is practically impossible in conditions of human association that the necessary degree of concentration be reached to induce tuberculosis in a healthy person, it is certain that, apart from the food-supply, whose importance as a possible source of infection it is difficult to estimate, effective methods of limiting the disease are theoretically found in isolating the patient, in destroying the bacilli at their point of origin, in improving the general health of the individual up to the point of non-susceptibility, or in limiting the range of activity of the bacilli by better hygienic and sanitary conditions. Although greater precision in diagnosis has undoubtedly contributed to the gradual diminution in the death-rate from phthisis which has been noticed during the past ten years, improved hygienic and sanitary conditions must be considered a most important factor in producing this result, more important even than the diffusion among the masses, as some enthusiasts have claimed, of the knowledge of the bacterial origin of the disease and of the necessity of combating its spread by their destruction, unless the lower classes of other places have shown a greater aptitude for assimilating such knowledge than has been noticed in our out-patient clinic.

What has already been accomplished by such measures gives great encouragement for further efforts in the same line, and though we can hope by their aid only to limit and not prevent the dissemination of tuberculosis, they have the merit of being more practical than the more radical methods proposed, since they can be more readily enforced by our health boards, and do not add to the suffering of the patient by branding him as an outcast. It is difficult to exaggerate the attitude of the so-called intelligent part of the community toward patients with scarlet fever or diphtheria and their families. I speak from personal experience in saying that social ostracism could scarcely be made more complete, and I know of one family, in which several cases recurred at intervals of a few months, which was finally forced to move into another house in order to enjoy the privilege of visits from their nearest relatives. Ostracism can be borne if it lasts but a few weeks, and is unquestionably useful in limiting the spread of a disease, but continuing for years it would be intolerable. It is scarcely probable that the demoralization of the public in the latter case would be as complete, but the change in popular opinion toward other infectious diseases within ten years has been so marked that it suggests a distinct danger in the case of phthisis which should be risked only if it could be offset by a corresponding amount of good not obtainable in other ways, conclusive evidence of which is as yet entirely wanting. Dr. Knight,[1] in discussing the question of the isolation of phthisical patients, and the compulsory notification and registration of them and of their houses, says in a paper on the prevention of tuberculosis that "leaving the whole matter in the hands of the family doctor both in regard to the amount of information to be given and what precautions shall be taken, cannot be as efficacious as if this was done by an officer of the board of health. Unless the family physician thoroughly believed and was personally interested, it would not be thoroughly done." To such a statement in itself no objection can be made. Neglect to give specific instructions, as he says, is almost invariably the result of indifference, but the question may fairly be asked if this may not be better than the active hostility toward compulsory notification and registration felt by a large number, possibly a majority of physicians, who could see in them but a useless annoyance to the patient, and a probable source of pecuniary loss, and who would be tempted under such circumstances with little violation of their consciences to conceal from the patient and his family the nature of his trouble. Precautions which might otherwise be taken might thus be neglected through ignorance. No harm, however, but only good can result from educating the community up to a knowledge of the nature of consumption and of the necessary preventive measures, provided it can be done without sensationalism.

A step in the right direction has been taken by our Board of Health in issuing its circulars, and the example could profitably be followed by all our out-patient departments and dispensaries. The following instructions which are somewhat fuller than those of the Board of Health, have been prepared for distribution among the Boston City Hospital out-patients. They are given now to almost every patient as soon as a diagnosis is certain, since it has seemed that, especially in this class, the advantages gained by the more active co-operation of the patient who realizes the serious character of his disease, were greater than the disadvantages, in the way of discouragement, which a knowledge of the nature of his affection in the early stages might entail. An effort has been made to avoid all directions which might excite unnecessary alarm and yet make them sufficiently strenuous to be of practical value. They have been received by the

[1] International Medical Magazine, July, 1894.

patients apparently in the spirit in which they were given, and while it is impossible to say how far they have been followed, they do not seem to have increased the difficulties of the patient by alarming his friends as to any danger which they may run by associating with him. The circular runs as follows:

(1) Consumption is a contagious disease, but the breath of consumptives is not directly infectious.

(2) The seeds of the disease are found in the phlegm or spittle which is coughed up, but it is not a source of danger till it has become dry.

(3) Do not, therefore, spit upon the streets or upon the floor of your house or shop.

(4) In-doors use a special spit-cup which either contains water or is lined with paper. The cup must be often emptied into the pan of the water-closet or into a bright fire, never anywhere else, and then washed out with boiling water.

(5) Out-doors use a bit of rag or paper which should be burned as soon as possible.

(6) Handkerchiefs should never be used for the phlegm; if used at all they must be boiled for half an hour.

(7) Keep your room clean; use a damp cloth for dusting.

(8) Throw the windows wide open when you leave your room; at night sleep with the windows somewhat open from the top.

(9) Consumptive patients should sleep alone.

(10) Consumptive mothers should not nurse their children.

Of the causes to which the patients ascribed their illness, exposure, "catching cold," naturally came first with 57 cases. The inhalation of dust was supposed to be responsible for 15, grippe 13, rapidly succeeding pregnancies 7, injury 3, and pneumonia 3. In 8 the first symptom noticed was hemorrhage, more or less severe. There was a history of malaria in 3 cases, and of the abuse of alcohol in 10; 19 had had pleurisy from a few months to a few years before, 15 however, had had pneumonia. Two had suffered previously from lupus of the face and one from Pott's disease. Three had had syphilis, one year, fifteen years, and twenty-six years ago respectively. Among the complications there were found 6 cases in which the cervical glands were affected, apparently before the development of the pulmonary trouble, 4 had fistula in ano, and 2 valvular cardiac disease. One case was complicated by patches of tubercular caries on sternum, ribs and ulna.

Many of the cases were seen for the first time after the disease was considerably advanced, so that it was often impossible to tell where it originated, but those in which one lung only was attacked showed a marked predominance of the right side, 59 to 32, in 47 the disease being confined to the right apex, and in 28 to the left.

Owing to the very incomplete condition of the records as well as the short time during which many of these cases were under observation, the results of treatment can only be given in the form of an impression, which is, however, less liable to be wrong in out-patient practice than among other classes of patients, since there is usually but one factor to be estimated. In private or hospital practice when it is possible to modify the diet and general manner of life, doubt always arises as to whether improvement, should it take place, is to be credited to this or to the drugs prescribed, while among out-patients such modification is rarely possible and then usually but to a limited extent. It is of little use to order a special diet to those who are already a drain upon a family struggling for the bare necessities of life, or to recommend an abundance of fresh air to those who fear a draught more than death, or to give special directions as to exercise where intelligence is lacking to appreciate its value. Drugs, however, are usually conscientiously taken, so that whatever change for the better takes place can with a certain amount of confidence be ascribed to them. This limitation of one's resources makes the treatment of such patients at best discouraging work, yet it has seemed to me in watching the progress of these cases, that a larger proportion of them improved than previous experience had led me to expect, while a cure, as shown by the disappearance of all signs and symptoms, occurred in a few instances. Routine treatment, when the prognosis was not absolutely fatal, consisted in the administration of guiacol (occasionally creasote) in doses rarely exceeding five minims three times a day, together with arsenic and Merck's digitalin. In a few cases the dose of guiacol was gradually increased to fifteen or twenty drops, but no advantage could be seen in the larger amount. Except in one or two cases, where it excited some digestive disturbance which disappeared with a reduction in the dose, patients took it without trouble, almost the only complaint ever made being of the somewhat acrid taste and the persistent odor of the breath, of which they were themselves very conscious. The most marked effects for good were seen in the improvement in the general well-being of the patient, and were shown by a gain in appetite and weight, and a decrease in the cough, even in many where the physical signs remained stationary or even seemed to be advancing.

## TUBERCULOSIS AMONG OUR NEAT CATTLE.[1]

BY DR. F. H. OSGOOD.

Tuberculosis is a contagious and infectious disease so widely disseminated, so insidious in attack, and so fatal in results, that it is, no doubt, the most important disease which we are called upon to combat. Not only does it cause one-seventh of the deaths of mankind, but it is the most widely distributed and disastrous disease among our cattle. Since the discovery, a dozen years ago, of the bacillus tuberculosis, and the demonstration of the identity of the disease in man and the lower animals, a great interest has been manifested in the question of the meat- and milk-supply in our large cities. This interest has given rise to the establishment of an inspection service, which, notwithstanding its necessarily superficial character, has revealed many startling facts respecting the prevalence of tuberculosis among our milch cows and beef cattle; so that at the present time there is little or no question concerning its quite general prevalence.

Accurate statistics as to its extent are not yet attainable, but the abattoir reports show in Prussia 6.3 per cent., in Berlin 12 per cent., in Dresden 14.4 per cent., in London 25 per cent., in Midlothian 20 per cent.; in England, during an outbreak of contagious pleuro-pneumonia, in 1890 and 1891, there were slaughtered, as being infected, or having been exposed, 12,000 animals, all of which were subjected to critical post-mortem examinations, and 12¼ per cent. were found to be tuberculous.

[1] Read before the Suffolk District Medical Society, Section for Clinical Medicine, Pathology and Hygiene, January 16, 1895.

The result of the work at our own quarantine stations at Brighton and Watertown, where every animal is subjected to the tuberculin test, before being allowed entry to the State, show that of the animals being brought there for sale, during the first week, 15 per cent. of them were tubercular; during the second week 12 per cent., during the third week 8 per cent., during the fourth week 4½ per cent., and up to December 15th, in the total examination of 1,700 animals, 6 per cent. were affected with the disease. Animals so tested and found diseased, if they have not been within the borders of the Commonwealth for at least six months are destroyed without compensation.

In our examination of animals in this State, we have found some herds with every animal tuberculous, though kept in the most careful way, many of them apparently in the best of condition. Other herds, under precisely similar surroundings, were entirely free from the disease; but in these cases it could be clearly shown that the animals had been bred upon the premises, and no animals brought from without, during a period of at least nine years. Where, however, there has been an interchange of animals during this period of time, in a large majority of cases there is a variable percentage of disease. In many instances the introduction of infected animals into apparently healthy herds has resulted in the transmission of the disease to a large per cent. of their number. In many expensive herds, kept for private use to insure a pure milk-supply, we have found the disease in startling proportions, frequently as high as 80 or 90 per cent.; the autopsy showing lesions of the worst type in well-nourished animals.

The point has been raised that it is impossible to exterminate contagious disease. In this connection I would point to the fact that the incurable contagious diseases among the lower animals can be combated only by slaughter of infected animals, rendering possible the extermination of the disease which might not be possible in men. It may not be without interest in this connection to speak of the importation of a number of animals, some thirty-four years since, consigned to the "Chenerys," some of which were affected with contagious pleuro-pneumonia. The disease spread among our cattle so rapidly and disastrously, that special legislation was secured, which provided that not only those animals manifesting evidence of the disease should be destroyed, but that also all animals which had been exposed to the contagion. The results were gratifying in the extreme. The disease was thoroughly eradicated at an expense of $60,000, since which time, for a period of about thirty years, there has not been known a case of contagious pleuro-pneumonia in Massachusetts. Some of these animals were sent to New Jersey, but the same methods were not adopted; the policy of that State was to destroy animals which showed evidence of the disease, without destroying those that had been exposed; the disease spread over New Jersey, Pennsylvania, New York, Virginia, and the District of Columbia.

In 1887 it was gaining a foothold in the West, when the United States government took into their hands the extermination of the disease, adopting the methods pursued in Massachusetts, some thirty years before; but so rapidly had it spread that five years were required and many millions of dollars before it was possible to exterminate the disease; since which time, some two years ago, there has not been known a case of contagious pleuro-pneumonia in the United States.

The history of the treatment of this disease in Great Britain, and the immense amount of money that has been expended, only show the wisdom of the policy adopted by Massachusetts so many years ago.

Until 1892, tuberculosis was not considered of enough importance in Massachusetts to receive even passing notice. At this time, however, a bill was passed entitled, "An Act to more effectually prevent the spread of tuberculosis among cattle." Under the provision of this Act an earnest endeavor was made by the Board of Cattle Commissioners to do all in their power toward the suppression of the disease; but the legislature of 1894, realizing more fully the importance of the subject, enlarged the Commission, increased its powers, and added to the appropriation, making possible the adoption of a new policy, which, it is believed, will prove efficient in accomplishing such end.

Cattle seem especially predisposed to tuberculosis, as has been explained by authors in different ways. It may be that their normal temperature 102° F., is better suited to the growth of the bacillus, as it develops with great rapidity in fowls, whose normal temperature is 107°. Then, too, the health and vigor of cattle is greatly diminished by the conditions under which they are kept, namely, the unsanitary stables, lack of exercise, and the prolonged lactation of the dairy cows, under all the stimulation possible. Their constant breeding throughout their lives, also constitutes a tax upon the system which leaves them in no condition to resist disease to which they are exposed.

In many of our city dairies cattle are tied in the stable from October to April, often remaining for months, without moving out of their stalls, their heads confined in stanchions; and not infrequently their coats are removed by clipping, that they may be able to stand the temperature to which their stables are heated, for the highest production of milk is the only object sought, to attain which, everything else is sacrificed. The ruinous effect of this policy is shown by the great percentage of disease among our dairy cattle, as compared with those that live an out-door life.

The disease may be transmitted by inhalation of the bacillus, by ingestion of the meat or milk of tuberculous animals, and by direct inoculation through an abrasion in the skin. Numberless instances of infection by milk may be quoted, both by experiments on small animals and accidental infection of people using the milk. German, French and American investigators, working independently, found about the same time, that animals using the milk from tuberculous cows rapidly became the victims of the disease. An interesting experiment was made by taking six little pigs about three weeks old. Two were placed in a pen and fed upon cereals; the other four were placed in a separate pen and fed upon the milk of a tuberculous cow. At the end of two months the post-mortem of the cow revealed extensive pulmonary tuberculosis, but no lesions in the mammæ. The pigs were also killed and examined. The grain-fed animals were poor, not having had the flesh-forming food, but they were free from the disease. The milk-fed pigs were fat and hearty, but every one was tuberculous. Hirchberger also cites a precisely similar instance which came to his notice. The owner of a herd, learning of their infection with tuberculosis, discontinued selling

the milk, but used it to feed his hogs. When they went to the slaughter they were found affected with general tuberculosis.

Inoculative experiments are so positive and so frequently quoted that I will not cite them, as you are undoubtedly familiar with many.

The result of feeding experiments upon the lower animals leads us to consider the probable transmission of the disease, especially to children and invalids, their ability to resist the disease being at a minimum. Milk is often their favorite food, and is usually taken in the uncooked state. Direct experiment on man, is, of course, impossible; but no doubt you are all familiar with cases of accidental infection, as quoted by many observers. From these I select two, not that they are of necessity the strongest upon record, but because they are well authenticated, and occurred in the immediate vicinity.

A cow died of general tuberculosis in Providence, R. I., the lungs, most of the abdominal viscera, muscular tissue and udder being tubercular. The milk had been used in the family. In August the baby was taken sick, and died in seven weeks of tubercular meningitis. Post-mortem showed tubercular deposits in the membranes covering the brain, and some in the lungs. Two years later a two-year-old child in the same family died of tubercular bronchitis; and seven years after a nine-year-old boy, "delicate" for years, died of "quick" consumption. So far as is known the family on both sides were rugged and healthy.[2]

In the spring of 1890, Dr. Gage, City Physician of Lowell, Mass., had as a patient an infant which died of tubercular meningitis. Its parents were healthy and the surroundings good. It had never been fed on anything but the milk of a single cow. The cow's milk was microscopically examined, and found to contain the bacilli of tuberculosis. Guinea-pigs inoculated with her milk developed the disease. A second child, fed upon the same milk, was developing similar symptoms to those discovered in the child that died. Dr. Gage could find no way to prevent the sale of the milk, unless he bought and paid for the cow out of his own pocket. So far as he knew, she was still being used for a milk-supply a year later.[3]

Prof. James Law, of Cornell University, calls our attention to another danger which heretofore has rather escaped attention; namely, there is being constantly produced in tuberculous animals the product called tuberculin, varying in quantity with the number and activity of the bacilli present. This is diffused throughout the animal economy, the blood, lymph, and milk all containing it. When introduced into a person or animal having tuberculosis its effect is well known; namely, it excites the bacillus to renewed activity, thus augmenting the disease, and, therefore, although the milk may be absolutely free from bacilli, much harm may be done by this product, since sterilization has upon it no effect whatever. That its effects are not everywhere recognized is no evidence that they are not produced, as Professor Law very well says, "It is the scrutiny, and not the facts, that is wanting." We have not been looking for these facts, and so have not seen them; but that such effects may be produced there seems to be little room to doubt.

[2] Ernst: Report to Massachusetts Society for Promotion of Agriculture, p. 4; also reprint in Hatch, Experiment Station of Massachusetts Agricultural College, and Bulletin No. 8, p. 16.

[3] Ernst: Hearing before Committee on Public Health, Massachusetts Legislature of 1891, publications of Massachusetts Society for Promotion of Agriculture, p. 19.

This matter is certainly worthy of consideration, although it is right for me to state clearly that this view has not, as yet, been generally accepted by the medical profession at large. Tuberculin is not destroyed by sterilization, nor by a temperature of 212° F. If present in the animal when alive, it will certainly be present in its flesh and milk; and those who make use of these infectious substances as food must run a risk of injury. From the results of the post-mortem study, by which we have learned that in large cities at least one-half of the poor population are more or less affected by tuberculosis some time in their lives, it is evident that an equal number of those who make use of the flesh or milk of tuberculous animals are likely to suffer the greatest injury thereby, through the intensification of the tubercular process or the diffusion of the circumscribed disease. If then it be true that the temperature of 212° F. offers nothing in the way of protection, it is evident that a thorough individual inspection of each animal is the only means of accomplishing valuable results; and such inspection must include a careful physical examination together with the application of the tuberculin test.

In view of the prevalence of bovine tuberculosis and the consequent danger to us from such conditions of our food-supply, there is no doubt that its prevention and control are among the most important sanitary problems before us to-day. So slow and insidious is the course of this disease that it may be present for a long time, even for years, the animal apparently in the best of condition.

### DIAGNOSIS.

Up to within a very short time, the only positive means of diagnosis was microscopic examination of, or inoculative experiments with, the nasal vaginal, or mammary secretions whereby the presence of the germ could be demonstrated. These methods could not be put into general application. Physical examination is very difficult and unsatisfactory in a disease which may affect so many organs and tissues. The recognition of the disease in the early stages is almost impossible, because in whatever organ it may be situated, the changes are so slight, that the functions are not seriously interfered with, and consequently no marked symptoms are developed. There are certain anatomical difficulties in the way of making a perfect physical examination of cattle that are not met with in man. In cattle fed for milk or beef, the digestive function is all important, the abdominal organs having been developed by nature and breeding until they encroach upon the thoracic cavity. The first stomach, or rumen, with a capacity of fifty-five gallons, presses forward against the diaphragm, crowding it into the thorax, materially alters the sounds elicited upon percussion over the posterior portion of the lung. This influence is so irregular, and at times so great as to render the results obtained by percussion in this region of but little value. Ausculation is also interfered with by the soft breathing of cattle, by the thick layer of interlobular connective tissue, by the confusing sounds which originate in the rumen, as well as by the thick skin and mass of muscular tissue interposed between the ear and lung. When the tubercular lesions are located in the liver, intestines, mesenteric and mediastinal glands, it is impossible to make a positive diagnosis till after death; but, fortunately, we now have an agent by the use of which the disease can be detected in its early stages. Although Dr. Koch's

endeavors to find a cure for the disease ended in disappointment, the result of his researches led Professor Gutman, of Dorpat, Russia, in 1891, to experiment upon the cattle. He found that inoculation with tuberculin caused in them a characteristic reaction. Since that time tuberculin has been used in many parts of the world with almost uniform satisfaction in the detection of tuberculosis in cattle.

In making the test the temperatures are taken once or twice prior to the inoculation, which is generally made in the evening. About nine hours are usually required before the reaction occurs, though it may be delayed until the eighteenth hour. The temperature is taken every two hours beginning with the ninth hour after inoculation, until about the twentieth. In a typical case the fever ranges from two to five degrees above the normal, increasing regularly to the maximum, and then showing a gradual decline as the tuberculin is eliminated from the system. In conducting the work throughout the State up to December 15th, the Commission have made over 6,000 tests upon cattle, of which 810 were destroyed as tubercular and the post-mortem confirmed the diagnosis in every instance. There have, however, been destroyed 26 animals in which no disease was discovered; 20 of these were killed at the quarantine stations at Brighton and Watertown during the early part of our experience in a practically new field. These apparent mistakes were made, in several instances, owing to the policy adopted by the Commission, namely, while these animals showed no reaction they appeared to us upon physical examination to be tuberculous. We did not dare to put the brand of the Commission upon them as a guarantee that they were free from tuberculosis, although tuberculin had said so. In every one of these cases the animals proved free from disease in spite of their appearances, and the carcasses were sold for beef.

Another condition with which we were confronted was that some of the animals just unloaded from the cars were about to calve, and were, consequently, in an irritable condition. We considered it better to seize them as they were suspicious, and if free from the disease the loss to the State would be less than if we continued them in quarantine for a re-test. Since this time we have gained such experience that our markings have been almost absolutely correct.

The government stations and live-stock commissions of this country, Canada, Great Britain and Europe, are all agreed that tuberculin is a reliable agent for the detection of tuberculosis in cattle, and from our own experience we are satisfied to base our future work upon its accuracy as a diagnostic agent.

## THE FLAXSEED-MEAL POULTICE AS A STERILE DRESSING.[1]

BY R. W. LOVETT, M.D.

*Surgeon to Out-Patients, Boston City Hospital.*

FOR an indefinitely long time the flaxseed-meal poultice held its place as an invaluable surgical dressing. With the advent of antiseptic surgery, however, it began to be condemned as dirty; and its use has been generally discountenanced by surgical writers, in spite of the fact of its undoubted practical utility in many conditions. The present paper represents an attempt to determine by experiment the question, whether this form of dressing can be considered a sterile one.

As an instance of the practical usefulness of flaxseed-meal poultices the following series of cases may be mentioned. After operations for chronic or acute glandular abscess, the writer has treated cases in two ways. In the first series of cases a wet corrosive dressing, with perhaps iodoform, was at once applied, and so far as possible was kept continuously wet. In the second series of cases a flaxseed-meal poultice was used from the first, and was changed every two or three hours. The cases observed have amounted to some forty in number altogether; and in those treated by the flaxseed poultices the patients suffered less pain, the induration disappeared more quickly, and the progress was in every way more favorable than with the corrosive dressing. To a certain extent the same is true with regard to felons and similar inflammatory conditions.

The following experiments deal with the flaxseed-meal poultice as a dressing considered from a bacteriological standpoint:

(1) In the diphtheria ward some flaxseed-meal was taken from a tin box in which it was kept, and boiling water was poured upon it in the ordinary copper poultice dish. It was kept hot over the gas heater for three minutes, a little hot water being added from time to time. It was then poured out in the usual way, smoothed with a clean knife and covered with a piece of gauze not sterilized. A culture from the inner surface of the poultice, including the gauze, showed it to be absolutely sterile.

(2) In the surgical out-patient dressing-room, where fifty to one hundred wounds are dressed daily. The air in this room is foul on account of the large number of patients always there and on account of the presence of many foul leg-ulcers, etc. A poultice was made in a clean copper tin by pouring boiling water onto the meal. The meal was taken from a tin box kept in the room. The water and meal were mixed with a knife. No precautions were taken to render the poultice sterile. A culture from the meal as it was poured out was sterile.

(3) Ordinary gauze, not sterilized, was placed over the inner surface of the meal. A culture showed a few cocci resembling pus cocci and a few thin bacilli.

(4) The hands were sterilized; the poultice dish was thoroughly cleansed; the meal and water were heated for three minutes over the heater.

Culture from the meal as poured out showed a few long, thick bacilli, probably non-pathogenic.

(5) Sterilized gauze was placed over the inner surface of the meal and wet in the moisture of the poultice. A culture from this was sterile.

(6) A poultice made in the ordinary way without precautions, covered with non-sterilized gauze. A culture from inner surface showed many confluent colonies of whitish color, which microscopically were seen to consist of short, thick bacilli, probably non-pathogenic.

(7) Poultice made as in No. 6, but heated for five minutes at a temperature somewhat above 212° F. A culture showed a few small, whitish colonies seen to consist of micrococci.

(8) December 12th. Men's surgical ward. Poul-

[1] This paper will appear in the Boston City Hospital Reports, Sixth Series.

tice made without precautions; cooked thirty seconds. A culture showed colonies of colon bacilli.

(9) Poultice cooked five minutes; otherwise same as No. 8. A culture showed a few colonies of colon bacilli.

(10) December 13th. Surgical out-patient dressing-room. Poultice made with aseptic precautions; sterile gauze, aseptic hands, etc.; cooked thirty seconds. A culture showed a pure growth of fine bacilli but no pus cocci.

(11) The same as No. 10. Cooked five minutes. A culture showed various bacilli of different forms, but no pus cocci.

(12) Surgical private ward. The poultice was made with all aseptic precautions, and sterilized gauze was used. The meal was boiled for three minutes. A culture showed various organisms present.

(13) The same precautions as in No. 12. The poultice was boiled for ten minutes. A culture showed various organisms.

(14) Women's surgical ward. The meal was boiled for three minutes and poured out. No gauze was used. A culture was sterile.

(15) Out-patient surgical dressing-room. The meal was boiled for three minutes. No gauze was used. A culture showed only one colony of long, thin bacilli.

(16) Surgical out-patient dressing-room. The poultice was made with all aseptic precautions, and the meal was boiled for two minutes. A culture showed long, thin bacilli and cocci.

(17) The poultice was made with all aseptic precautions, and was boiled for five minutes. A culture showed long, thin bacilli and cocci.

These experiments show plainly, that although apparently by chance, the flaxseed-meal poultice may be perfectly sterile, yet in the majority of cases it is not so. Nor can it be rendered sterile by the most scrupulous care in its preparation — as shown, for example, in experiments Nos. 16 and 17. Experiments made in heating the meal for ten minutes or more reduced it to such a gelatinous mass that it was not suitable for surgical use, so that the times given here are as long a period of sterilization as is practicable. The organisms found were in most cases probably non-pathogenic and micrococci were not often present. The place where the poultice was prepared seemed to have little effect on its character, experiments Nos. 12 and 13 having been made under the most favorable conditions, while experiment No. 1 was done in a ward containing many of the foulest cases of diphtheria.

In conclusion, it may be said that the flaxseed-meal poultice is a dressing often sterile, and, if not sterile, containing, as a rule, organisms which are probably not pathogenic; but that it may contain pus cocci. It may be added that no care in its preparation can be relied on to render it sterile.

The writer is indebted to Dr. Stokes of the Pathological Department of the hospital for his kind assistance.

A STATUE TO HELMHOLTZ. — The Emperor of Germany announces that he will contribute 10,000 marks towards the erection of a statue in Berlin to Helmholtz's memory. This is the first contribution by royalty or any distinguished functionary of State to commemorate the achievements of either doctor or scientist, so far as our memory serves us.

## A REPORT ON THE BACTERIOLOGICAL INVESTIGATIONS OF AUTOPSIES.[1]

BY J. H. WRIGHT, M.D.,
*Assistant in Pathology, Harvard Medical School;*
AND WM. R. STOKES, M.D.,
*Resident Assistant Pathologist, Boston City Hospital.*

(Concluded from No. 13, p. 296.)

### GENERAL INFECTIONS WITH THE STAPHYLOCOCCUS PYOGENES AUREUS.

IN this group we consider those cases in which the bacteriological examination showed a general mono-infection essentially with the staphylococcus pyogenes aureus. One of the cases of diphtheria is included here because the general infection with the staphylococcus seemed to have its origin in an operation wound of the hip, rather than the throat. We also report here more in detail the two cases of endocarditis with staphylococcus septicemia.

CASE I. Infection-atrium a decubitus over the scapula. Edema and hypostatic congestion of lungs. Acute splenic tumor. Arterio-sclerosis of aorta and heart hypertrophy. Staphylococcus pyogenes aureus in spleen, lung, liver and kidney and cerebral meninges. Streptococcus and micrococcus lanceolatus in lung.

CASE II. Ophorectomy for cancer. Metastases in retroperitoneal lymph-glands, omentum and liver. Circumscribed peritonitis. Acute splenic tumor. Chronic diffuse nephritis. Chronic pleuritis with effusion. Hypostatic congestion and edema of lungs. Staphylococcus pyogenes aureus in kidney and blood of heart.

CASE III. Laparotomy for chronic salpingitis, slight peritonitis. Soft spleen. Staphylococcus pyogenes aureus in the peritoneum, spleen and blood of heart.

CASE IV. Operation for congenital dislocation of hip. Abscess about hip-joint extending around ileum, beneath peritoneum, up to the kidney. Secondary abscess in left shoulder, kidney and lung. Diphtheria. Staphylococcus pyogenes aureus in primary abscess, kidney, spleen, liver and lung. Bacillus diphtheriæ in air-passages and lung.

CASE V. General infection with actinomyces. The cultures showed a general infection with staphylococcus pyogenes aureus also. This case is fully reported elsewhere by Dr. Mallory.

CASE VI. Carbuncle of upper lip, metastatic abscesses of lung and kidney. Acute endocarditis, acute splenic tumor, acute hyperplasia of cervical and mesenteric lymph-glands. Acute parenchymatous degeneration of liver and kidneys. Acute degeneration of heart muscle. Staphylococcus pyogenes aureus in carbuncle of lip, kidney, spleen, liver, lung, pericardium and blood of heart.

CASE VII. Pyo-pneumothorax, perforation of diaphragm. Extensive purulent excavation of liver, general peritonitis. Pleural effusion (left side), fatty degeneration of liver. Staphylococcus pyogenes aureus in remnants of lung, liver substance, liver pus and in kidney.

CASE VIII. Acute ulcerative endocarditis, acute pericarditis, infarction of kidney, unresolved pneumonia, empyema, chronic passive congestion. General hypertrophy and dilatation of heart. General

[1] This paper will appear in the Boston City Hospital Reports, Sixth Series.

edema of connective tissue. Staphylococcus pyogenes aureus in heart-lesion, spleen, kidney, kidney infarction, liver and blood of heart.

Case IX. Purulent broncho-pneumonia, empyema of one side, broncho-pneumonia and acute pleuritis of other side. Multiple miliary abscesses in kidney. Staphylococcus pyogenes aureus in lung (purulent broncho-pneumonia), liver and spleen. Kidney abscesses sterile.

Case X. Acute alcoholismus. Congestion of lung and stomach. Acute splenic tumor. Acute parenchymatous degeneration of liver. Staphylococcus pyogenes aureus in lung, liver and kidney. Spleen sterile. Pneumococcus also in lung. A mouse inoculated with an impure culture of the pneumococcus found in the lung died in forty-eight hours with typical encapsulated diplococci in the blood.

### ANOMALOUS GENERAL POLY-INFECTIONS.

Under the head of anomalous general poly-infection we group certain of the cases in which the staphylococcus pyogenes aureus and the streptococcus, or either of these organisms and the micrococcus lanceolatus, have been found together in the same case in some of the internal organs other than in the lung. The poly-infections of this character which have been observed in diphtheria, scarlet fever, erysipelas and puerperal cases are not included in this group, but are considered elsewhere.

Case I. Cirrhosis of liver, chronic interstitial nephritis, dilatation of right ventricle of heart, fibrous myocarditis, general chronic passive congestion, ascites and hydrothorax. Staphylococcus pyogenes aureus in liver and kidney. Streptococcus and staphylococcus pyogenes aureus in spleen. No cultures from lung and heart.

Case II. Extreme hemoglobinemia, hemoglobinuria, icterus, acute splenic tumor, acute fatty degeneration of heart-muscle. Micrococcus lanceolatus and staphylococcus pyogenes aureus in kidney. Micrococcus lanceolatus and streptococcus in lung. Streptococcus in liver. Spleen sterile. Unknown bacteria in blood of femoral vein.

Case III. Meningitis purulenta, secondary to otitis media. Acute splenic tumor. Streptococcus in pus of otitis and in liver. Staphylococcus pyogenes aureus in kidney and lung. Bacillus coli communis in blood of heart. Spleen sterile.

Case IV. Acute lobar pneumonia, acute pleuritis, acute splenic tumor, urinary fistula, abscess of kidney, acute degeneration of kidneys, cirrhosis of liver, arterio-sclerosis of aorta and coronary arteries, atrophy of pancreas. Streptococcus in liver, staphylococcus albus (?) in kidney, large coccus in spleen. Various bacteria in lung.

Case V. Chronic diffuse nephritis, fatty kidney. Edema of brain and lungs, arterio-sclerosis of coronary arteries, mico-purulent bronchitis, acute splenic tumor. Micrococcus lanceolatus and streptococcus in liver. Micrococcus lanceolatus in kidney and spleen. Blood of heart negative. A mouse inoculated with the mixed culture from the liver, died in about forty-eight hours with a streptococcus septicemia, as shown by cultures from the organs.

Case VI. Chronic coxitis with suppurating foci, peritonitis with serious exudation, fibrinous focal pneumonia left lung, subacute nephritis and general amyloid infiltration. Micrococcus lanceolatus in peritoneal exudate, lung and kidney. Streptococcus in liver, spleen, and also in kidney.

Case VII. Bronchiectatic abscesses in lungs, organized pneumonia, subacute pleuritis with pus formation. Acute splenic tumor. Subacute nephritis. Micrococcus lanceolatus and staphylococcus pyogenes aureus in lung, pleural-pus and kidney. Staphylococcus pyogenes aureus in liver. Spleen sterile.

Case VIII. Acute croupous pneumonia, acute fibrinous pleuritis. Acute splenic tumor. Micrococcus lanceolatus and staphylococcus pyogenes aureus in lung, liver, kidney and blood of heart. Micrococcus lanceolatus in pleura, spleen and blood of femoral vein.

### DIPHTHERIA.

Up to the time of the well-known work of Frosch, it was generally believed that the *bacillus diphtheriæ* never invaded the internal organs, but was only to be found in the local inflammatory lesions. In ten out of fifteen autopsies on this disease, this investigator, by using large amounts of material for each culture, could demonstrate the presence of the bacillus either in the blood or in some of the organs. One of the most frequent situations in which it was found was in the pneumonic areas of the lungs. Previous to the work of Frosch but a very few instances are on record in which the bacillus has been met with in these situations. One of these is its occurrence in the spleen in a case reported by Kolisko and Paltauf. In the cervical lymph-glands it has been observed by Schmorl in seven out of ten cases. Recently Booker obtained it in cultures from the spleen, submaxillary gland, lung and blood of the heart in a case of diphtheria, and Kutcher observed it once in the liver and once in the kidney.

In the broncho-pneumonia of diphtheria the presence of the bacillus diphtheriæ was noted by Thaon in 1885, but its occurrence in this common complication of the disease does not seem to have received much attention until the last few years, during which time Johnston found it in a single case, Strelitz in one case out of eight, Flexner in one of two cases, Mosny in one of three, Kutcher in eight out of nine, while the frequency of its occurrence in the cases examined by Frosch, has been already mentioned. Of other bacteria associated with the broncho-pneumonia of diphtheria, the work of Thaon, A. Fränkel, Prudden and Northrup, Mosny and Netter, shows that the streptococcus is to be met with in the great majority of cases. In the two cases reported by Flexner, however, the micrococcus lanceolatus was present, and of the eight cases of Strelitz's, the same organism was present in five, in three of which it was accompanied by the pyogenic cocci.

The occurrence of a poly-infection in certain cases of diphtheria with both the specific bacillus and the streptococcus has been insisted upon by Barbier. This writer holds that there exist two forms of the disease, one a pure mono-infection with the bacillus diphtheriæ, the other a poly-infection with that organism and the streptococcus, or various (doubtful) varieties of it. This conclusion is based mainly upon the results of the bacteriological examination of the throat during life. The post-mortem demonstration, however, of the presence of pyogenic cocci in the internal organs has apparently been made in but a few cases.

Geneserich, in an examination of twenty-five autop-

sies on cases of diphtheria of different clinical types, found among these, four cases of invasion of the blood and internal organs with the streptococcus, while in many cases a general infection with the staphylococcus pyogenes albus was observed.

Bacteriological examinations of the various internal organs have been made in 31 cases of diphtheria, in 5 of which scarlet fever was coincident, and in another case typhoid fever. The bacillus diphtheriæ has been found by culture in the lung in 30 out of 31 cases examined, in the liver in 9 out of 29 cases, in the kidney in 6 out of 31, in the spleen in 5 out of 31, in the blood of the heart in 5 out of 26, in the mesenteric lymph-glands in 7 out of 16, in the cervical lymph-glands in 4 out of 9, in the bronchial lymph-glands in 2 out of 3, in the brain tissue in 2 out of 5 cases, and in the mucous membrane of the stomach in 3 cases. In 21 of the 31 cases, or in nearly 70 per cent., there has been found a more or less general invasion of the internal organs by the pyogenic bacteria, of which the streptococcus was the one most frequently met with.

The streptococcus was present in one or more of the large viscera (exclusive of the lungs), or in the blood of the heart, or in both, in twenty cases. In five of these cases, in addition to the streptococcus in certain organs, the staphylococcus pyogenes aureus or the micrococcus lanceolatus, or both, have been found also in some of the organs of the same case.

Among the streptococcus septicemias was the case of diphtheria and typhoid fever reported by Morse, in which the typhoid bacillus was also found in the various viscera. The only case of pyogenic infection in diphtheria in which the streptococcus was not concerned, but in which the staphylococcus pyogenes aureus was cultivated from all the large viscera, was one with a recent operation wound about the hip-joint, which should be regarded as the probable infection-atrium for the staphylococcus. Because of its unusual features, this case should be excluded from consideration as an ordinary case of poly-infection in diphtheria, as should also be excluded for the same reason, one of the cases of general streptococcus infection, in which the infection-atrium was probably a recent operation-wound in the abdominal wall with abscess formation. Excluding, therefore, these two surgical cases, there still remain nineteen cases of poly-infection in which the infection with the bacillus diphtheriæ was complicated by infection with the pyogenic bacteria.

This fact is of importance in connection with the treatment of diphtheria with antitoxin, for while the antitoxin is certainly capable of neutralizing the effects of the diphtheritic poison under certain conditions, yet there is no evidence that it can neutralize the effects of the pyogenic infection as well. If it is generally true that 60 per cent. of all cases die with a general infection with the pyogenic cocci in addition to the infection with the bacillus diphtheriæ, the failure of the antitoxin to effect a cure in a certain proportion of cases can be readily understood. It will be interesting to observe in future, when the antitoxin treatment has come into general use, whether many cases of pure uncomplicated diphtheria come to autopsy as at present.

Of the thirty-one cases, broncho-pneumonia was present in nineteen. The cultures from the lung in these broncho-pneumonias gave the following results:

The bacillus diphtheriæ (not accompanied by other pathogenic bacteria) in eight cases. The bacillus diphtheriæ and the streptococcus in five cases; the bacillus diphtheriæ, the streptococcus and the staphylococcus pyogenes aureus in two cases; the bacillus diphtheriæ, the streptococcus, the staphyloccus pyogenes aureus and the micrococcus lanceolatus in one case; the bacillus diphtheriæ and the staphylococcus pyogenes aureus in one case; the streptococcus (not accompanied by other pathogenic bacteria) in one case, and the bacillus diphtheriæ, the streptococcus and the micrococcus lanceolatus in one case.

From these results it is apparent that no one organism is to be regarded as the cause of the broncho-pneumonia of diphtheria. In fact, some or all of these species of bacteria above mentioned may be present in the lungs without the occurrence of broncho-pneumonia, as the following results show. Of the twelve cases in which no pneumonic condition was present, the cultures from the lungs in six cases (including two cases of pulmonary infarction) showed the presence of the bacillus diphtheriæ as the only pathogenic organism present, in two cases the bacillus diphtheriæ and the streptococcus, in two cases the bacillus diphtheriæ and the staphylococcus pyogenes aureus, and in two other cases the bacillus diphtheriæ, the streptococcus, the staphylococcus pyogenes aureus and the micrococcus lanceolatus.

Undoubtedly a large portion of the bacteria developing in the cultures from the lung are derived from the smaller bronchi, and not from the lung substance proper.

An interesting case, not included in our cases of diphtheria above analysed, in which the bacillus diphtheriæ was found, may be referred to here. The case was essentially one of broncho-pneumonia in an old man, no other well-marked lesions being made out at the autopsy, although the larynx and trachea were not examined. There were no symptoms during life. The cultures showed the presence of typical forms of the bacillus diphtheriæ in the lung and liver, in addition to various unknown bacteria. The organism, however, both from the lung and liver, was found to have no virulence towards guinea-pigs. This lack of virulence towards guinea-pigs has been occasionally observed in the bacillus diphtheriæ. We have noted it ourselves in a number of instances, even when the bacillus was derived from fatal cases of diphtheria. In addition to this case we have also met with the bacillus diphtheria in the lung in two other cases, in one of which it was found to be typically virulent towards a guinea-pig. In neither of these cases was there any suspicion of diphtheria during life and the air-passages were not examined at the autopsy.

### SCARLET FEVER.

Crooke, in 1885, found micrococci in the spleen and kidneys of 30 cases of scarlet fever; and in the same year Fränkel and Frendenberg found the streptococcus in cultures or sections from the submaxillary glands, the liver, the spleen and kidneys in three cases of the disease. Raskin observed the streptococcus in the purulent lymph-glands and joints, and four times in the blood of the heart in scarlet fever; and Leubartz examined a case with similar results. In the kidneys, in scarlatinal nephritis, Babes obtained constantly the same organism. The occurrence of a streptococcus general infection has also been constantly observed by Kurth at autopsies on scarlet fever.

Autopsies have been performed on 11 cases of scarlet fever, in five of which diphtheria was coincident. A well-marked general infection with the streptococcus was demonstrated in four cases (diphtheria being coincident in two); a general infection with the micrococcus lanceolatus in one case; and in another case a general poly-infection with the micrococcus lanceolatus, and the staphylococcus pyogenes aureus; these bacteria being found in the various organs either separately or together. In still another case, in which diphtheria was coincident, the culture from the spleen showed the presence of the micrococcus lanceolatus and that from the kidney, both the streptococcus and the staphylococcus pyogenes aureus.

In the four remaining cases the cultures from the various organs (exclusive of the lungs) were sterile, or contained various unknown bacteria; and no general pyogenic infection could be demonstrated. It may be mentioned that diphtheria was coincident in but three of the seven cases of general infection with pyogenic cocci. Broncho-pneumonia was observed in nine of the eleven cases. The cultures from the lung in these cases resulted as follows:

The streptococcus was found in four cases (including two cases of coincident diphtheria in which it was associated with the bacillus diphtheriæ); the bacillus diphtheriæ in two cases; the micrococcus lanceolatus in one case; the micrococcus lanceolatus and staphylococcus pyogenes aureus in one case; and in one case a mixture of three of these species of bacteria. It is apparent, therefore, that no one species of bacteria is to be found constantly in the broncho-pneumonia of scarlet fever. This has also been shown to be true of the broncho-pneumonia of diphtheria.

### TYPHOID FEVER.

But nine cases of typhoid fever have come to autopsy. The chief points of interest in our study of these cases may be briefly given as follows: The typhoid bacillus has been found in the spleen in seven of the nine cases. In the two negative cases the failure to find the bacillus may be explained by the fact that both cases had entered the stage of healing. This early disappearance of the typhoid bacillus is interesting. It is worthy of note that in one of these cases (an acute endocarditis) micrococcus lanceolatus was present. In two cases there was a poly-infection with both the typhoid bacillus and the streptococcus, diphtheria being coincident in one of them. As to the distribution of the typhoid bacillus through the organs other than the spleen, our observations are not as complete as could be desired. Our results on this point may be summarized as follows: The typhoid bacillus has been found in the liver in four out of seven cases in which cultures were made from that organ; in the kidney in three out of seven cases; in the blood of the heart in two out of four; in the mesenteric gland in three out of five cases; and in the bile in two out of three cases.

In the identification of the typhoid bacillus and its differentiation from the bacillus coli communis, great care was exercised, the liability of confusing it with that organism being always borne in mind. The typhoid bacillus in these cases was differentiated from the bacillus coli communis by the absence of gas production in its sugar-agar culture, by the appearance of its potato and litmus-milk cultures, by the absence of indol production, by its motility, and by the ease with which its locomotor organs could be stained. Most of these tests were gone through with in every case to make certain the identity of the bacillus.

### BRONCHO-PNEUMONIA AND FOCAL-PNEUMONIA.

The most important and extensive investigations of the bacteriology of the various forms of acute focal inflammations of the lungs are those of Finkler, Netter and Mosny. Finkler, from an examination of 37 cases of broncho-pneumonia and other forms of acute focal-pneumonia, found that various species of bacteria occurred in these processes, but that the streptococcus was most frequently met with in the focal forms other than true broncho-pneumonia.

Netter studied 95 cases of broncho-pneumonia, 53 of which were in adults and 42 in children. Of the 53 cases in adults, 35 were mono-infections in which the micrococcus lanceolatus was found in 15, the streptococcus in 12, the bacillus of Friedlander in 9, and the pyogenic staphylococci in 3; while 14 were poly-infections with two or more of these species of bacteria. Of the 42 cases in children, 25 were mono-infections, in which the micrococcus lanceolatus was found in 10, the streptococcus in 8, pyogenic staphylococci in 5, and the bacillus of Friedlander in 2; while 17 were poly-infections with two or more of these species of bacteria. Netter concludes from his study, that neither in children nor adults is there any relation between the species of bacteria and the type of inflammation in the lung.

Mosny studied 17 cases and found the streptococcus in 11, in five cases accompanied by other bacteria; the micrococcus lanceolatus in four, and the bacillus of Friedlander in one case. Three of Mosny's cases were pseudo-lobar and in these the micrococcus lanceolatus was present.

In the course of this work cultures have been made from the lung in 16 cases in which broncho-pneumonia was present, exclusive of cases of diphtheria and scarlet fever. In eight of these cases the micrococcus lanceolatus was found as the only pathogenic organism present, in two the streptococcus, in three the staphylococcus pyogenes aureus, in one the micrococcus lanceolatus and the streptococcus; and in two only the bacillus coli communis or various unknown bacteria grew in the cultures.

In two cases of atypical pneumonic consolidation the micrococcus lanceolatus and the streptococcus were respectively present.

From these results it is clear that, as in the broncho-pneumonias of diphtheria and scarlet fever, the species of bacteria associated with pneumonia conditions other than the lobar type are subject to great variation.

Of other pathological conditions in the lung, from which cultures have been made, tuberculosis only will be considered. In all of five cases of various types of pulmonary tuberculosis either the streptococcus or the staphylococcus pyogenes aureus, or both, have been found in the diseased lung. From one of these cases the bacillus diphtheriæ was also isolated, and found to be characteristically virulent for a guinea-pig. No examination was made of the throat or trachea at the autopsy, for there was no suspicion of diphtheritic infection.

---

A WARNING TO MIDWIVES. — It is reported that a midwife has been committed to trial in England charged with manslaughter, on the ground of having communicated puerperal fever to her patient.

## Clinical Department.

### PERSISTENT ATTEMPTS AT SELF-DESTRUCTION; A REMARKABLE METHOD OF SUICIDE.

BY CHARLES H. MORROW, M.D., GLOUCESTER, MASS.

IN November of the year 1894, I was called to attend A. B., a man who had passed middle life, was unmarried and lived alone. He had for years been troubled with indigestion and was a confirmed pill-taker. He now believed he had heart disease, but after examination I informed him that he had not. He wished me to visit him as often as I considered necessary and I called two days later; during this time he was frequently on the street, and made several social calls. He was noticeably despondent.

In the afternoon, five days after my first visit, responding to a summons, I found my patient in bed. In the early morning of that day he had made an attempt upon his life. I found an incised wound two inches in length, beginning over the apex of the heart, extending towards the sternum, and penetrating the chest near the sternum, the organs contained in the chest being apparently uninjured; a second incised, non-penetrating wound was found just above the one described; there were two incised wounds on the anterior surface of the left forearm near the wrist, but the arteries were not cut. There was a small wound of the skull and its coverings at the vertex in the median line at the point of junction of the coronal and sagittal sutures which he informed me he had made by driving a nail through his skull with a hammer. While penetration of the skull was quite apparent a probe could not now be made to pass through it. A small wound was found near the one described, which had probably been made by a nail, but which had not penetrated the skull.

He informed me that he was tired of life, believed he had water around the heart, and had made an incision for the purpose of letting it out; he also desired to know the exact location of the heart and vital points in the brain. The implements which he had used could not be found. Just after the attempt on his life he had called a woman occupying a portion of the house, who found him sitting in a chair with a basin in which there was considerable blood, which had flowed chiefly from the chest wounds. His clothes had absorbed considerable blood. She observed the head of a nail protruding from the skull, but on returning after a short absence from the room it had disappeared. It would seem that the skull wound had been first made, as it would apparently be impossible to make it when weak from the loss of blood. The end-cutting wire pliers by means of which he had extracted the nail were found. He progressed favorably, and after a few days gave every evidence of recovery. The highest temperature noted was 100.5°. As his condition improved his expressions of dissatisfaction at the failure of his attempt became more pronounced.

On the ninth day after his first efforts at suicide I was informed that the nurse had left him for a short time, and during his absence the patient had arisen, obtained a hammer and nail, and made a second attempt at suicide. The point of entrance of the nail into the brain was the same as before and it was extracted by the nurse with the pliers which the patient had himself used on the former occasion. The nurse stated that the head of the nail was so close to the skull that it was with difficulty he secured sufficient hold upon it to allow its extraction; he also stated that the nail was so tightly held by the bone that a considerable outlay of strength was required for its liberation. The first nail used was now found and identified by the blood which had clung to it. It was the ordinary smooth, round, wire nail so much in use, and measured five inches in length and three-sixteenths of an inch in diameter. The nail used on the second occasion was somewhat larger, and measured five and one-half inches in length and one-fourth of an inch in diameter. The hammer was an ordinary-sized one, having a claw for nail-extraction. The knife used was a fish-cutter's knife; an idea of this knife is obtained if we imagine a six-inch bread-knife with the cutting edge ground out in a uniform curve from the handle to the end of the straight portion of the cutting edge, that is, the end of the knife is as large as formerly, the blade narrowed at the centre.

A rise in temperature followed this second attempt, the highest recorded being 102°. Death occurred on the fifth day, or on the fourteenth day after the first attempt at self-destruction. Power to communicate ideas by speech was lost two days before death; but his mind readily responded, and showed normal understanding until death. Two days previous to death a twitching of the muscles of the right side of the face was noticed, and was soon after apparent in the right arm and hand.

Laceration of the brain and its coverings was demonstrated after death. The course of the nails was downward and backward towards a point one inch to the left of the junction of the longitudinal and lateral sinuses.

## Reports of Societies.

### CLINICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

JOHN L. AMES, M.D., SECRETARY.

REGULAR Meeting, Wednesday, January 16, 1895, DR. G. M. GARLAND in the chair.

DR. G. G. SEARS read a paper entitled,

REMARKS ON TWO HUNDRED CASES OF PHTHISIS.[1]

DR. V. Y. BOWDITCH: Dr. Sears's paper brings up several interesting points for discussion. Certainly, in regard to the point of heredity in consumption, I have been led to adopt the belief that it is not transmission of a tuberculous condition from parent to child, but that a vitiated system can be handed down which makes a fruitful soil for the germ to grow in.

In reference to our methods of diminishing the liability of infection from one case to another and the action of boards of health, it has always seemed to me that a middle ground is the safer. I had the strongest feeling against the action taken by some of the boards of health at first who would almost ostracize the poor patient the instant the bacillus was found in his sputa—it seems to me a cruel and unnecessary position to take. I do believe that certain measures, especially those adopted by the Massachusetts Board of Health and the City Board of Health, are capable of doing a vast amount of good. I have

[1] See page 323 of the Journal.

been very much surprised to find how amongst the poorer classes there seems to be already a knowledge of how to dispose of the sputa of tuberculous patients. Several times in questioning what was done with the sputa I have asked whether handkerchiefs were used, and they have said, "No, we use a piece of paper and throw it into the fire." It is a hopeful sign, I think, that people are awake to the fact that dried sputum is a danger element, and that its destruction by fire is the safest method.

It seems to me that Dr. Sears's suggestions in regard to out-patients are excellent. There is nothing in them one would take fright at. In the City Hospital we have lately adopted a new method, or, at least, it is already on the boards to be adopted, recommended by the medical staff to the superintendent who is to put it in force, and that is, instead of using the ordinary china spit-cups, a certain kind of paper spit-cup is used at the bedside. These cups when not too full are taken by the nurses, piled up together and put in a cheap cardboard box prepared for the purpose, with a rubber strap placed around it, then put into an iron rack and carried down to the fire-room. There the boxes are thrown immediately into the fire. That diminishes the possibility of infection from cuts on the hands, etc., among nurses who complain that in order to keep the china cups clean they have to put their fingers in and rub. Dr. White tells us that he has had cases of tuberculous trouble in nurses originating in the hands.

DR. VICKERY: I have enjoyed listening to the paper very much, and been instructed by it. This question about the attitude that the healthy part of the community should hold toward persons afflicted with contagious diseases is a difficult matter. Look at it from another side, which was brought to my mind by one of the doctors in this city who goes about visiting the families of those school-children who have scarlet fever and diphtheria. Perhaps in the whole city there are fifteen or more cases reported among school children daily. Now, supposing instead of being diphtheria or scarlet fever, it was small-pox, just think what a stir there would be, and how people would like to move out of Boston for the sake of their health; and yet unless very recent methods are going to change the prognosis, diphtheria is fully as fatal a disease as small-pox would be among children who had been well vaccinated. I think it is a very good thing to be frightened if you are frightened at the right things; and I am frightened at diphtheria, for instance, and scarlet fever: it is a bad thing to have in your house. A family will nurse one child, isolate him, suffer all sorts of privations, send the other children off and have everything repainted and repapered, and the other children come back and one of them comes down with scarlet fever in that clean house. This brings me to one point about which I think we all agree, and that is, after a consumptive has died, his home should be visited by the board of health and cleaned up. It seems to me that would not hurt anybody, and just the same as soldiers march from a funeral a little faster than they went, the family might feel they had taken a new start and were not going to have any more such things among them.

About the treatment, my experience confirms somewhat what Dr. Sears said about guiacol. When creasote was first recommended I tried it conscientiously, and found that almost invariably patients seemed to be worse for it. They got upset, and a good many of them never came again. Now I give a very small dose of it, and it is really surprising how much good it seems to do. The benefit seems to be primarily a stimulation of appetite and digestion. The formula I have employed (but did not originate) is as follows:

| | | |
|---|---|---|
| Creasoti fagi | | gtt. xxiv |
| Tr. gentian. comp. | | ʒi |
| Spe. vini rectificati | | ʒss |

Sig. One teaspoonful in water before meals.

The combination is much like Fraentzel's.

DR. PRESCOTT: I would like to call the attention of the Section to a method of treatment of consumption brought to my notice last September by Dr. Wood of the United States army. It is a method published by Dr. Carossa, in the *Centralblatt für Bacteriologie* for last June, and consists in the continuous inhalation of the essence of peppermint and the administration of peppermint and creasote internally combined with hyperalimentation and all the wine that an Italian soldier can take. Dr. Carossa reported forty-four cases treated by this method. Four cases were of general tuberculosis and all died: one case had a severe hemorrhage, and died while under treatment: one case died in sixteen months, as it was said from re-infection, having gone back to the same hovel where she had lived previously, and had contaminated the room by spitting all over the floor and walls. All the rest recovered; thirty-two were discharged absolutely cured, and the rest were benefited or discharged nearly cured. Twenty cases were in the second stage, two in the third stage, and the rest were in the first stage.

It was drawn to my attention last September, and I immediately put a patient under treatment. Since then I have had ten cases in all, three of them having been benefited to no great extent; they are no worse than last September; the number of bacilli is no greater; and some of the symptoms, like cough, the amount of expectoration and the night-sweats, are improved, but further than that there has been no improvement. One who went to New Mexico, and was in New Mexico sometime before she began the peppermint treatment, without any great improvement, started in upon it there, and has gained eight pounds in three or four weeks, is very much better in every way, so much so that she feels very much encouraged, and her husband does too. She had had amenorrhea nearly a year, but the courses returned on December 28th, and she now has only a very slight cough. I have not had a chance to examine her sputum, but everything else points to recovery. That, of course, cannot be attributed wholly to treatment, but at least the treatment has benefited her. A doctor who went there in the last stages, and who had some peppermint given him by my patient, was so much benefited, although there was no hope of recovery, that he wrote saying, if he lived a thousand years he could not thank her enough for the relief to the cough and dyspnea and night-sweats he had received. The other six cases were men in the Reformatory at Concord, Mass., whom I saw through the kindness of Dr. G. E. Titcomb, the physician in charge. Every one has improved, and gained in weight from two to eleven and-a-half pounds. Their expectoration has diminished so much that it is now practically nothing (I have not been able to get any from them for a month

to examine, and the last time I examined it the number of tubercle bacilli was very much diminished). Two have left the institution, one without symptoms of any sort, and he has been lost sight of. The other has gained steadily from the time he started treatment, and he is still under treatment. The other four have given up treatment as being practically well, have gone back to work, and with such improvement that you cannot get any sputa to examine for bacilli. The number of cases is very small. I speak of them with a good deal of diffidence, simply wishing to call attention to the method of treatment and to report what improvement has been obtained.

The method I used was this: A piece of cloth about ten centimetres long and five wide is folded upon itself so as to make a piece one and a half centimetres wide and five long, and this is held to the nose by a string or elastic passed around the head, and is to be worn continuously. Upon that four or five drops of the essence of peppermint are put every three or four hours, and the patient wears it except when eating. The doctor impresses upon the patient the necessity of every twenty to thirty minutes taking deep breaths and holding the inspired air so that the peppermint can come in contact with the bacilli in the lungs. Peppermint and creasote are given internally in a mixture made of eight parts each of the spirit of peppermint and pure creasote, 20 parts of chloroform, 225 parts of glycerine, and 550 parts of alcohol.

I do not know what kind of stomachs the Italian soldiers have; but the doctor says he gives a tablespoonful of that mixture every four hours. I have never found anybody who could take it that way, and most of them cannot take it any way. Half a teaspoonful every four hours is all I have been able to give.

The first patient, I think, was a young girl of sixteen, who took it straight. Everybody else wants to take it in as much water as they can get. Dr. Carossa says it can be put into a tumbler of water and sipped if the stomach does not retain it readily. Then in addition to the peppermint and the creasote taken into the stomach and peppermint inhaled, he gives 400 c. c. of wine in the twenty-four hours. But the first symptom to disappear are the night-sweats, and every patient who has had night-sweats has had them disappear inside of the first two weeks; and within three weeks the cough has diminished very much, as well as the amount of expectoration.

DR. BOWDITCH: I have used this method, and have used the oil of peppermint. If one does use that he has to be careful, as the oils vary very much in quality. Some are extremely irritating and some extremely nauseating.

DR. GARLAND: I met a doctor from Virginia a few years ago, who used the oil of peppermint for coryza. He told the patient to moisten the nostrils first with water and then with the oil of peppermint directly on the nostrils, with a great deal of benefit by clearing the head where the nostrils were closed.

I should like to ask whether in private practice the patients object to this thing while going about. Of course, in the Concord prison they can wear it all day; but what advice would Dr. Prescott give to a private patient about town as regards the number of hours he should use this apparatus?

DR. BOWDITCH: I think I have tried it in six or seven cases. The most of these were at the Sharon Sanitarium, and there was no difficulty in controlling them. Another case was a lady in Milton. She wore it day and night, and made no objection to it. One other case was a silly girl, who objected to it at the outset, and I discontinued it. My experience has been negative as far as results at the sanitarium have been concerned. In the lady at Milton, there was an astonishing change in her cough and night-sweats, and after six or eight weeks she was decidedly better. It seemed something more than coincidence, but finally she became nauseated with any attempt to use it. She is now going rapidly down hill. In strict justice to the method proposed, however, I ought to add that the internal treatment with creasote and peppermint was not used at the same time.

DR. PRESCOTT: I have only had four private patients, and one of these was a young girl who wore it around the house, and did not go out except to ride or to come up to see me in the car, and then she made a cone of her handkerchief instead of wearing the cloth. The second one was a woman of about forty. She made a cone which she preferred to the cloth. This she put over the nose and kept saturated. She liked it very much. I think she would have improved more, but she had an attack of acute endocarditis. But as far as the lungs were concerned she was no worse. The third patient has worn it just the same way; but she doesn't go visiting at all, and I don't suppose they could. I think, too, from reading Dr. Carossa's method, that the best results were obtained by keeping the patient in bed until after the disappearance of the signs; and I suppose one reason of that was because they could keep them more under surveillance.

DR. ABBOTT: I should like to ask Dr. Osgood how he would explain this fact: Some thirty years or more ago Dr. Bowditch made a statement which marked an advance in our knowledge of tuberculosis beyond anything known up to that time as to the conditions under which it prevailed. In that paper, published in 1861 or 1862, he showed that in certain parts of the State there was much more tuberculosis than in others; and that in the sea-coast counties of Barnstable and Nantucket tuberculosis in human beings was relatively greater than in any other places in the State, Nantucket having the highest ratio; and yet I understand that the examinations of cattle in Nantucket have shown the least tuberculosis of any place thus far, only five or six in six hundred. Now, there is a better opportunity in that island to make an observation than in any other place in the State. It is an isolated community, with no migration to that place at all. They use, undoubtedly, their entire milk-supply from those animals. Probably they use a large part of the beef of those animals. If there is a close connection between the consumption of the products of tuberculous cattle and the prevalence of tuberculosis among human beings, should we not expect to find upon that island corresponding ratios in these two sets of observations?

DR. F. H. OSGOOD presented a paper on

TUBERCULOSIS AMONG OUR NEAT CATTLE.[2]

DR. ABBOTT: I think the point is correct that it may be one factor, but by no means the greatest. In reference to whether we know what kind of milk our milkmen carry. In the method in which milk is distributed in Boston it would be impossible except in a very few instances. The milk is brought in by large

[2] See page 326 of the Journal.

contractors who distribute it, and sometimes it is put into mixers holding from one hundred to several hundred gallons each, so that the "one can" business and "one-cow's milk" is often a mere hypothesis.

The PRESIDENT: I wish to express my own gratification and appreciation of the value of this paper, and I imagine that I convey the sentiments of the gentlemen in thanking Dr. Osgood for the pleasure and the profitable evening he has given us.

## Recent Literature.

*A Practical Treatise on Orthopedic Surgery.* By JAMES K. YOUNG, M.D. Philadelphia: Lea Brothers. 1894.

The author states that the book is designed as a guide to students and practitioners, and he has judged well of the necessary requirements for a scope of such a presentation of the subject. The work is a good representation of the general opinions of to-day in orthopedic surgery; and in offering this the author has given full attention to recent literature in the various departments of the subject. The text is well written, and the illustrations, which are numerous, are good.

Portions devoted to the description of disease and to etiology and diagnosis are particularly well presented, and distinctions in diagnosis in many instances are made clear by comparative tables; but it would have added more to the value of the work to have given in general more space to the discussion in greater detail of questions of treatment in the matter of application of apparatus, which is so essential to the successful treatment of this class of cases. It is to be regretted that the various methods employed in the treatment of hip-disease should not have been considered more with reference to the objects which they are designed to accomplish and the education which leads to their choice rather than as schools of treatment that would be inferred by the names of American and English methods.

The presentation of the subject of etiology and development of lateral curvature is particularly good and deserves mention; but the question of the treatment seems to be rather slighted. In view of the prominence and interest which is now being displayed in this department, and also the need of putting this on a scientific basis, it seems an omission to dismiss the question without most thorough consideration, especially that of treatment of resistant cases which require more than simple gymnastic measures or retentive appliance.

The portions devoted to the neurological side deserve special mention, not only because it is rare to find this so carefully treated in works of this kind, but from its own worth. The author evidently recognizes the advantage to the orthopedic surgeon of a thorough understanding of this branch, both for itself and for its aid in general orthopedics, and to have this presented so well from the orthopedic side gives it special value.

One is impressed with the thoroughness which Dr. Young has shown throughout the work, and not the least, in his attention to recent literature and presenting recent advances in many departments. To present a subject in a brief form always involves danger in the omission of important facts, but the author is here to be commended on his judgment in selection.

## REPORT OF THE ST. LAWRENCE HOSPITAL FOR THE INSANE.

THE managers of the St. Lawrence Insane Hospital, Ogdensburg, N. Y., have just issued their eighth report. The hospital seems well equipped with buildings, surgical and medical outfits, libraries, laboratories, etc., and the reports of the medical directors show a commendable zeal to improve the large opportunities there offered. The number of patients on September 30, 1894, was 1,100. The average *per capita* cost for maintenance, including officers' salaries and clothing, was four dollars and thirty cents weekly.

Under the head of "Medical Science," Dr. Wise, the medical superintendent, speaks somewhat enthusiastically of the work of his associates, whose aim is to carry into effect these objects: "the application of the most advanced and enlightened views in relation to the treatment of the insane; minute and precise clinical observation of cases; the acceptance of every opportunity afforded towards the solution of problems connected with the causation and pathology of insanity.

Under the head of "Laboratory Methods," Dr. Robert G. Cook, resident physician, describes the processes employed of hardening, section-cutting, staining and mounting of morbid specimens of nerve and brain tissue. He has given several colored plates illustrative of pathological changes in the brains of subjects who had died at the hospital.

Dr. J. M. Mosher presents specimens of the clinical records and bedside notes of this hospital. A blood chart has recently been added to the series of blanks in daily use.

The chapter by Dr. J. M. Mosher on "The Relations of Physical Disease and Mental Disorder" is of especial interest and value. The conclusion is reached, "that the differences and distinctions between affections of the mind and body are more apparent than real, and that success in the treatment of disease of the former is attained on purely medical methods no

less than in the treatment of affections of any other part of the organism. Mental disease as an entity, whether its manifestations be mania or melancholia, exhilaration or depression, disorder of the will or the emotions, yields to the preponderating physical depravity and remains only as a complicating group of symptoms, often perplexing and obscure, but subordinate."

The writer agrees with Dr. Edward Cowles (Shattuck Lecture, 1891), in teaching that in the genesis of insanity, the departure from health is initiated by a train of neurasthenic symptoms, of which the earliest is the development of pathological from physiological fatigue. He affirms that neurasthenia, as preeminently the type of perverted nervous function, has the closest relationship to insanity, of which, in fact, it is a well-nigh universal complication. "In chronic cases long past the initial neurasthenic stage, its impress remains in the enfeebled circulation, intestinal torpor, dilated pupils, retarded and benumbed sensations, motor debility and inactive reflexes." The sequence and relations of the neurasthenic manifestations have been shown to be, on the physical side, lack of control of nerve-force, failure of co-ordination, and increased excitability with quick exhaustion; the earliest mental indication is weakness of the faculty of attention, alteration of the bodily feelings, producing a sense of ill-being and of effort. So far the symptoms are those of normal tire amenable to the relief obtained by usual processes of recuperation. The morbid state follows the grafting upon these, symptoms of introspection, retrospection, apprehension, worry and hypochondria, irritability and restlessness, from which the change to suspicion and delusion is but a step.[1]

Dr. Mosher thinks that for these cases, rest is the prime indication. When this may be best secured by withdrawal from sources of irritation, and the novelties of sight-seeing and similar mental stimulation, from the sympathetic and too fidgety interference of well-meaning but oppressively-anxious friends, isolation becomes imperative, often in the hospital. There, induced by routine manner of living, by well-ordered direction of trained nurses, and by nutritious food properly adjusted in time and quantity for the digestive capacity, improvement is often rapid and permanent. The action of tonic drugs is re-enforced by electricity and massage. At a proper moment in convalescence, dulness is sought to be overcome by the stimulation of carefully-regulated diversion, and the physical and mental recuperation to be completed by calisthenics, drives, short walks and easy games, as croquet and tennis.

Disorders of digestion, according to this writer, are not less frequent complications of insanity than of its associated neurasthenic state. Their correction is essential to successful treatment, and may be expected to exert a prominently favorable effect upon the mental disease. Gastric and intestinal dyspepsia, functional derangement of the liver, constipation and its sequelæ, cholelithiasis and intestinal parasites are such frequent symptoms, that cases so affected have furnished grounds for the belief in the so-called sympathetic insanities. Recovery from acute melancholia following fecal impaction is reported by Dr. Hutchinson, and Mosher also has recorded a similar case in which disinfection of the primæ viæ was followed by relief of stuporous melancholia and restoration of the patient to his home and vocation. The study of this form of auto-intoxication throws much light on the causes and complications of acute insanity. Several interesting reports in illustration and vindication of this statement are given.

No less interesting is the study of the insanities dependent on diseases of the circulatory system and of the genito-urinary system. Dr. Mickle's analysis shows mitral regurgitation to be most frequently accompanied by depression with delusions of persecution and suspicion; mitral stenosis with impulsive excitement and discontent; aortic regurgitation with loquacity and delusions of exaltation and of internal sensations, such as magnetic influences; and aortic stenosis with impulsive violence and delusions of persecution and poisoning. Several illustrative cases occurring at St. Lawrence Hospital are reported by Dr. Mosher.

With regard to uremic insanity, it would appear that there is a large field yet to be explored in which the relations of renal insufficiency to various forms of mental alienation may be set forth. Mosher gives four conspicuous cases of uremic insanity, of which two resulted in death, one in chronic insanity, and one in restoration to mental health.

The question of the relations of insanity and tuberculosis presents great interest, and the same may be said of constitutional diseases such as gout and diabetes. The frequent co-existence of phthisis and insanity has been acknowledged by all authorities, and the substitution of one for the other in tuberculous families has been noted. Phthisical insanity may be of the mildly delusional, slightly demented type, or of the melancholic, monomania of suspicion type. "It is a very striking fact," says Dr. Mosher, "that nearly all pure cases of monomania of suspicion sooner or later die of phthisis."

There is an interesting paper by Dr. Hutchings on "The Douche-Bath, with Cases." These douche-baths, in the form of a coarse, cold spray, have been found very valuable in mania and dementia. The exposure should be brief, and subsequently energetic friction and massage employed.

Dr. James Burton contributes a paper on "The Blood in the Insane." He arrives at the general conclusion that in cases of senile dementia, as a rule, there is increase of leucocytes, while in cases of general paralysis they are markedly decreased; also that in cases of maniacal excitement the number of leucocytes is greatly increased.

There is an excellent paper by Dr. Robert G. Cook

[1] Cowles: Neurasthenia and Mental Symptoms. The Shattuck Lecture, 1891.

on "General Paralysis," and an elaborate analysis by Dr. Sawyer of "One Hundred Consecutive Autopsies at the St. Lawrence Hospital." This is a contribution of value to the aggregate statistics of the morbid anatomy of persons dying insane; it is illustrated by a number of plates, and a comprehensive table.

The volume is a good example of the kind of work which might be done at all our great insane hospitals; we hope that the managers of other institutions of the same kind may be stimulated to do likewise.

## AN EPIDEMIC OF LEPROSY IN RIGA.

Although it would seem that no further proof of the contagiousness of leprosy was needed, so many instances having been reported of its occurrence in persons who had been in intimate contact with other lepers, yet in view of the reluctance of a number of eminent foreign and American dermatologists to accept this view, the following statistics[1] of the occurrence of the disease in the poor-houses of Riga, may be appropriately and usefully reproduced.

During the last few years leprosy has been on the increase in Riga, but it has been very difficult to determine the causes, as many of those living in the suburbs are removed from medical supervision, and the period of incubation being so long, little weight can be laid on the facts supplied by the patients themselves. Still von Bergmann has succeeded in establishing the fact of contact between most of these cases and lepers that were known to him.

Von Reisner is physician to the leper hospital in Riga and can prove that the great majority of the seventy-five patients in the hospital have been in contact with lepers. Three cases of leprosy having appeared in one of the poor-houses of the city within a short period, an examination of the remaining inmates by von Reisner led to the discovery of five more cases. Of these eight cases two were of the tubercular form; the remaining six were cases of nerve leprosy. All were so marked that there could be no question as to the correctness of the diagnosis, and the bacillus lepræ, searched for in all, was found in the two cases of the tubercular form. Cases 1, 2 and 3 form a group by themselves. They had had neighboring beds for years and as they were Catholics, were separated from the other inmates. Case 1 had been in the institution twenty years; Case 2, ten years; Case 3, fifteen years. Case 1 came from a district known to be a focus for leprosy. In the second group, all examples of nerve leprosy, Cases 4, 5, 6, and 7 had either occupied neighboring beds or had been in intimate association with one another in the same room.

In another poor-house in the city, situated near the former, thirteen cases of leprosy were discovered. In almost all of the cases the patient had either had a neighboring bed, or had been in constant association with one or more of those affected.

[1] Arthur von Reisner: Monatsheft. für prak. Derm., February 15, 1894.

Farther he relates a case that seems to speak positively for the contagiousness of leprosy, a man whose occupation was that of a travelling juggler. He had never visited any places where leprosy was common, but four years before, he had travelled for a year with a merchant who was afflicted with leprosy. Although he kept away from him as much as possible, it sometimes happened that they were obliged to share the same sleeeping-room and to use the same towel. Two years afterward the first signs of leprosy appeared, and later unmistakable nodules of the forehead.

Of these twenty-three cases of leprosy, nine were instances where one who had occupied an adjoining bed to a leper was found to be affected; six had lived in close relationship with a leper for many years; four brought in the affection from without; four could only be explained by frequent association with the other lepers in the institution. The writer remarks that this is the same picture presented by every chronic, contagious disease, as heredity was in all cases excluded. When the feeble virulence of the disease is considered, 22 cases in from four to five years from a total of 340 inmates of the two institutions is a high figure. The writer's view is that advanced age predisposes to the contraction of leprosy, and that normal dietetic and hygienic conditions do not protect from it. He closes by describing some remarkable improvements that have occurred in cases of leprosy by the use of gurjun balsam. Cases of the tubercular form treated both externally and internally with this drug never failed to show some improvement. In one case which was treated by this method for ten months, a complete disappearance of the leprous tissue was effected. The patient returned soon afterward, however, with an acute febrile attack followed by dense, reddish-brown infiltrations covering nearly all the skin of the extremities and of the face.

## DIAGNOSIS OF CHRONIC HYDROCEPHALUS IN EARLY STAGES, BEFORE ENLARGEMENT OF THE SKULL HAS OCCURRED.

The difficulty in the diagnosis of hydrocephalus is naturally much increased when the collection of fluid in the ventricles has not yet led to enlargement of the skull. The diagnosis must then rest wholly on the clinical symptoms. Of these an exceedingly important one is the well-recognized spastic condition of the extremity muscles, which, however, varies within wide limits. This condition occurs not infrequently before the head has begun to enlarge, and especially in those cases in which an external hydrocephalus alone exists, or is accompanied by a collection of fluid in the ventricles. In cases of uncomplicated internal hydrocephalus the enlargement of the head is apt to occur at an early period in the disease, and so lead to an immediate correct diagnosis. Attacks of recurring eclampsia are of less importance than the more permanent spastic conditions. Congenital spastic rigidity of the limbs (Little's disease) is usually due to defec

tive development or to diffuse sclerotic processes in the cortex, and may occur quite independently of hydrocephalus. Especially important in differential diagnosis are the following facts well stated by v. Ranke (*Jahrbuch f. Kinderheilkunde*, Part IV, 1895):

(1) In congenital spastic rigidity the lower extremities usually are alone affected, whereas in hydrocephalus the arms are attacked as well, and at times even the muscles of the body.

(2) The congenital spastic condition is usually first noticed when the child begins to walk; the rigidity resulting from hydrocephalus, on the other hand, is for the most part an exceedingly early symptom.

(3) Accompanying eclamptic attacks are an indication in favor of hydrocephalus.

The differentiation of hydrocephalus from tetany is usually not difficult, owing to the progressive tendency of the one, and the tendency of the other, after a lapse of two or three weeks, toward recovery. Furthermore, cases of tetany with spontaneous tonic contractures in all extremities are very rare, and when they occur characteristic positions of the hand (obstetric hand) make diagnosis easy.

## MEDICAL NOTES.

Amalgamated Twins. — Dr. F. B. Heisordt (*Journal of the American Medical Association*) reports the birth of twins, the mother being a light-haired German woman and the father a negro; one of the twins was white and one black.

Semi-Centennial Anniversary of the Buffalo Medical and Surgical Journal. — This excellent contemporary proposes to signalize its semi-centennial anniversary, which will occur in a few weeks, by increasing the number of its pages from 64 to 80, and making other improvements.

A Tax on Physicians. — The *North Carolina Medical Journal* writes editorially, in sharp language concerning a recent bill in the State Legislature levying a tax of ten dollars a year on every practising physician. Such legislation is unprecedented, and seems to have absolutely no reasonable foundation.

The Medical Mind Fettered. — The Pennsylvania State Medical Society wants no papers longer than ten minutes, this year, at its annual meeting. A maximum limit of ten minutes is rather running brevity into the ground. It is hard to see how any great amount of wisdom could be crowded into so exceedingly short a space of time.

The Hospice Salpêtrière, made famous by the names of Pinel, Esquirol, Trélat, Vulpian, and Charcot, was first established in a building that had been originally a factory of saltpetre, whence its name. The buildings were first converted into an arsenal, and then in 1653 set aside as a home for aged and indigent women. In 1684 a prison for the detention of prostitutes was built in the centre of the grounds. A century later this building was turned into an asylum for the incurably insane. In 1862, when Charcot first became attached to the institution as *chef de service*, the population of the Salpêtrière was about five thousand.

The Influenza Epidemic in England. — The fatality of influenza in London last week (*British Medical Journal*, March 16th) showed a further considerable increase. The deaths primarily referred to this disease, which had been 24, 111, and 296 in the three preceding weeks, further rose to 473 during the week ending Saturday last, March 9th. This number considerably exceeds that recorded in any week during either of the two previous epidemics, and, with one exception, was higher than in any week on record. The mortality among elderly persons from the disease showed an even greater excess than in the preceding week, 255, or nearly 54 per cent., being of persons aged upwards of sixty. The calculation of the death-rates from influenza last week at different age-periods gives the following interesting results: Among persons under twenty years of age the mortality from influenza was equal to an annual rate of 1.5 per 1,000 estimated to be living at that age-period; among persons aged between twenty and forty the rate was 1.6 per 1,000; among persons aged between forty and sixty the rate was 8.1 per 1,000; among persons aged between sixty and eighty it was 40.6 per 1,000; while among persons aged upwards of eighty the rate was no less than 144.1 per 1,000. If the deaths are divided into two age-periods only — under sixty and above sixty years of age — it is found that among equal numbers living to one death from influenza among persons aged under sixty, there were 17 deaths among persons aged upwards of sixty. The deaths referred to diseases of the respiratory organs in London, which had been 840, 1,120, and 1,448 in the three preceding weeks, were 1,366 last week, and exceeded the average by as many as 824; of these 1,366 deaths, 938 resulted from bronchitis, against an average of 325; and 336 from pneumonia, against an average of 143. Many of these deaths, although primarily attributed to one or the other of these diseases, were indirectly due to influenza. In some of the large provincial towns, where influenza is fatally prevalent, very high death-rates were recorded last week, notably in Brighton, Halifax, Liverpool and Plymouth, in all of which the death-rate exceeded 40 per 1,000.

### BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — During the week ending at noon, April 3, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 38, scarlet fever 27, measles 311 (nine days), typhoid fever 4.

Bequests to Hospitals. — By the will of the late Moses Kimball, of Boston, $21,000 is bequeathed to the New England Hospital for Women and Children, $5,000 to the Massachusetts Charitable Eye and Ear Infirmary, and $5,000 to the Boston Dispensary.

Massachusetts Hospital for Inebriates. — The hearing at the State House before the Committee

on Public Charitable Institutions on the bill to enforce the use of the Keeley cure at the Massachusetts Hospital for Dipsomaniacs and Inebriates will take place on Tuesday, April 9th, for the petitioners, and Wednesday, April 10th, for the remonstrants, at 10th A. M.

The Non-Suppression of Bovine Tuberculosis. — The Bill at present before the Massachusetts Legislature for the suppression (!) of bovine tuberculosis has taken this form and substance: (1) An appropriation of only $100,000 for the Commission. (2) Full compensation to owners. (3) No use of the tuberculin test without the owner's consent.

Bovine Tuberculosis. — The Governor of New Hampshire has vetoed the bill recently passed by the legislature of that State appropriating $100,000 for the suppression of bovine tuberculosis. Farmers vote!

Death at the Age of One Hundred and one Years. — Jonathan Scott Ellis died at Farmington, Me., March 30th, at the age of one hundred and one years and eight months, from the effect of a fall received while he was preparing a razor to shave himself. It is reported that he had not required medical attendance for over eighty years previous to this injury.

NEW YORK.

A Death Attributed to Antitoxin. — On March 29th Bertha Valentine, a young girl seventeen years old, residing in Williamsburg (Brooklyn, E. D.), who was suffering from diphtheria, said to be of a mild character, was inoculated with antitoxin by the family physician. Almost immediately afterward she was seized with violent convulsions, and within five minutes was dead. The case was referred to the coroner; and the coroner's physician, Dr. J. M. Clayland, after making an autopsy, reported that death was due to the effects of the antitoxin injection. The attending physician, Dr. J. L. Kortright, is of the opinion that the fatal result was probably due to the fact that in putting up the vial used, some virulent poison had been mistakably labelled as antitoxin. The preparation employed was imported from Behring's laboratory, and was purchased in New York. Dr. Kortright has had quite a large experience with antitoxin in the treatment of diphtheria, and has been very favorably impressed with its efficacy in the disease. He has generally used the Pasteur antitoxin. It is stated that Miss Valentine contracted diphtheria from a young cousin, nine years old, who was visiting at the house. In this instance the disease had advanced to a hopeless stage before the family physician was called in. Dr. Kortright employed antitoxin (the Pasteur preparation) as promptly as possible, but death ensued in a short time. The Behring antitoxin used in Miss Valentine's case will be carefully examined by experts, and tests will be made with it upon animals.

Death of the Dahomey Giant. — "Colonel" Gilbert, formerly known as Barnum's Dahomey Giant, died on March 29th at the age of thirty-four. He was seven feet, five inches in height, and had been exhibited ever since he was seventeen. While travelling in Minnesota two years ago he met a young woman almost as tall as himself and married her. They then appeared together at museums. The body was taken to Scranton, Penn., for interment, and the coffin required a box nine feet long to hold it.

Weekly Mortality. — There were reported in the city 900 deaths during the week ending March 30th, against 887 for the preceding week, and 995 for the average of the corresponding weeks during the past five years. There were 40 deaths from diphtheria, an increase of five over the previous week, and 111 from pneumonia, a decrease of 34 as compared with the previous week. Twenty deaths were reported as due to influenza.

First Aid to the Injured. — A society composed of graduates of the course in first aid to the injured has lately been organized with the title, "First Aid to the Injured Alumni." Lectures will be given and meetings held in the United Charities Building.

Insufficient Appropriation for Quarantine. — At a meeting of the Quarantine Commissioners held March 29th, State Engineer Adams reported that the Ways and Means Committee of the lower house of the Legislature at Albany had cut $83,000 out of the annual quarantine appropriation, including $61,000 for a fire-proof building on Swinburne Island and $10,000 of the estimate of $35,000 for repairs and maintenance. The Health Officer, Dr. A. H. Doty, stated that he could not get along with this reduced appropriation, especially for repairs and maintenance. Extensive repairs are urgently needed, and he is at present building a pathological laboratory. A committee was accordingly appointed to go to Albany to explain the situation and endeavor to have the items restored.

## Miscellany.

### EXAMINATIONS BY THE MASSACHUSETTS BOARD OF REGISTRATION IN MEDICINE.

The Board of Registration in Medicine held examinations on the 6th and 12th of March in Boston, and on the 29th of March at Springfield.

At the first, 47 applicants were examined and one was rejected. At the second, 10 were examined and three rejected. At the last there were 34 applicants, but the result is not yet determined.

The law allows those who have been rejected to be re-examined at any regular meeting of the board any time within two years without additional fee, and thereafter as often as they may desire upon payment of the fee of ten dollars.

The examination is a written one on the following subjects: surgery, physiology, pathology, obstetrics and practice of medicine. Graduates of schools recognized by the board as giving a good medical education, regular, homeopathic or eclectic, are given one question on each of the five subjects allowed by the law. Non-graduates are given five questions. Seventy per cent. is required to successfully pass.

The first report of the board is in the hands of the State printers. The appendix will contain the names of all those who have been registered who made application prior to the first of January.

Another examination will be held some time during the present month. Notices are sent to those whose applications are on file.

## A PASTEUR INSTITUTE AND VIVISECTION.

AN exceedingly temperate and able article has appeared in the February number of the *Indian Medical Gazette*, by Surgeon-Colonel Harvey, relating to the founding of a Pasteur Institute in India. The article was called forth by the misguided opposition to the scheme, of the Bengal Branch of the Anti-Vivisection Society. As has usually been the case, the anti-vivisectionists have taken up the cudgels armed with quite insufficient facts, but nevertheless have succeeded in stirring up public sentiment to a considerable degree.

It is Dr. Harvey's purpose in his paper, and he succeeds most admirably, to go over with care and fairness the much disputed ground, and from the standpoint of a large-minded man, who is not personally a vivisectionist, to weigh the arguments for and against the practice. His conclusions are simply those to which every one must come who has the best interests of scientific medicine at heart, and who is able to see the inevitable tendency of future investigations. To the moralist it may appear a strange anomaly that progress must be along lines, which entail death and a certain amount of suffering to lower animals, but in the light of the brilliant results of experimental medicine during the past few years, it is hard to see any other alternative for the future. Aided by Dr. Harvey's article the Pasteur Institute will doubtless be founded, and enter upon a career of constantly increasing usefulness.

## SUCCESSFUL LAPAROTOMY FOR REVOLVER WOUND OF THE ABDOMEN IN A PREGNANT WOMAN.

THE Paris correspondent of the *Lancet*, writing under date of March 12th, gives the following account of a most remarkable case:

"M. Albarran presented to the Société de Chirurgie on the 27th ult. a young woman aged nineteen years who was admitted to the Hôpital Cochin for a bullet wound in the umbilical region at a spot four fingers' breadth from the median line. Five hours and a half after the receipt of the wound she had vomited only once — during her removal to hospital. The patient was collapsed, and there was ascertained to be some dulness at the lower part of the abdomen. A penetrating wound with internal hemorrhage was diagnosed, and immediate laparotomy was had recourse to. During the preparations for the operation the state of the breasts led to a vaginal examination, and a pregnancy advanced to from the fourth to the fifth month was detected. Four wounds of the small intestine, necessitating the resection of twenty centimetres of the bowel, were seen directly the abdomen was opened; a fifth intestinal wound was sutured, and search for the source of hemorrhage which continued revealed a perforation of the mesentery involving a branch of the superior mesenteric artery, which was tied. The fundus of the gravid uterus was the seat of a small wound through which protruded a loop of the umbilical cord. Wishing to terminate the operation promptly, M. Albarran resected the loop on a level with the uterine surface, the stump being returned into the uterine cavity. The abdominal incision was then quickly closed. The next day abortion took place, but nothing of interest occurred afterwards to retard complete recovery."

## REPORT FROM AN EARLY CASE OF TUBERCULIN INJECTION.

IN a recent number of the *Philadelphia Polyclinic*, the following statements are made:

"We have just learned through his physician, Dr. George W. Free, of Harrisburg, formerly of Laramie, Wyoming Territory, that the young man, a patient of Dr. J. Solis-Cohen, with tuberculosis of the lungs and larynx upon whom, through the courtesy of Police-Surgeon Dr. Angney, the first injection of tuberculin was made in Philadelphia, December 17, 1890, at Jefferson Medical College Hospital, in the presence of Drs. Henry Hearn, Harris and others, is alive and well, with a strong voice, vigorous and without any evidence of disease.

"In this case subsequent injections were made on the 19th and 30th of December, and on January 6th, 9th, 11th and 14th, after which the previous hygienic and medicinal treatment was resumed."

It is a matter of considerable interest to have a definite report after the lapse of over four years, of one of the cases originally treated with tuberculin. One case of course proves nothing, and the apparent cure may perfectly well have been due to other agencies than the tuberculin injections; nevertheless, evidence even of so uncertain a character has its decided value.

## THE CONTROL OF VIVISECTION.

PHILADELPHIA, PA., March 27, 1895.

MR. EDITOR: — May I, through your columns, sound a note of warning in regard to certain circulars and petitions which have been more or less widely circulated by Dr. Albert Leffingwell, of Cambridge? I am led to do this both by the remembrance of the fact that members of the medical profession are not rarely led by their good nature and inadvertence to give their names improperly, and also by the fear that some physicians may be misled by the positive false statements contained in these circulars.

It is astounding that even the wildest fanaticism should so blind a man of apparent culture and honesty as to lead to such publication as is contained in the following paragraph (italics as in circular):

"11. While State laws generally prohibit cruelty, yet, in the great majority of cases, *there is no law, no college rule, or regulation even*, preventing the infliction upon living animals of the utmost conceivable torture, *so long as it is done within the walls of the college laboratory and by permission of the instructor.*"

I do not know in detail the laws of all the States in the Union; but certainly in Pennsylvania and in many, if not in most of the other States, the college instructor or the college student who is guilty of cruelty is just as liable to punishment as is the carter or the huntsman who abuses the horse or dog.

It is probable that no American physiologist believes in

unrestricted vivisection; it is certain that the statement that unrestricted vivisection exists in most parts of the United States is a falsehood. What the American physiologist contends for is that vivisection requires no special brand to be placed upon it; that the vivisectionist needs no other restriction than that placed upon all other members of the community by the general law. Every physiologist familiar with antivivisection literature knows that it is full of misstatements, so that this attempt to manufacture public opinion by the circulation of what should be called by the Saxon word "lies," is concordant with the history of the past in warranting a strong suspicion that signatures to the document circulated by Dr. Leffingwell will not be honestly dealt with. I therefore venture to suggest that the proper receptacle for the circulars is the waste-paper basket.

Very respectfully yours,
H. C. WOOD, M.D.

## THE AMERICAN HUMANE ASSOCIATION AND VIVISECTION.

CAMBRIDGE, March 30, 1895.

MR. EDITOR: — The American Humane Association is at present engaged in an attempt to ascertain the views regarding scientific experimentation upon living animals entertained by the leaders of thought and opinion throughout the United States and Europe. For the purpose of giving definite form to impressions and concepts that are sometimes vague, and for the more ready classification of replies, there have been drawn up for comparative consideration, four different statements of opinion, couched in clear and emphatic terms, and expressing views radically distinct from one another. It is, of course, impossible to represent all existing shades of opinion in Europe and America by these four statements, and every recipient is specially requested to erase all clauses with which he cannot agree, and to favor the Committee with the fullest expression of his own particular views. That the four statements thus presented, do fairly represent existing shades of sentiment, is evinced by the fact, that while many slight changes in phraseology are often made, yet *all* of them — and particularly the first two which favor this form of research — have received the signatures of leading scientific men throughout the United States, and that, without erasure or change in any respect.

It has recently been decided to test medical opinion on this subject in one or more States more minutely than would be possible for the entire country. Every physician in Massachusetts whose standing in the profession is evinced by a certain period of practice will be asked to express judgment on the question. No such census of opinion has ever before been attempted, and the Medical Committee hope that the response of the profession may be as complete as possible. I trust, sir, that not only the members of the medical profession who favor extreme views in either direction may respond, but that there will also be afforded a representation of that sentiment favorable, within limitations, to all vivisection founded on utility, but not to the wantonness of a Magendie, or the cruelty of a Mantagazza. I am, sir, etc.,

ALBERT LEFFINGWELL.

## COLD IN THE TREATMENT OF PNEUMONIA.

PHILADELPHIA, March 30, 1895.

MR. EDITOR: — My last paper on "Ice-Cold Applications in Acute Pneumonia," gives a record of seventy-four cases so treated and only two deaths.

Being desirous of making a full collective report on this subject, I take the liberty of asking those members of the medical profession who have tested this measure to kindly give me the result of their experience with it. Full credit will be given to each correspondent in the report which I hope to publish.

THOMAS J. MAYS, M.D., 1829 Spruce Street.

## METEOROLOGICAL RECORD,

For the week ending March 23d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | Weather. * | | Rainfall in inches. |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Daily mean. | Daily mean. | Maximum. | Minimum. | 8.00 A. M. | 8.00 P. M. | Daily mean. | 8.00 A. M. | 8.00 P. M. | 8.00 A. M. | 8.00 P. M. | 8.00 A. M. | 8.00 P. M. | |

| Waltham | 22,058 | 4 | 1 | — | 25.00 | — | — | — |
| Quincy | 19,642 | — | — | — | — | — | — | — |
| Pittsfield | 18,802 | 3 | 0 | — | 66.66 | — | — | — |
| Everett | 16,585 | — | — | — | — | — | — | — |
| Northampton | 16,331 | 8 | 1 | — | 25.00 | — | — | — |
| Newburyport | 14,073 | 5 | 0 | — | 40.00 | — | — | — |
| Amesbury | 10,920 | 3 | 1 | — | 33.33 | — | — | — |

Deaths reported 3,018: under five years of age 970; principal infectious diseases (small-pox, diphtheria and croup, measles, diarrheal diseases, whooping-cough, erysipelas and fevers) 302, acute lung diseases 590, consumption 368, diphtheria and croup 127, scarlet fever 41, diarrheal diseases 41, measles 23, typhoid fever 23, cerebro-spinal meningitis, whooping-cough, and erysipelas 15 each, malarial fever 2, small-pox 1.

From measles New York 14, Providence 4, Brooklyn 2, Boston, Cleveland and Clinton 1 each. From typhoid fever Philadelphia 10, Lowell 3, Cleveland and Pittsburgh 2 each. New York, Brooklyn, Boston, Cincinnati, Springfield and Clinton 1 each. From cerebro-spinal meningitis New York 6, Boston and Worcester 2 each, Brooklyn, Providence, Lynn, Somerville and Chelsea 1 each. From whooping-cough Brooklyn 4, New York 3, Philadelphia and Boston 2 each, Cambridge, Springfield, Brockton and Chelsea 1 each. From erysipelas New York 5,

New Bedford 3, Philadelphia, Brooklyn and Boston 2 each, Providence 1. From malarial fever Washington 2. From small-pox Cincinnati 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530, for the week ending March 16th, the death-rate was 32.2. Deaths reported 6,534: acute diseases of the respiratory organs (London) 1,120, whooping-cough 113, diphtheria 52, measles 51, diarrhœa 36, fever 27, scarlet fever 22, small-pox (London) 1.

The death-rates ranged from 15.6 in Norwich to 48.0 in Brighton; Birmingham 30.9, Bolton 32.3, Croydon 34.5, Gateshead 26.1, Hull 22.9, Leeds 34.0, Leicester 20.7, Liverpool 37.1, London 33.4, Newcastle-on-Tyne 34.5, Nottingham 32.2, Oldham 44.0, Preston 40.3, Salford 30.0, Swansea 28.5.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 23, 1895, TO MARCH 29, 1895.

The extension of leave of absence on surgeon's certificate of disability, granted FIRST-LIEUT. HENRY R. STILES, assistant surgeon, is still further extended two months, on surgeon's certificate of disability.

The leave of absence for one month is granted CAPTAIN JEFFERSON D. POINDEXTER, assistant surgeon.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 30, 1895.

L. B. BALDWIN, surgeon, detached from Pensacola Navy Yard, and ordered to the U. S. S. "Montgomery."

J. S. HOPE, assistant surgeon, ordered to the U. S. S. "Montgomery."

HOWARD WELLS, surgeon, detached from the U. S. S. "Montgomery," and granted three months' leave.

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING MARCH 30, 1895.

G. T. VAUGHAN, passed assistant surgeon, to proceed to Philadelphia, Pa., and assume command of service, March 28, 1895.

G. H. GARDNER, assistant surgeon, granted leave of absence for fifteen days, March 22, 1895.

H. S. CUMMING, assistant surgeon, to rejoin station New York City, New York, March 16, 1895.

PROMOTION.

J. M. EAGER, commissioned as passed assistant surgeon, March 26, 1895.

## APPOINTMENTS.

The following changes have taken place in the Carney Hospital Staff:

*Resigned.*

DR. A. COOLIDGE, Jr., from position of physician to out-patients.

DR. J. E. GOLDTHWAIT, from position of surgeon to out-patients.

*Appointed.*

DR. J. E. GOLDTHWAIT, to position of orthopedic surgeon to out-patients.

DR. G. E. THOMPSON, to position of physician to out-patients.

## SOCIETY NOTICE.

PHILADELPHIA PATHOLOGICAL SOCIETY.—At the semi-annual conversational meeting of the Philadelphia Pathological Society to be held in the hall of the College of Physicians, northeast corner 13th and Locust Streets, on Thursday, April 25, 1895, at 8.15 P. M., Dr. George Dock, of the University of Michigan, will deliver an address entitled "Trichomonas as a Parasite of Man." Members of the profession are cordially invited to be present.

AUGUSTUS A. ESHNER, M.D., *Secretary.*

## RECENT DEATHS.

DR. WILLIAM S. W. RUSCHENBERGER, an eminent naval surgeon and scientist, died March 24th, in Philadelphia, at the age of eighty-eight years. He was a graduate of the University of Pennsylvania and served with distinction in the medical service of the U. S. Navy. In 1871 he was commissioned medical director on the retired list, with a relative rank of commodore. He was an active member of the Academy of Natural Sciences, whose vice-president and president he has successively been. He was a notable fellow of the College of Physicians, whose secretary and vice-president he had been. He was also a member of the American Medical Association, of the American Philosophical Society, and of the Historical Society of Pennsylvania. He had made a considerable number of contributions to scientific literature.

DR. JOHN A. RYDER, Professor of Comparative Embryology in the University of Pennsylvania and a very distinguished embryologist, died on March 26th, at the age of forty-three years. He was for a time embryologist to the United States Fish Commission, and made numerous valuable contributions to the art of fish-culture and in other departments of biology. In 1886 he was made professor of Comparative Embryology in the University of Pennsylvania. He was a strong advocate of the mechanical theory of evolution.

## BOOKS AND PAMPHLETS RECEIVED.

The Surgical Treatment of Inguinal Hernia. By Henry O. Marcy, A.M., M.D., LL.D., of Boston, U. S. A. Reprint. 1894.

Transactions of the Medical Society of the State of North Carolina, Forty-first Annual Meeting held at Greensboro, N. C., May 15, 16 and 17, 1894. Washington, N. C.: Jackson & Bell. 1894.

The Medical Annual and Practitioner's Index: A Work of Reference for Medical Practitioners. Thirteenth year. Bristol: John Wright & Co., Stone Bridge. London: Simpkin, Marshall, Kent & Co., Limited. 1895.

Leçons sur les Maladies Nerveuses (Salpêtrière, 1893-1894). Par le Dr. E. Brissaud, Professeur Agrégé à la Faculté de Médecine, Médecin de l'Hôpital Saint-Antoine, Recueillies et Publiées par Henry Meige. 1 vol. grand in-8°, avec 240 figures (schémas et photographies). G. Masson, Editure. 1895.

Digestive Protrolysis, being the Cartwright Lectures for 1894, delivered before the Alumni Association of the College of Physicians and Surgeons of New York. By R. H. Chittenden, Ph.D., Professor of Physiological Chemistry in Yale University. New Haven: Tuttle, Morehouse and Taylor. 1895.

A Manual of Bandaging, Adapted for Self-Instruction. By C. Henri Leonard, A.M., M.D., Professor of Medical and Surgical Diseases of Women, and Clinical Gynecology in the Detroit College of Medicine. Sixth edition, with 139 engravings. Detroit, Mich.: The Illustrated Medical Journal Co., Publishers.

Suggestions to Hospital and Asylum Visitors. By John S. Billings, M.D., Director of the Hospital of the University of Pennsylvania, and Henry M. Hurd, M.D., Superintendent of the Johns Hopkins Hospital, with an introduction by S. Weir Mitchell, M.D. Philadelphia: J. B. Lippincott & Co. 1895.

Enlargement of the Prostate; Its Treatment and Radical Cure. By C. W. Mansell-Moullin, M.A., M.D., Oxon., F.R.C.S., Surgeon to, and Lecturer on, Physiology at the London Hospital; Late Radcliffe's Travelling Fellow and Fellow of Pembroke College, Oxford, and Hunterian Professor at the Royal College of Surgeons. Philadelphia: P. Blakiston, Son & Co. 1894.

Syphilis. By Alfred Cooper, F.R.C.S., Eng., Consulting Surgeon to the West London Hospital; Senior Surgeon to St. Mark's Hospital for Fistula; Late Surgeon to Lock Hospital, etc. Second edition, enlarged and illustrated by colored plates. Edited by Edward Cotterell, F.R.C.S., Eng., Surgeon (Out-Patients) London Lock Hospital, etc. Philadelphia: P. Blakiston, Son & Co. 1895.

The Medical, Pharmaceutical and Dental Register-Directory and Intelligencer with Special Medical, Pharmaceutical and Dental Departments Containing Detailed Information of Colleges, Hospitals, Asylums, Medical Societies, etc., for Pennsylvania, New York, New Jersey, Maryland, Delaware and the District of Columbia. Third edition. Philadelphia: George Keil, Publisher and Editor. 1895.

Memoranda and Tables of Human Anatomy. Vol. I. Being a Complete Description of the Muscles, Ligaments, etc., for the use of Practitioners and Students of Medicine. By Justin Herold, A.M., M.D., Ex-deputy Coroner of New York, etc., and Sebastian J. Wimmer, M.A., M.D., Author of Tables and Notes on Human Osteology, etc., with a preface by James E. Ganetson, A.M., M.D. Philadelphia: The Medical Publishing Co. 1894.

Manual of Chemistry; a Guide to Lectures and Laboratory Work for Beginners in Chemistry, a Textbook Specially Adapted for Students of Medicine, Pharmacy and Dentistry. By W. Simon, Ph.D., M.D., Professor of Chemistry in the College of Physicians and Surgeons of Baltimore, in the Maryland College of Pharmacy and in the Baltimore College of Dental Surgery. Fifth edition, thoroughly revised. With forty-four illustrations and eight colored plates, representing sixty-four chemical reactions. Philadelphia: Lea Brothers & Co. 1895.

## Lecture.

### THE CARE OF THE BREASTS AFTER LABOR.[1]

BY EDWARD REYNOLDS, M.D.

GENTLEMEN: — In the treatment of the breasts after labor, our object is to so regulate the amount of milk in the breasts, that the patient will be spared the pain and other evil consequences which follow an undue engorgement of them. To this end, we have at our disposal the following expedients with which to work, the baby, the breast-pump, massage, the bandage, the collodion dressing, the poultice, the ice-cap and the ice-poultice.

The first step in any subject is to acquire a practical knowledge of the machinery with which you are to work; and I propose now to demonstrate to you the use of each of these methods of treatment, and at the same time to speak briefly of the principles which should guide you in their employment.

*The Baby.* — Nursing is the physiological and only natural method of emptying the breast; but it is often insufficient, and is, moreover, contraindicated by the presence of inflammatory disease of the organ. We may say then that we use the baby only when the breast can endure the stimulating effect of nursing, when we wish to keep up the milk, and when there is nothing in the milk that will be harmful to the child.

*The Breast-Pump.* — The use of the pump should never be pushed to the point of causing pain; and it is therefore well to restrict ourselves to such a pump as this, that is, to one which is not exhausted by a piston or by a rubber bulb, but by a tube which connects it with the patient's mouth. She is instructed to suck upon the tube and to stop whenever it causes pain. This pump also has the advantage of being easily cleansed. It is known as the Phœbe Bailey breast-pump.

The breast-pump is in itself irritating to the breast, and seldom empties it completely, as it is only capable of withdrawing the milk which is already in the large ducts near the nipple; but it is often useful as an adjuvant to massage, as the breasts are often more easily emptied by this combination than by massage alone.

The pump should never be applied to an inflamed breast.

*Massage.* — The technique of massage to the breasts may be divided into two parts, the first having for its aim the decreasing of the sensitiveness of the inflamed lobe; the second, emptying of the milk. Exactly how massage decreases the sensitiveness of the breast has not been adequately explained; but it is a fact that after a few minutes' massage a breast which has been exquisitely sensitive will gradually decrease in sensitiveness. The fact applies to all inflammations of the breast; yet, as we shall see, there are inflammations of the breast, in which, though the immediate effect is beneficial, its remote effect is harmful, and therefore massage must be restricted to one class of cases.

[The process of emptying an engorged breast by massage was here demonstrated.]

(1) When massage is applied, it should begin with the movements which decrease sensitiveness, that is, with extremely light strokes with the tips of the fingers from the periphery of the breast towards the nipple. The breasts or fingers should be lubricated by some emollient, it matters little what; and this stroking movement from the periphery towards the centre continued. At first only the lightest possible touch can be employed, but in a short time slightly deeper pressure may be used with equally soothing effect. If at any moment there is pain, slightly less pressure must be used. The process is continued until quite deep stroking is borne without causing pain. The breast will be by this time pretty soft, and the second motion then begins.

(2) In the generally engorged breast the whole breast should be gathered between the edges of the hands, lifted gently from the pectoral muscles, and squeezed gently from the periphery towards the nipple. If there is only a certain portion of the breast affected, the massage must be especially directed towards this, which should be gently urged as a whole towards the nipple. Great care should be used not to cause real pain. Each pressure is usually followed by the appearance of a little thickened milk from the ducts connected with that portion of the breast which is under the hand, and this process should be continued until the affected portion is soft, or until tenderness reappears. A bandage should be applied after the massage, and the massage should be used not at regular intervals but whenever the breasts become uncomfortably tense.

*The Breast-Bandage.* — [Here the breast-bandage was applied before the class.] The breast-bandage is one of the best means we have of meeting the more common affections of the breast. It is used to give rest and quiet to the breast, just as the splint is used in sprains. It is intended (1) to give surgical rest in all cases in which there is trouble with the breast; (2) it is also used in cases where we are afraid the weight of a pendulous breast will lead to engorgement and inspissation; (3) it is used as a means of applying pressure and keeping the breast from filling.

The bandage used in the Boston Lying-in Hospital is a T-shaped piece of cloth, which is applied by passing the tail of the T under the patient, across the scapular region, and bringing the ends of the cross-bar together, one above, the other below the breasts. This ready-made bandage may be replaced by an extemporaneous T made from a couple of towels. One should be folded at a convenient width to go across the back, not so narrow as to cut nor so wide as to be inconvenient to the patient. The cross-bar of the T should be folded to the size of the patient's breasts, being measured on the patient's chest and so folded that when applied it will extend an inch or an inch and a half beyond the periphery of the breasts. This should be folded in the middle, and then attached to the first strip by means of a safety-pin, which should be inserted through the back strip first, into the front strip, and out again, so that when the bandage is applied, the pin is outside and cannot make pressure against the patient. A single safety-pin in the middle is ordinarily sufficient; when the breasts are large, two pins should be used, one at each edge. The tail should then be placed under the patient's back exactly opposite the nipples and drawn just so far through that when the bandage is pinned the end of the cross towel is just outside the outer edge of the breast. Usually it is necessary to apply shoulder-straps to keep the upper edge of the bandage from slipping down. This piece of cloth should be attached at its middle point to the

[1] A lecture delivered in the wards of the Boston Lying-in Hospital during the Summer Courses of Harvard University for 1894.

middle of the towel at the patient's back, being fastened after the tail is in position to insure that the attachment is at the spinal column. The free ends are brought one over each shoulder and pinned to the upper edge of the bandage in front directly above the nipples. Either part of the bandage in front may be fastened first; everything being in position, the bandage is drawn forward across the patient's breasts which are moved out of the way by the hands of the patient. The middle of the free end of the tail which goes under the patient's back should be opposite the middle of the outer edge of the breast. The upper half of the bandage is usually secured first and its upper edge should at once be attached to the shoulder-strap at a point opposite the upper middle line of the breast to prevent the upper edge of the bandage from slipping down and pressing on the breast tissue. When the upper part of the bandage has been attached the lower part is drawn across and fastened by its lower edge to the tail in the same manner. It is then attached opposite the middle of the lower edge of the breast to the binder to prevent it from slipping upwards. The patient is then asked to raise the breasts towards the median line in order to have the bandage clear of them while it is being pinned. The rest of the bandage is drawn smoothly across the breast and pinned to the tail in the same way, the pressure gradually diminishing from the outer edges of the bandage to the edges nearest the nipple. The hand of the physician or nurse should be inside of the bandage to avoid the danger of sticking the pin into the patient. The bandage should be so applied that there is considerable pressure at its edges, and that the pressure is gradually and smoothly diminished toward the nipple. The breasts are also drawn near to the median line as well as subjected to this uniform pressure. That the pressure on the inner, may be the same as that on the outer sides of the breasts a piece of absorbent waste is placed between them and the bandage is drawn over it in the median line by a safety-pin passed from edge to edge of the bandage. If a single safety-pin is not enough, two or more may be looped together in the form of a chain. The milk often begins to run from the breasts at once. If the end of the tail is long enough it may be laid across the nipples to absorb the milk which runs from them.

*Contractile Collodion.* — In extreme cases where it is absolutely necessary to keep the breast empty, we may use a dressing of crepe lisse and contractile collodion, whereby the breast is forced into a small mass, against the ribs; but this dressing is very distressing to the patient. This, like all other pressure dressings, should be applied so far outside the breasts that there is no chance of cutting off an island of breast tissue.

*The Poultice.* — The hot poultice may be made of any convenient material enclosed between two pieces of cloth. It is used for the relief of the symptoms attending a distinct phlegmon, when we have given up all hope of its resolving and are waiting, as we sometimes may for a short time, before opening the abscess.

*Cold Applications.* — Cold dressings are used for checking inflammatory affections in their inception and before pus appears. Cold may be applied to the breasts in several ways: (1) Small tubes made into a spiral through which cold water continuously flows may be placed over the affected breast. These spirals may be large or small, depending upon whether the application is to be made to the entire breast or to individual spots. (2) More commonly we use a rubber ice-bag containing ice so finely divided as not to irritate the breast. (3) The ice-poultice is an excellent substitute. This is prepared from bran with small fragments of ice scattered through it. As the ice melts the meal absorbs the water. The meal also prevents the ice from irritating the sensitive breast. There should be enough meal to prevent dripping, but still plenty of ice well distributed through it.

[These appliances were here shown.]

We are now in a position to consider the several branches of our subject: (1) the care of normal breasts after labor; (2) the arrest of lactation either (*a*) at its beginning or (*b*) after prolonged nursing; and (3) the care of threatened abscess of the breasts, to which we shall have to add the operative treatment of fully-developed abscesses.

### CARE OF THE NORMAL BREASTS.

We must be guided in this (1) by the character of the breasts and (2) by the manner in which the milk comes into them. On the whole the most satisfactory way in which the milk can appear is when it comes slowly and gradually. In such cases it is sometimes rather late for the baby, but almost never makes any trouble for the mother. In other cases the milk appears very suddenly, the breasts fill up in a few hours to a high degree of tension, and there is probably more milk secreted than after lactation has become established. The breasts become large and tense and the skin over them becomes shiny; the patient complains of pain, and sometimes has a slight elevation of temperature. If the milk comes slowly no treatment is needed other than regularity of nursing; the infant should be placed to the breast as soon as the mother is rested from her labor, and thereafter once in six hours; the child thus gets a little sweetish colostrum, and this not only satisfies its appetite but also tends to loosen its bowels. Nursing also stimulates the contractions of the uterus by reflex effect; and, finally, encourages the appearance of the milk, and tends to bring it gradually rather than with a rush. As soon as lactation is established the breasts should be nursed alternately, once in two hours.

When the breasts are very large and heavy, they may be rendered more comfortable to the patient, and any danger of inspissation of the milk can be prevented by the application of a light bandage as a matter of routine. This is much more comfortable to the patient if made from the material known as stockinet, which is elastic enough to yield to the respiratory movements, and at the same time supports the breasts. It should not, of course, be applied very tightly.

When the milk comes with a rush and the breasts become tense and painful, much discomfort and risk may be saved to the patient if a reasonably firm bandage is applied at once. This renders it very difficult for the breasts to become overdistended. The bandage in itself is somewhat uncomfortable to the patient, but it is well worth enduring to get rid of the greater discomfort due to distended breasts. When the breasts are already distended and painful, the use of the bandage may also be supplemented by massage.

### ARREST OF LACTATION.

If it becomes important to dry up a breast at the very start, that is, when there is a stillborn child, or when it has been decided in advance that the baby is

not to nurse, it may be done by the breast-bandage, massage, and, occasionally, the use of the breast-pump. The bandage should be applied in advance of the appearance of the milk, and as firmly as the patient can be induced to endure it. When in spite of the bandage the breasts become full, massage and occasionally the breast-pump find their use, and should be employed after the manner which was shown to you, until the secretion ceases. The application of the ice-cap or ice-coil over the bandage will sometimes do much to discourage secretion. When the reason for drying up the breasts is that they have been nursed long enough and that the child is ready for other food, the process is much easier and safer. The breasts are physiologically ready to cease their activity, and all that is necessary is to break up their habit of secreting. If the baby, which has been applied to the breast at regular intervals, is put on the bottle and the breasts are let alone, they soon become tense; if then they are emptied they will usually go for a longer time, and so the successive intervals lengthen. When the intervals have become thoroughly irregular the emptying of the breast should not be done by the baby because it is not good for the child itself; it may then be done by the breast-pump, supplemented if necessary by a little massage. In case pain or tenderness comes on, the patient should be put to bed, a tight bandage should be applied, and the breast treated by massage, and, if necessary, by the ice-cap.

### THREATENED ABSCESS OF THE BREAST (EXHIBITION OF A CASE).

This case, gentlemen, was delivered fourteen days ago. Ten days after delivery there came a pain in the left nipple. The following morning there was a slight rise of temperature, and in the evening a temperature of 102°, with the appearance of a slightly sensitive red lump in the inner and upper quadrant of the left breast. The child was removed from the breast and an ice-cap and breast-bandage were applied; the next morning the temperature was 100°, and the tenderness and redness were much decreased. That night cautious and very light massage was applied to the affected part; this emptied the breast as a whole, but did not relieve the affected lump. Since then the temperature has been normal, the lump in the breast still remains, and the blush on the skin still continues. There is a history of a blow six or seven months ago, not followed by any serious pain or lameness. How much this has to do with the case I cannot say. On examining the breast we feel a hard lump one and one-half inches long and one inch broad in the upper and inner part of the breast. The blush on the skin is shaped like a piece of pie, narrow at the areola and broad at the periphery of the breast. The prognosis is doubtful. The treatment for the last three days has been light bandaging, the ice-cap, and abstinence from nursing. The local treatment will not be changed, unless the use of the knife becomes necessary. With this case as a text we will take up the general subject of abscess of the breast.

In what I am about to say of threatened abscess of the breast, I feel bound to divide the cases into two classes, which are quite different in pathology and prognosis. This is one of my individual views and so far as I know is not supported by any other authority, but I have no hesitation in teaching it, as it is founded on many years of observation and has been deduced from a large number of cases. I believe that there are two definite varieties of mammary abscess. The one is due to inspissation of the milk within the ducts and acini of a given lobe of the gland, caused by a migration of bacteria from the nipple into the ducts. In the second and less common class, on the other hand, the essential pathological entity is a phlegmonous inflammation of the connective tissue of the breast, due to absorption of poisons by the lymphatics, precisely as occurs in other parts of the body.

*Inspissation Abscesses.*— Clinically, you will find in this first class of cases a more or less rounded, irregular, lobulated, hard mass of definite outlines, usually extremely sensitive to pressure and seldom accompanied by redness of the skin over it. It is usually extremely painful to the patient, even when the breast is at rest, and is usually attended by a sudden and marked elevation of temperature. In such cases, on thorough massage, you will see the ducts which connect with the affected lobe discharge quantities of a semi-fluid, almost cheesy substance, followed by natural milk. The discharge is attended by complete subsidence of the lumps, and an almost complete disappearance of the pain and sensitiveness. Under the rest which follows an application of the bandage the whole thing usually clears up within from twenty-four to forty-eight hours. If this inspissation of milk in the ducts is neglected it however rapidly extends, and if it is still left untreated the formation of pus occurs as in other varieties.

The natural history of the inspissation form of threatened abscess is that of sudden enlargement attended by pain and elevation of temperature. The prognosis of this form is good, under treatment.

*Phlegmon.*— The second form I believe to be the ordinary surgical phlegmon. There is usually, if not invariably, a cracked nipple, or a pimple in the areola, at the place of entrance of the poison into the ordinary lymphatics of the breast. These cases are characterized by comparatively little pain and tenderness, (pain, as you know, is usually symptomatic of distention, the connective tissue of the breast is very loose, and consequently there is not much pain in this variety). The elevation of temperature is slower and more gradual, and often in a fully developed abscess there is but a very slight pyrexia. There is marked reddening of the skin over the affected region, the outline of which is shaped like a piece of pie, as in the case you saw in the ward. The natural history of this form of threatened abscess is that of insidious onset. The prognosis is bad, because we cannot remove the cause. In this variety the use of massage or of any mechanical meddling is harmful. The treatment should be conducted upon ordinary surgical principles. The case in the ward I now believe to be due to this cause and not to inspissation of the milk in the ducts. Therefore, massage was not given after the first day.

*Treatment.*—Of the two forms of threatened trouble in the breast, we readily gather that inspissation is to be treated throughout by abstinence from nursing, rest in bed, massage and the bandage. I say throughout, because when a case of inspissation has been so neglected that the inflammation has got outside of the ducts, it becomes a case of phlegmon and must be so treated. The other form is to be treated during the early stages by ice and by surgical rest, obtained by means of the bandage and by keeping the patient in bed; and during the later stages by poultices.

When we have reason to believe an abscess has formed, either form must be treated by the knife. In cases which have gone on in an unfavorable way, it is always better to make an unnecessary incision than to let the breast open spontaneously, because breasts which open spontaneously almost never run a short course, while those which are treated by early incisions are usually healed within ten days or a fortnight.

OPERATIVE TREATMENT OF MAMMARY ABSCESS.

When a breast has refused to get better for from five to six, or at the outside, ten days, according to the acuteness of the case, and when a hard phlegmonous lump surrounded by edematous material which is getting worse can be felt, do not wait for a soft spot to appear in the centre, but make an exploratory incision early.

The technique of the operation is of the very greatest importance. In the first place, absolute asepsis is necessary. The skin of the breast should be disinfected as it would be for a celiotomy, that is, first scrubbed with soap and water, then sopped with permanganate of potash, then cleaned with oxalic acid, and finally scrubbed with a nail-brush and corrosive. The hands and instruments should be treated with the same care.

An extremely important point in the operation is that the lacteal ducts should not be divided or wounded. A duct which has been divided or torn across becomes obliterated, and the next time the breast fills up, that is, with the next child, the milk secreted by the acini which have been cut off collects and there will then be inspissation with the risk of another abscess.

The object of the operation is, then, to evacuate the pus without dividing any of the lacteal ducts. These ducts radiate towards the nipple and if the cut is made in this direction it is least likely to injure them; they, however, branch so frequently that if the operation were done with the knife throughout, there would be almost no chance of avoiding the ducts. The technique which I think should be pursued is as follows: The knife should make an incision radiating from the nipple, through the skin and subcutaneous tissue, and this cut should be long enough to permit the finger to pass through it easily. Then a director or large probe should be pushed down to the centre of the bunch and moved about until it finds the pus. Next a dilator should be run down on the director and the passage dilated. The finger should next be forced into the centre of the abscess, no cutting being done after the skin has been divided. The finger should be swept around everywhere to break down all the tissue that is soft enough to be broken down with any readiness.

Care must be taken to find all the pockets or side openings, which usually exist, and that the partitions between them are broken down; and any one of them which is at a distance from the incision must be exposed by a counter-opening. To make a counter-opening, take a long probe and carry it under the guidance of the finger to the farthest point of the pocket in question, then push it on until you see the point dimpling the skin upward; make a fresh skin incision at this point, dilate it, and put the finger in again, feeling about for fresh pockets as before.

After the counter-opening is made, the whole cavity should be syringed out with a corrosive-sublimate solution, 1–2,000, or perhaps better with a fifteen-volume solution of peroxide of hydrogen diluted with equal parts of water. The whole cavity should be puffed full and the process repeated until the solution comes out perfectly clear. Then put in rubber drainage-tubes, or gauze strips, so that each of the subsidiary cavities has direct drainage. If the pus is thick use rubber tubes, if it is thin you may use gauze. If rubber tubes are used, substitute gauze as soon as possible, because the pressure of the tubes may cause them to ulcerate through the neighboring ducts.

Having opened, disinfected, and drained, put on a sterile dressing, packing it all around the breast, and then bind the whole breast down against the ribs pretty firmly with an elastic gauze bandage, so that the walls of the cavity may have a chance of being brought together and of healing by first intention.

The wound should be redressed within twenty-four hours, and if you are compelled to leave rubber drainage-tubes in, dress again in from twenty-four to forty-eight hours more. All drainage should ordinarily be gotten rid of in a week or ten days. If this method be thoroughly carried out, I think it will yield uniformly good results.

### NEURASTHENIA.[1]

BY B. W. BARTLETT, M.D., ROWLEY, MASS.

NEURASTHENIA is a functional disease of the nervous system characterized principally by asthenia and exhaustion, and manifesting itself by headache, insomnia, cerebral depression, neuro-muscular enfeeblement; often by various symptoms referable to the spinal cord (rachialgia, spinal irritation) and by atonic gastro-intestinal dyspepsia. It is described by Beard as cerebral or spinal according as the predominant symptoms are referable to the higher or lower nerve centres.

ETIOLOGY.

Beginning with those causes which are least recognized, I would mention, first, a dry atmosphere. On this cause (to which, by the way, Dana attributes considerable weight) may be in part dependent the unusual prevalence of neurasthenia in our Northern climate. I would not venture much speculation as to how dry climates favor neurasthenia. The fact, I believe to be unquestioned. Extremes of heat and cold predispose to nervous debility. In the Southern climates, and in the small islands surrounded by water, marked extremes of temperature are uncommon, and we find less susceptibility to nervous excitability in the inhabitants of these climates as contrasted with the inhabitants of the Northern States, in which severe winters are followed by a high range of temperature during the summer months. The cold of the winter obliges residents to remain much of the time indoors, subjected to a dry, overheated atmosphere. On the other hand, the hot weather of summer is relaxing and does not tend to encourage athletic sports and pastimes. It is noteworthy in this connection, that in England where the climate is more moist and equable, athletic exercises can be indulged in during all seasons of the year. I regard these factors as predisposing to neurasthenia by their debilitating influence; and to faulty habits of eating and drinking may be attributed a similar predisposition. The principal and exciting causes are

[1] Read before the Essex North District Medical Society.

such as directly conduce to nerve tire and enfeeblement.

(1) *Prolonged Mental Application*, as to study or business, using up cerebral and nervous energy. This cause is especially operative when conjoined with dyspeptic troubles, and with insomnia. A man will endure very severe and very persistent mental strain if he can sleep well at night, and if the digestive organs are vigorous.

(2) *Worry*. There is one reason why our civilization so predisposes to neurasthenia — the present age is one of worry. Men and women are competing for a position for office, for honors, or else they are struggling to retain a position; hence there is constant anxiety and care. Many are engaged in commercial enterprises which give them great worry and little rest. Many a stock-gambler, many a speculator in "futures," has become a broken-down neurasthenic. Many merchants doing a large business give themselves too little sleep, and prematurely become nervous wrecks. How often among professional men, scholars, literary men, we hear complaints of tired limbs and aching eyes and heads! This is especially true of those who turn day into night and night into day. It is from the great army of the unrested that our modern neurasthenics are for the most part recruited.

(3) There are also *Emotional Causes*. Grief, disappointment, remorse, brooding over losses and crosses, promote wear and tear of brain and nerve.

(4) *Sexual Abuses and Onanism* enter for their share in the etiology of the disease.

(5) *Sudden Shocks* (as in railroad accidents), excessive physical exertion, excessive child-bearing, may produce neurasthenia. Nor must we omit reflex irritations, such as prostatic and urethral disease, mechanical displacements of the womb, disturbances of the stomach, intestine or liver, and ocular deficiencies, as hypermetropia and astigmatism. But many of the causes above mentioned are perhaps rather predisposing than exciting. Bouchard, who has written so admirably on auto-intoxication, advances the notion that neurasthenia in many cases (and notably in the gastric form) is due to auto-intoxication by ptomaines and even by leucomaines. He calls attention to the fact that toxines secreted by the animal cells (leucomaines) formed in circumstances of vitiated nutrition may produce nervous exhaustion of an intense and peculiarly intractable kind.

### SYMPTOMS.

Among the various symptoms on which authors dwell there is one which I should emphasize, namely, the tired feeling after exertion. I may, however, remark that this tired feeling is often lost in melancholia and other forms of insanity, as Dr. Cowles has so well pointed out in his Shattuck Lecture. All patients with whom I have had to do have complained of this symptom. They awake in the morning unrefreshed by their sleep, which is seldom or never unbroken. The attempt to walk, to do housework, to read, even in some cases to sit up, soon fatigue them. Muscular exercise causes aching in the back and limbs; reading, an aching in the eyes and headache. There is almost constantly a painful sense of lassitude, such as one experiences who is coming down with a fever. All these sensations are an expression of an ill-nourished condition of the nerves and nerve centres. Volition is weakened; the power to co-ordinate harmoniously the various higher cerebral activities is lessened, if not lost. Neurasthenics have difficulty in concentrating and keeping their attention on any subject for more than a brief time; their thoughts are continually wandering in accordance with the incoming flow of excitations which they are unable to inhibit. Of course, this is only an exaggerated degree of that weakness of voluntary control from which we all, except a few gifted minds, suffer more or less. The neurasthenic patient is also subject to headache, which often comes on spontaneously, often follows mental application. Sometimes the headache is almost continuous, though it is generally remittent; it is very likely to supervene after a period of rest. The painful paroxysms are accompanied sometimes by sensations of vertigo, tinnitus aurium, obnubilation of the sight and at times by hyperesthesia of the scalp (Beau). Charcot was so struck by a symptom in connection with this headache of neurasthenic patients, namely, a sensation of constriction about the head and temples, as though the head was compressed in a tight helmet, that he was in the habit of designating these patients by the name *galeati* (helmet-wearers). In my own cases I have not found headache to be so predominant a symptom — except as a sequel of mental application and excitement.

*Insomnia*.— This has been present in the majority of cases. Neurasthenic patients, as a rule, are poor sleepers. Some patients lie awake till a late hour of the night, and get only a morning nap; others go to sleep at once, but awake after a few hours and lie awake till morning. Most patients soon begin the use of some hypnotic to aid them in procuring sleep. An increase in the dose of the drug (whether it be opium, chloral, sulfonal) is soon necessitated. I believe with Folsom, that it is better to be satisfied with a few hours of natural sleep than to resort to the use of hypnotics. I do not believe that the benumbing effect which follows these drugs is a true rest to the brain cells. If any hypnotic must be administered, a dose of bromide, sulfonal or trional may do as little harm as anything, and under all circumstances, should be administered temporarily, great care being taken that the patient shall not become dependent on the drug. We have in static electricity an agent of great value in the treatment of insomnia. I certainly have obtained very favorable effects from Franklinization. The head-plate is used, and the electricity is conveyed in the form of breezy currents, which are agreeable and soothing. By means of the discharging head-electrode, the patient is also electrified through the clothes. The *séance* lasts about half an hour, and the patient often goes to bed prepared to go to sleep.

Before dismissing the subject of headache, I should say something about headaches from eye-strain. Defective accommodation seems to be a frequent cause of pain in the head in neurasthenic people. In my experience I have found it to be a severe pain, extending through the head from the eyes to the occipital region, and of an explosive character, recurring at short intervals after overwork of the eyes. Many children suffer from similar headaches till the hypermetropia or other eye-trouble is remedied by properly fitting glasses.

*Rachialgia, Backache*.— Neurasthenic patients frequently complain of pain in the back coming on after exertion, or without known cause, a pain which is elicited by pressure along the vertebral column. The

tender spots over the spine which characterize this condition, were formerly considered as pathognomonic of an individual morbid entity with definite syndrome, to which was given the name of "spinal irritation." The latter is not a disease apart, but simply an indication of exaggerated sensibility of the vertebral column, and belongs to the train of symptoms of *neurasthenia, with spinal form.* Spinal irritation is often attended with general cutaneous hyperesthesia; irritability of the breasts, ovaries and womb in women; fleeting pains of a neuralgic type in various parts of the body; a rapid or slow pulse, which fluctuates widely during periods of excitement or fatigue; excessive perspiration of the feet and hands; muscular twitchings; chilliness; creeping sensations along the spine; itching of the skin; weakness of the bladder and rectum; and other symptoms of disordered and perverted innervation which Beard has so well described.

*Aversion for Fluids.* — The neurasthenics are, I believe, proverbial for their dislike for liquids, and usually this condition has lasted so long that there is positive deficiency of water in the economy. The skin covering the body becomes dry, if not scaly. The urine is scanty to a high degree, some patients scarcely voiding four ounces in twenty-four hours. The tongue and mouth are dry; in fact, the whole alimentary canal loses its natural moisture. The blood contains less than the normal proportion of water, and this I believe in a measure accounts for the deficiency of the secretions, and the constipation.

*Dyspepsia.*— All the varieties of dyspepsia may be met in the neurasthenic. Mathieu, who has written an able treatise on neurasthenia emphasizes the dyspeptic troubles in this disease. He also shows the strong affiliation which exists between the so-called essential dyspepsia and neurasthenia; in his estimation, every dyspeptic is a neurasthenic; he thinks, moreover, that neurasthenia without some degree of dyspepsia is a very rare event. He distinguishes three forms of nervous dyspepsia: (1) Neuro-motor dyspepsia, with or without hydrochloric deficiency; (2) hydrochloric excess; (3) hydrochloric deficiency and permanent gastric stasis, with or without organic hyperacidity. A large proportion of these dyspeptics have dilated stomachs, and suffer from morbid fermentations which give rise to toxic ptomaines; the latter are absorbed, and injuriously affect the nerve centres, possibly (as Bouchard thinks) causing the depression of spirits, the languor and hebitude and other nervous disorders of which the victims of gastric neurasthenia complain.

*Vertigo.*— A frequent symptom of neurasthenia, which seems in most cases to be linked to the dyspepsia and due to the auto-intoxication above mentioned, is vertigo. Neurasthenic patients are frequently dizzy when they are hungry, and along with the vertigo there may be a state of partial nausea. Others are dizzy after eating; the face becomes turgid and flushed; the head feels heavy; the mental faculties are torpid; if the patient attempts to walk, he totters like a drunken person. The exact pathogeny of this form is not known.

*Melancholia.*— No one has set forth more clearly than Dr. Edward Cowles, of the McLean Asylum, the relationship of neurasthenia to certain forms of insanity, and especially to melancholia, which seems to derive its being from a neurasthenic condition. He has shown that there is a definite gradation from the psychical depression which characterizes neurasthenia to true melancholia; in fact, every melancholic patient is a neurasthenic.

### TREATMENT.

The treatment of neurasthenia comprises seclusion, rest, feeding, massage and electricity. Seclusion is indispensable in order that the patient may have freedom from care, and sequestration from the injurious home environment, where an injudicious sympathy may do much to foster a chronic invalidism. Again, seclusion enables the patient to be wholly under the control of the physician, a matter of vital importance, for there are no set rules of treatment for restoring these women to health. Each case stands by itself; each case is a study; each has an individuality to which the medical treatment must be adapted. Dr. S. Weir Mitchell first demonstrated the value of rest, with forced feeding, in the treatment of neurasthenia. The question of nutrition is of vital importance, because these patients are either wholly without appetite, or they reject wholesome food. Their nervous system seems to undergo waste in excess of repair, and they are always menaced with complete mental break-down. By beginning the treatment with iron, with malt and with a diet of skimmed milk, usually after a week's time the patient begins to crave solid food. Fixed rations of wholesome food at fixed hours are now given, together with as much new milk between meals as the patient can possibly digest; and it is wonderful how much food a delicate woman can soon dispose of. A goblet of milk is always given at bedtime to render the stomach hyperemic, and thus decongest the brain and promote sleep. The therapeutic effects of massage and electricity on the circulation are very striking in nerve exhaustion. Massage exercises the muscles without any effort of volition, and therefore without expenditure of nerve force. Electricity does the same This is very important in the treatment, for all voluntary muscle work is nerve work, and the nerve capital in these cases is too small to be drawn upon. Again, both massage and electricity raise the body temperature, stimulate the nervous system, promote the secretions, and increase the peristaltic action of the bowels. Static electricity, as a general tonic and also as a stimulant to depressed nervous functions, seems to be particularly of service. I employ this form of electricity constantly in the treatment of neurasthenia with marked benefit. Sittings of from ten to twenty minutes give remarkable improvement in dyspepsia and habitual constipation. The electrical current also soothes, quiets the nerves, and promotes sleep. Among the internal remedies are the bromides of sodium and potassium, ergot, the triple valerinates, phosphorus, strychnia and arsenic. The usefulness of liquids internally has been alluded to. I have a word to say about hot water as a beverage. A cupful should be drank one hour and a half before each meal, with the temperature as high as it can be borne. It increases downward peristalis, it stimulates the secretion of urine and alters its character very rapidly. It produces a gentle perspiration and a sense of warmth in the skin. It relieves dyspeptic symptoms. Haig has suggested that the beneficial results of giving large quantities of milk might be partially due to the percentage of water contained in milk and the washing out from the blood of all toxic material.

I may, in this connection, be permitted to allude to a patient, Mr. A. B., who came to my Home some six months ago for treatment: The case has several interesting features. First, there was a close resemblance to some degenerative disease of the brain and spinal cord, as dementia with tabes dorsalis or chronic myelitis. Second, there was marked prominence of symptoms the result of ocular defects. The patient was a man twenty-eight years old, whose mother always suffered from severe headaches, and who died in her second confinement. Two maternal aunts were tuberculous. The father was neuropathic. A. B. was robust from boyhood, but cannot remember when he did not suffer from headache. He was fitted for college at the age of seventeen, but was unable to pursue his studies further. He was of good habits; married at twenty, and became a trader; was kept constantly within doors at his business; was successful and made money. A sedentary life and devotion to business broke him down. The headaches increased in frequency and were so severe as to require frequent injections of morphia for their relief. By the aid of powerful hypnotics he was able to get some sleep. He was unable to exercise his eyes on account of the aggravated cephalalgia; and on account of some degree of photophobia, he wore a silk protector, in spite of which strong light was painful to him. Mentally he was much depressed, and suffered from both delusions and hallucinations. His method of speech was slow and hesitating; he was unable to think of the right word to express his ideas (amnesic aphasia), and the ideas themselves were formed with great difficulty. He had but little control over his upper extremities; because of the twitching of the muscles he was unable to grasp or hold articles in his hands firmly. He was ataxic in his gait. There was pain and tenderness over the spine. Sensation was normal and so was control of the sphincters. There was complete loss of sexual tone, but no atrophy of the testicles.

During his three years of sickness he had been treated for rheumatism and various cerebral and spinal diseases. When he came to the Home I was led to give attention to the condition of the eyes, and found the ocular defects most marked. There was pronounced astigmatism and asthenopia. The disorder of refraction had probably existed from birth, and the long-continued muscular strain, for both recti interni were weak, allowing a marked divergence of the eyes, had so irritated the nervous system as to cause the hyperemia of the brain and spinal cord, which, in turn, had produced such woful results. To relieve this eye-strain, I employed prisms worn constantly with their bases inward. I then made use of large prisms held between my fingers before the eyes with their bases outward, for ten minutes at a time twice a day. This gave the eyes a gymnastic exercise. The morphia was at once dropped from twenty grains per day to one and a half grains at night; and after ten days it was wholly discontinued. He was taking thirty grains of sulfonal every night to procure sleep, and this was discontinued at once; and I gave instead bromo-soda, bromo-caffeine, elixir of the valerinate of ammonia, etc. A hot tub-bath was given every third evening. I also ordered a hot sponge-bath to the whole spine every night, together with static insulation; and heavy sparks drawn from the back of the neck sufficed to relieve all pain and procure refreshing sleep every night. We gave the patient, the first thing in the morning a large cup of strong coffee without sugar or milk; then after one hour of massage and dry cupping along the whole length of the spine, he was allowed a breakfast of some light, farinaceous food with malt extract and five drops of Freligh's tonic. Three times a day, about an hour after meals, he had a tumbler of warm milk with fifteen grains of potassium iodide. The dinner and supper were eaten with the family, beef and chicken being allowed *ad libitum*, and the malt and tonic medicine being given after meals. Improvement began at once. He could soon use his eyes without fatigue or pain. The headaches gradually went away, the mind became clear, and the aphasia disappeared as the improvement continued. He would now sleep seven or eight hours every night without hypnotics. Exercise was regularly taken at the gymnasium, all excessive bodily movements being avoided on account of the spinal asthenia. He can now walk five or six miles a day, and has nearly regained his usual health. He has recovered the use of his arms and hands and plays the piano without difficulty. So complete is the restoration, that he will soon be able to return to his business.

## SURGICAL TREATMENT OF PANCREATITIS, WITH A CASE.[1]

BY J. W. ELLIOT, M.D.

MUCH attention has been given to the cysts of the pancreas, and many cases have been reported as cured by operation. The hope that surgery will be useful in cases of inflammation of the pancreas is based on the following considerations:

(1) The presence of scars in the pancreas found at autopsies shows that a limited pancreatitis may recover. The celebrated case of Trafoyer reported by Chiari,[2] where after an illness of three or four weeks a slough was discharged from the bowels, which Rokitansky recognized as the sequestrated pancreas, is evidence in the same direction.

(2) Experiments on dogs by Mehring and Minkowski, show that part of the pancreas may be removed without impairment of health, whereas if the whole gland is removed a permanent diabetes is produced and the animal dies.

In man the tail of the pancreas has been successfully removed in one or more cases. Senn refers to a case reported by Kleberg,[3] where the pancreas protruded from an abdominal stab-wound. The protruding organ was ligated at its base and cut off; the part removed was examined microscopically and found to be a pancreas. The patient recovered.

(3) Several autopsies have revealed an abscess which could have been operated on with relief, and finally Körte[4] reports a recovery after operation in a case of suppurating pancreatitis.

Dr. Fitz,[5] in his now classical monograph, divides pancreatitis into three varieties: hemorrhagic, suppurative and gangrenous. In the recorded cases of hemorrhagic pancreatitis (exclusive of traumatic cases), death has usually followed the first symptoms so quickly that surgical intervention would have been impossible. It is therefore the suppurative, and possibly the gangrenous, pancreatitis, which should properly claim the attention of surgeons at this time. I therefore propose to study the signs and locations of the inflammation with reference to the possibility of recognizing and draining abscesses and thereby limiting the extension of the process.

Dr. Fitz gives the following admirable account of the symptoms based on an analysis of 22 cases:

"The cases of acute, suppurative pancreatitis usually began suddenly, with severe, generally intense, gastric, epigastric or abdominal pain, vomiting, and sometimes great prostration. The vomiting might be incessant and distressing, or it might give temporary relief to the pain. The ejected fluid was sometimes stringy and brown. The bowels were usually constipated, although diarrhea might occur within the first twenty-four hours. This latter symptom was not fre-

quent at a later date of the disease. Fever, usually slight, was the next conspicuous symptom, being manifested about the third day. At the same time the upper abdomen, especially the epigastrium, was likely to become distended, tympanitic and sensitive. Hiccough, sometimes quite obstinate, was not infrequent in this stage, and occasional chills were met with. The abdomen in general then became moderately swollen, tense and tympanitic."

When death occurred in the course of a week or more, he sometimes found the pancreas studded with hundreds of small abscesses.

"An acute, suppurative pancreatitis, however, very rarely terminates at this early date. The symptoms already described may persist for three or four weeks, with progressive emaciation and debility, and death occur from exhaustion. Under such circumstances the single abscess has been found surrounded with adhesions."

The local condition, and especially the presence of a tumor, is, of course, a most important consideration for the surgeon. It is also of immense importance in the diagnosis. In the early cases the presence of a tumor was rarely noted.

In the table of cases collected by Dr. Fitz up to 1889, the presence of a tumor is recorded in only one case. According to Balt, as quoted by Körte, Lusana, up to 1882, was the only one who had succeeded in palpating the swollen gland. My small experience does not accord with these facts, as in two out of three cases which have come under my observation a well-defined tumor has been present, and in the case here reported, the tumor corresponded exactly to the position of the pancreas and led at once to a correct diagnosis. Körte,[6] in a recent article, reports three cases where a tumor was present; and I am indebted to him for a part of what follows.

As the tumor in these cases usually represents a pus collection, we can profit here by a recapitulation of the results of autopsies bearing on this point: The pus is almost always retro-peritoneal in the early stages, and not infrequently remains so to the end. In the traumatic cases the peritoneum may be ruptured at the start, in which case the inflammation may begin in the omental bursa.

The inflammatory process may start at any point in the pancreas. If it is most intense at the tail, a pus-cavity may form in the left upper abdomen near the spleen or kidney. If the process attacks the head of the pancreas, the pus-cavity usually breaks into the omental bursa and becomes encapsuled there. At times the para-pancreatic tissue is involved and the whole gland is surrounded by a pus-cavity which extends from the duodenum to the spleen.

The pus may break into the general peritoneal cavity or into the duodenum, but it more commonly burrows down behind the peritoneum, and is often found in the mesocolon as low as the pelvis, on either the right or left side. It may also extend into the root of the mesentery.

In regard to the positions of the tumors actually observed, Musser[7] noticed an ill-defined epigastric tumor, which was found at the autopsy to represent a pus-cavity bounded by the posterior wall of the stomach in front, by the pancreas, duodenum and transverse colon below, and by the peritoneum above and behind. Körte cites four cases beside his own in which a tumor was observed. In two of these cases the tumor was behind the stomach, and in two it was in the left abdomen just below the ribs.

Körte found, in his first case, ten days after the disease began, "a resistance in the left epigastric region which extended to the left loin." He explored this tumor through a cut in the loin, and found it to be a large abscess surrounding a sloughing pancreas, which he removed. At the autopsy a large abscess was found between the stomach, spleen, diaphragm and kidney.

In his second case, a month after the first symptoms, which were characteristic, he found an evidently fluctuating resistance in the outer part of the left abdomen, dull on percussion. This was explored by an extra-peritoneal incision through the loin, and proved to be a large retro-peritoneal abscess which extended from the pelvis up to the kidney and inwards to the spine. A sound could be passed up behind the stomach. This patient recovered.

In his third case, on the seventh day of the disease, he felt a swelling on the left side, deep in towards the loin, and fifteen days later a tumor was felt just below the ziphoid cartilage behind the stomach. This was found by an operation to be an abscess between the stomach, colon and spine. The patient died.

My first case was seen on the fifth day of the attack. There was then present a prominence in the epigastrium which felt like a doughy tumor. This extended, with ill-defined borders, under the ribs on the left side, to the loin; it could be plainly felt in the left upper abdomen. The percussion note was resonant. This tumor was explored by laparotomy, and proved to be a necrotic pancreas with an para-pancreatic abscess running the whole length of the organ.

The second case which came under my observation was seen by the courtesy of Dr. J. C. Warren in his wards at the hospital three and one half days after the first symptoms. A hard tumor was easily felt on the right side, just below the liver. This was found at the autopsy to be the root of the mesentery filled with blood, pus and a hard inflammatory cake. The inflammatory process had also extended into the mesocolon and to the kidneys on both sides.

I saw a third case in consultation with Drs. Minot and Cutler: here the probable diagnosis was made on seeing the characteristic epigastric swelling although no tumor was found.

Here we have ten cases with accurate descriptions of tumors. In three the tumor was epigastric. In three it was epigastric, extending along the ribs toward the left side. In three it was in the left upper abdomen, below the ribs. In one case it was on the right side, below the liver. These tumors were observed from three and a half days to one month after the first symptoms.

From these few cases one can see at once that there are three, and perhaps four, typical forms of tumors which will often be found in these cases: (1) An epigastric tumor behind the stomach, due to pus in the omental bursa; (2) A tumor running from the epigastrium to the spleen, just below the ribs, due to an enlarged pancreas or a para-pancreatic abscess; (3) burrowing of a retro-peritoneal pancreatic abscess may give rise to a tumor in the left loin, or more rarely on the right side below the liver.

These tumors will sometimes be difficult or impos-

[6] Archiv. für klin. Chir., 1894, Heft iv.
[7] American Journal Medical Sciences, 1886, N. S., xci, p. 449.

sible to feel on account of a tympanitic and painful condition of the abdomen, also on account of a fat abdominal wall. As the inflammation which causes them is retro-peritoneal, they will usually be indistinct and vague to the touch, and they will also often be tympanitic on percussion, as the bowel may lie over them. Such tumors will best be found by careful and skilful palpation. Inflation of the stomach and transverse colon is useful in determining whether a tumor is in front or behind those organs. I venture to predict that the presence of a tumor will be noted much oftener in the future.

Senn, I believe, was the first to seriously suggest surgical treatment for pancreatitis, although he had done no operation. As the matter stands to-day, there seems to be good ground for surgical interference in proper cases; but only one successful case has been reported. This was done by Körte, and has already been referred to. A second case was reported by Pearce Gould [1] as a cyst of the pancreas. This case is considered by Körte, on account of the acute symptoms and the character of the fluid found, to have been a case of suppurative, and not a cyst pancreatitis. Lloyd calls attention to the probability of the traumatic cases of so-called pancreatic cysts being effusions into the lesser omental cavity, and not cysts of the pancreas. Fitz [2] says that "these effusions may represent the extension from the pancreas of an acute inflammatory process to the peritoneal covering, which is the posterior wall of the lesser omental cavity." This point of view would transfer some of the successful pancreatic cyst operations to pancreatitis operations, and thereby make a better showing for surgical interference in pancreatitis. My own opinion is that the traumatic cases should neither be classed as cysts nor as pancreatitis; but as injuries of the pancreas. They, therefore, do not belong to the subject of this paper. Cases of hemorrhage of the pancreas due to an injury have repeatedly been operated on with success.

The possibility of recovery, even when fat necrosis is present, is shown by a case of Osler's referred to by Fitz, where an exploratory operation was done for intestinal obstruction. No obstruction was found; but there was a dense, thick, indurated mass in the region of the pancreas and at the root of the mesentery, and foci of fat necrosis were found in the mesentery and omentum. The patient recovered.

All the authorities — Fitz, Senn and Körte — agree that the acute stage is not a favorable time to operate. This is certainly true when the patient is more or less in a state of collapse, as is often the case. It seems to me, however, not impossible that with an early exploratory incision the diseased part of the pancreas might be removed, or that the disease might be limited by gauze packing.

At present our attention is directed to opening pus-cavities and limiting their extension. If pus has collected in the omental bursa, the incision should be made in the middle line from the ziphoid cartilage down. The bursa should be opened by tearing through the omentum between the stomach and transverse colon. The omentum can be stitched to the abdominal wall before opening, and in this way the abscess-cavity is shut off from the peritoneal cavity. If the abscess-cavity extends along the pancreas, a counter-opening should be made in the lumbar region just below the twelfth rib. When the pus is evidently retro-peritoneal and burrowing in the lumbar region or in the mesocolon, the opening should be made in the back, as for extirpation of the kidney, then with a blunt dissector the pus-cavity should be searched for without opening the peritoneum.

[1] London Lancet, August 9, 1891.
[2] Pepper's Theory and Practice of Medicine.

Case I. Gangrene of the pancreas, with fat necrosis; operation; death.

The patient, a large and fat man, aged fifty-one, entered the Massachusetts General Hospital, August 1, 1894. He had been well and strong, but had suffered more or less from rheumatism. Five days before entrance he was suddenly taken with an attack of severe vomiting; a few minutes later he felt a hard pain in the left side, which pain had continued ever since. At first it was more general, but later it became localized near the spine of the ilium. He had taken a dozen or more quarter-grain morphia suppositories. He had vomited several times each day, and the bowels had been moved by enemata. There had been no chills nor sweating.

Examination of the abdomen showed a dome-shaped prominence in the epigastrium, which felt like a doughy tumor. This mass extended along the border of the ribs on the left side to a point just above the superior spine of the ilium. Its borders were not at all sharply defined, and it was resonant on percussion. The outer end was decidedly tender. The urine was normal, no albumin or sugar being present. The temperature was 100.5°, pulse 100; tongue coated and breath foul. The diagnosis of pancreatitis was made. He slept fairly well that night without morphia; taking milk and lime-water without nausea or vomiting, and good movements of the bowels followed an enema; but he had the expression of a very sick person.

On August 2d, Drs. Richardson and Mixter saw him in consultation, agreed to the diagnosis, and advised operation.

*Operation.*— A four-inch incision was made in the median line over the most prominent part of the tumor. The omentum was found much thickened and studded with white spots of fat necrosis. Two openings were made through the omentum — one straight down in the median line, which gave no result; and one down to the left into the doughy tumor to a point corresponding to about the middle of the pancreas. From this opening came a quantity of greasy, bloody fluid. Both openings bled freely, and were packed with gauze.

On the following day the gauze was removed, and six ounces of brown, muddy fluid of slightly foul odor, ran out. A drainage-tube was placed, and the fluid continued oozing out. On examination, Dr. Whitney found that it contained clumps of pus-cells, altered blood corpuscles, free fat, and bacteria in great abundance.

The patient died in three days.

At the autopsy Dr. Whitney found a disseminated fat necrosis, most marked in the region of the pancreas, and gangrene of the pancreas. The following is his description of that organ: "Lying at the posterior part of the mass removed was the pancreas imbedded in slaty, discolored necrotic fat tissue. On dissecting it out, it was necrotic for its greater part. Only a portion of the tail and of the head retained any semblance of normal structure, and these were

sharply separated from the dirty, slaty-colored structureless mass. There were two openings from the ducts, which were normal. The splenic artery was thickened and its coats slightly roughened. The splenic veins contained a recent thrombus continuous with thrombi in the pancreatic veins. There was no evidence of any recent hemorrhage. The spleen was increased one-half in size, firm and dark-red in color.

## HEMORRHAGIC PANCREATITIS.[1]

BY ELBRIDGE G. CUTLER, M.D.

Case I. On February 1, 1893, I first saw Mrs. A. H. H., aged about fifty-eight, and obtained the following history: She has had severe attacks of indigestion in the past fifteen years several times, keeping her in bed a month or six weeks with each attack. The attacks have been preceded by constipation, anorexia and insomnia. Vomiting speedily follows and lasts two or three days, all food being ejected and almost all the liquid taken as well. It is impossible to trace the trouble to any one thing. When the stomach gives out it refuses everything. Never any chills, never any tenderness about the abdomen anywhere. Once she had an attack followed by jaundice, lasting two weeks. Has had no attack in the last two years. Says she has had no good movements of the bowels for a month, that is, no large, fully formed ones. "It seems as if at one place it passes through a very narrow passage," as the patient expressed it, pointing at the same time to the left side of the abdomen low down. She has frequently been called up to the water-closet in the morning by gas in the abdomen, but has never had to go several times before being relieved. There has never been slime or blood with the stools. She has lost ground in the last two weeks, and for six days has had more or less pain in the middle of the back.

The patient was short and rather stout, of dark complexion but of good fresh color. Physical examination of the heart and lungs was negative. The abdomen was full, moderately soft, no tenderness anywhere and normally tympanitic. The hepatic area of dulness was not increased. Spleen area normal. Urine healthy. Family history unimportant. With a laxative pill and regulated diet she did very well indeed till May 4th, when she caught a severe cold. She was kept in bed by it for four or five days, when she was able to be up and about.

On May 15th the cough recurred, and gave rise to abdominal pain on the right, just below the ribs, with vomiting two times. There was no tenderness or distention of the abdomen. All food distressed her. She was better the next day, and remained well till about the 6th of June, when I saw her again because food began to disagree, and she had constant pain in the right mammillary line just under the ribs. A single subcutaneous injection of morphia, followed by Carlsbad salts, kept her in comfort for four days. For some time the stools had been screened in vain, looking for gall-stones. On the 10th pain began again; on the 12th it was acute with occasional vomiting, and twice there were chills followed by cold sweats. As she did not improve and morphia was frequently necessary, I asked for surgical assistance, which was deferred. The next day there was jaundice; the abdomen became distended, especially in the upper part; the patient looked badly, vomited several times, had fever of 102° F. and a weak pulse. There was a slight trace of albumin in the urine; no sugar; considerable bile pigment. That night the patient was a little delirious. There was profuse sweating after sleep. Pain in the epigastrium, with tenderness, became very marked; and Drs. F. Minot and J. W. Elliot saw her with me in consultation. At this time the abdomen had become very much distended, was tender and hard; the pulse was weak and thready; the appearance very bad; vomiting of a black liquid in no large quantity was of frequent occurrence. The diagnosis of gall-stones, with probable secondary disease of the pancreas and peritonitis, was concurred in, and non-interference advised. The patient continued to fail and died next day.

At autopsy there was found a bloody fluid in the abdominal cavity, with peritonitis; very numerous spots of fat necrosis, chiefly about the region of the pancreas (some of them were seen by Dr. Whitney); and an enlarged pancreas surrounded and infiltrated with blood in its middle portion. The liver showed indistinct acini. In the gall-bladder were a number of faceted small stones; one was found at the outlet of the common duct, and one nearly at the end of the cystic duct. Further examination was not made.

Case II. J. H., fifty-two, married, born in Ireland and living in Boston, entered the Massachusetts General Hospital, September 26, 1894, with the following history: Father dead of gravel; mother and four sisters alive and well. Patient had scarlet fever at seven, and measles and small-pox at ten. Twenty years ago fell and hurt her back, and has had pain and lameness there occasionally since. Dyspnea also for ten years, worse of late. Dizziness, blurred vision, and occasional faintness after exertion. No swelling of feet or abdomen. Paroxysms of coughing when suffering from dyspnea, but no steady cough. More or less "stomach trouble" for five years, especially when overtired. An "all-gone" feeling after meals, relieved by vomiting. Less urine than formerly. Bowels regular.

Her present illness began with a headache on the morning of the 23d. On the 24th, after a breakfast of a pear and some bread, had severe cramp in the stomach, and vomited. Felt better some hours later, and went down town, where she vomited again twice. Later, abdominal cramps again, with continued vomiting and great weakness. Vomited on the night of the 24th and on the 25th. Had abdominal cramps on the 26th, and vomited twice. Pain worse over the epigastrium and both flanks. Tightness in the chest and dyspnea since the 24th.

The patient was very large and fat. Alcoholic look; dull, cyanotic countenance. Respirations rapid and labored. No cough. Heart slightly enlarged to left, slight systolic murmur. Harsh respiration throughout chest, moist râles at bases. Abdomen much distended, especially in upper part; very tense, particularly in epigastrium, about umbilicus and in the right iliac region. Marked tenderness over epigastric and umbilical regions; not extreme, however. Vaginal and rectal examinations negative. Edema of abdominal and thoracic walls, none of legs. Pulse 112, respiration 47, temperature 100.8°. Ordered liquids;

[1] Read before the Boston Society for Medical Improvement, January 21, 1895.

strychnia, one-fortieth of a grain every four hours; whiskey, half an ounce every two hours.

September 27th. Pulse more rapid and weak. First cardiac sound short. More râles in lungs. Abdomen not so distended or tense, no tenderness. Takes liquids well, no vomiting. No cough; labored breathing; much cyanoses. No pain. No result from an enema (the bowels had not moved). Fifteen ounces of urine in twenty-four hours; color, high; acid; specific gravity, 1.032; one-fifth per cent. of albumin; sugar, 6.1 per cent.; sediment contained degenerated renal cells, hyaline and granular casts of both diameters, with renal cells adherent; no blood; Diazo primary and secondary. Indican increased. Tincture of digitalis, ten minims every four hours.

September 28th. Last night, very cold hands and feet, marked cyanosis. Seen by Dr. S. J. Mixter, who advised non-interference, though he considered it an abdominal case. Much weaker this morning. Diffuse, moist râles through both chests. Abdomen less full and less tender. Vomited once last night and again this afternoon — dark, hemorrhagic-looking stuff. Some pain in chest, none in abdomen. Delirious last night, and noisy to-night; seems like alcoholic delirium. Out of bed twice last night. Suds and glycerine enema gave a normal-looking movement.

September 29th. Sent to a private room on account of noise last night. Refused all medicine till twelve. Restless and noisy. Pulse failed gradually, and patient died at 4.40 this morning.

The autopsy was performed by Dr. W. F. Whitney, eight hours after death. Rigor mortis present. Body well nourished. Excessive development of adipose tissue. Marked lividity of face and dependent portions of the body. Head not opened.

Thorax: Pleural cavities contained a little reddish fluid (serous), surfaces normal. Lungs retracted, dark-red in patches, collapsed, of a bluish-red color; on section, a little frothy sputa came from cut surface of uncollapsed portions. Pericardium: Surfaces normal. Cavity contains a normal amount of straw-colored fluid. Heart large, covered with abundant fat tissue; muscular substance pale, somewhat opaque; valves and cavities normal. Aorta of normal size, intima covered with slightly raised, opaque, irregular, yellow patches.

Abdomen: Peritoneum cavity contained a moderate amount of blood-stained serous fluid. Surfaces without any adhesions and in general smooth, but everywhere marked by white opaque spots from the size of a pin's head to that of a split pea, very slightly raised above the surface, and on section lying wholly within the fat tissue. These were found everywhere upon the subperitoneal fat, the omentum, the mesentery and in the fat about the upper surface of the diaphragm and mediastrium. These changes were most extensive in the fat about the pancreas and in the mesentery there. The pancreas itself was enlarged to about twice its normal size, firm, dry, of a dark blackish-red color, mottled by opaque yellowish-red patches. This appearance was throughout the entire organ. There was no evidence of normal structure anywhere. The splenic artery was of normal size, its internal coat slightly thickened, the openings of the pancreatic branches apparently normal. The splenic vein was normal; over a part of its wall was a recent, slightly adherent mass of fibrin and blood, only partly blocking up its lumen. There was very little clot in it. The pancreatic duct opened in the normal place, and was followed some distance into the organ; its walls were thin and smooth, and to the eye there was no evidence of any inflammatory condition.

Stomach and intestines presented no marked changes.

Liver was of normal size; the section-surface was pale, slightly opaque, lobular, outlines indistinct. Microscopic examination showed the cells infiltrated with fat drops and quite granular.

Spleen slightly increased in size, very soft; on section, structure not to be made out from the almost diffluent character of the pulp, which was of a pale-reddish color.

Kidneys of normal size; capsule stripped off easily; cortex and pyramids easily differentiated, the former of an opaque, grayish color. Microscopic examination showed the cells of the convoluted tubes filled with small glistening granules.

Uterus and adnexa presented nothing abnormal.

Cultures from liver and spleen showed the bacillus coli communis.

Diagnosis: Acute hemorrhagic pancreatitis, disseminated fat necrosis, acute splenic hyperplasia, granular degeneration of heart, liver and kidneys.

The symptoms of hemorrhagic pancreatitis are oftentimes suggestive rather than distinctive. The most common symptom is pain in the upper abdominal region, which may be very intense and is increased by pressure and deep inspiration. Accessory symptoms are nausea, vomiting, loss of appetite, irregularity of the stools (sometimes constipation, at other times diarrhea), and distention of the gastric region. If the case is about to terminate fatally, very soon there is much loss of strength, collapse supervenes, and the patient dies. The temperature may be normal, only a little elevated, or it may at times be high. The most common complication is peritonitis. Icterus, as in the first of my cases, is more seldom seen. Sometimes the symptoms are those of ileus; and, according to Eichhorst, if the pancreas is enlarged, it may press on the intestine and thus make it impassable. Sugar in the urine has been found in a few instances, as in the second of the above cases; and, as a symptom, it is with our present knowledge merely suggestive.

A probable diagnosis can be made with some certainty only when diseases of the stomach, liver and intestine can be excluded. In the majority of cases hemorrhagic pancreatitis remains either undetected or simply considered in the enumeration of the possible conditions. No material addition to our knowledge of the disease has been made since the publication of Fitz's admirable paper in 1889.

## SOME METHODS OF CHEST EXAMINATION SUPPLEMENTARY TO AUSCULTATION AND PERCUSSION.[1]

BY EDWARD O. OTIS, M.D., BOSTON,

*Visiting Physician to the Free Home for Consumptives, Member of the American Climatological Association, etc.*

Experience gained in the examination of over fifteen hundred chests of presumably well persons has convinced me that the means of determining the condition of the lungs other than auscultation and percussion are exceedingly valuable, and add not inconsider-

[1] Read before the Boston Society for Medical Improvement, January 7, 1895.

ably to the knowledge obtained by the latter methods. Moreover, they are applicable to most cases which consult us for suspected lung trouble.

The means I refer to are in use, some of them at least, in the gymnasiums where physical examinations are made, though probably not exactly with the same end in view which guided me in my investigations. They are:

Spirometry: the measure of the lung capacity, as well as the measure of the ordinary amount of air in the lungs.

Pneumatometry: the measure of the elastic power of the lungs, or strength of the lung tissue.

Thoracometry: the measure of the circumference and diameters of the chest — depth and breadth — both in natural and full inspiration, and tracings of the contour of the chests, also in natural and full inspiration.

These tests are of especial value in those incipient or suspected cases before we obtain any positive evidence of disease by auscultation and percussion. A class of cases in which any and all means of examination which will lead to a diagnosis are of especial value, for, as we all know, the earlier the diagnosis is made and the treatment begun, the better the prospect of arrest. Further, they naturally suggest a valuable means of treatment, namely, gymnastic exercise especially directed to chest and lung expansion.

The capacity of the lungs in health varies in the first place according to age, sex, and stature; and secondly, according to the height, width, and depth of chest, mobility of the chest walls, and also, which is of especial note, according as one has or has not been in the habit of fully expanding the lungs — practising breathing exercises. In 1,000 measurements of my own tabulation for an average height of 67 inches (170.2 centimetres) and an average age of 22.1 years, the average lung capacity was 240.6 cubic inches (3,944 cubic centimetres). In 8,000 measurements of Dr. Hitchcock, of Amherst College, for an average height of 67.9 inches (172.5 centimetres), and at an age of from seventeen to twenty-six years, the average lung capacity was 230 cubic inches (3,770 cubic centimetres). In 15,000 measurements of students, at about the same age as those tabulated by Dr. Hitchcock, collected by E. Hitchcock, Jr., of Cornell University, the average lung capacity was 236.6 cubic inches (3,880 cubic centimetres) for an average height of 67.8 inches (172.2 centimetres). I have also made from my own measurements of males from sixteen to forty years of age, averages of the lung capacity for heights from 66 to 72 inches, each average being the result of fifty observations, with the following results:

| Height. | Lung Capacity. | Average for each Inch or Centimetre in Height. |
|---|---|---|
| 66 to 67 inches, incl. 167.7 to 170.3 cms. | 231.62 cubic inches. 3,797 cubic cms. | 3.44+ cubic inches. 22.4 cubic cms. |
| 67 to 68 inches, incl. 170.3 to 172.8 cms. | 237.10 cubic inches. 3,903 cubic cms. | 3.46 cubic inches. 22.7 cubic cms. |
| 68 to 69 inches, incl. 172.8 to 175.4 cms. | 244.44 cubic inches. 4,007 cubic cms. | 3.5 cubic inches. 23.06 cubic cms. |
| 69 to 70 inches, incl. 175.4 to 177.9 cms. | 259.34 cubic inches. 4,250 cubic cms. | 3.66 cubic inches. 24.06 cubic cms. |
| 70 to 71 inches, incl. 177.9 to 180.5 cms. | 261.38 cubic inches. 4,284 cubic cms. | 3.64 cubic inches. 23.9 cubic cms. |
| 71 to 72 inches, incl. 180.5 to 183 cms. | 261.34 cubic inches. 4,284 cubic cms. | 3.5 cubic inches. 23.03 cubic cms. |
| General average . . . | | 3.52 cubic inches. 23.19 cubic cms. |

From this data we find that in males between sixteen and forty years of age for each inch in height, the lung capacity is 3.5 cubic inches or 22.5 to 23 cubic centimetres for each centimetre of height. From the observations of Hutchinson and Wintrich, Brehmer gives it as between 22 and 24 cubic centimetres for every centimetre in height, but 23 is a good working basis and sufficiently accurate.

For women we have the measurements of about 500 students taken at Mt. Holyoke and Wellesley Colleges by Dr. Colton and Miss Wood, which gives for an average height of 62.6 inches (159.1 centimetres), an average lung capacity of 145.8 cubic inches (2,390 cubic centimetres); and also 50 per cent. of 1,500 Wellesley students, the observations made by Miss Wood for a height of 63.2 inches (160.5 centimetres), giving a lung capacity of 150.3 cubic inches (2,447 cubic centimetres). The average age in each case was about nineteen years. From this we find that, with women, for every inch in height the lung capacity is about 2.3 cubic inches or 15 cubic centimetres for each centimetre. Brehmer makes it a little higher, between 16 and 17.5 cubic centimetres. Hutchinson found in his investigations, made many years ago, that the lung capacity varied from 174 cubic inches for a height of five feet to 262 cubic inches for a height of six, or for every inch of stature above five feet the lung capacity increased eight cubic inches. According to Waldenburg the lung capacity decreases after thirty and up to sixty years of age, nearly 1½ cubic inches per year of age. This I should doubt to be the case provided the individual continues the habit of deep breathing.

With the data then already given, knowing the height, we can estimate pretty nearly how much the lung capacity of each individual ought to be. If, on a spirometic test, it varies to any great extent from this, the man is either better or worse than we thought as to his chest expansive ability and lung capacity. If much below, either his method of respiration is faulty or his lungs are not normal. If the first supposition is true, the measurements of the circumference, depth and breadth of the chest in respose and full expansion will indicate this, for the difference of these three measurements under these two conditions of repose and expansion will be below the average, indicating insufficient mobility of the chest-walls.

Now, this may all happen in the latter case, namely, that the lungs are not normal and some of their tissue is disabled and thrown out of use, but we shall have the evidence which auscultation and percussion give us. If the evidence, however, from these tests is negative, and yet we have certain suspicious general symptoms, the failure of the spirometic test together with these measurements to come up to the average by a considerable degree, will, at least, make one suspicious as to the integrity of the lung tissue. I wish here incidentally to make an especial point upon the amount of air exhaled after an ordinary quiet inspiration, the way one generally breathes when one is thinking nothing about it. This, it seems to me, is a valuable bit of evidence, as showing how successfully and normally one is performing the act of respiration.

In examining patients with incipient pulmonary tuberculosis, the lung capacity was found to be below, and generally much so, the average. According to Waldenburg from 10 to 70 per cent. To illustrate: E. C., of medium stature, in fair general condition as

to strength, appetite, digestion, etc., and attending daily to business, was found to have a small area of tubercular infiltration at the apex of the right lung; the vital capacity was 195 cubic inches, the average being about 235 cubic inches. J. M. with evidence of induration and softening at the apex of the right lung, had a vital capacity of 85 cubic inches. H. A. S. with evidence of a moderate amount of tubercular disease at the left base from old pleuritic trouble, had a vital capacity of 185 cubic inches. W. H. D. with a slight infiltration in the outer clavicular region of the left apex, but with the perfect appearance of health and attending to his usual occupation, had a vital capacity of 150 cubic inches. In all of these cases the diagnosis was verified by the finding of tubercle bacilli in larger or smaller quantities.

Brehmer[3] goes so far as to say that the physician can with the aid of the spirometer determine whether the individual who comes to him for the first time to be examined, or is seen by him for the first time, has pulmonary tuberculosis or not, and that the spirometer is, *par excellence*, the means, and indeed the only one, to determine with certainty under all conditions the first beginnings of pulmonary trouble. "By it," he says, "we can determine whether or not any, even a very small portion of the lung tissue is unaccessible to air, and whether there exists any induration, although it may be surrounded by air-permeated lung tissue." Says Renzi, in his recent work upon phthisis,[3] "spirometry shows a diminution of the lung capacity even in the beginning of the disease."

On the other hand, if the general symptoms were suggestive of tubercular trouble but if the vital capacity was up to or beyond the average, it was a favorable piece of evidence against actual lung invasion. For example, E. J. T., a young woman with a marked family history of tubercular trouble, and with general symptoms strongly suggestive of it, came to me with a communication from her family physician that two months previous he had found the right apex suspicious. She had a vital capacity of 150 cubic inches, the average for a women, and the examination of the lungs by auscultation and percussion was negative, and no bacilli were found in the sputum.

Wintrich — quoted by Brehmer — narrates two cases in which the spirometer test determined the fact that no lung trouble existed in spite of suspicious symptoms. One was a governess who had suffered from an annoying cough, accompanied sometimes with a little blood. Her general condition was good but her friends were much alarmed, fearing disease of the lungs. The spirometer test, however, gave the average lung capacity for her height, namely, 17 cubic centimetres to one centimetre of height — about 2½ cubic inches to one inch in height — and consequently the cough was considered hysterical. The other, also a young woman, had for a long time a severe, troublesome cough, and it was feared that she also might have some deep-seated lung disease; but the spirometic test gave 2,720 cubic centimetres of lung capacity — her height being 165 centimetres, or 17 cubic centimetres to one centimetre of height — indicating that the cough was not the result of any lung invasion. One might naturally ask why could not auscultation and percussion have as well determined this fact, and also the examination of the sputum; but Brehmer answers this by saying that examples are by no means rare where neither the subjective symptoms nor the most exact examination by means of auscultation and percussion will, with certainty, reveal infiltration, but where the spirometer shows an important diminution of the lung capacity, and only after a year and a half or two years will auscultation and percussion give evidence of infiltration at the apices; and that the patients have after some years died of lung disease. As to the examination of the sputum — in one of the cases above quoted by Brehmer, there was no sputum, and in the other the slightest amount, if any. And further, a spirometic test requires but the slightest amount of skill and experience, and there are no sources of error if the spirometer is, to begin with, accurate, while examination of the sputum, if there is any, requires experience and skill and expensive appliances.

Further, when the diagnosis of tubercular invasion has been established, the test of the vital capacity is a factor of more or less value in forming a prognosis. As Renzi says: "It has especially a high prognostic worth, for when the breathing capacity is very considerably diminished, the prognosis is unfavorable." There may possibly be a slight danger of hemorrhage in taking this test, but as one would generally apply it only in incipient cases, this, it seems to me, is inconsiderable. It is a test which is very readily made and the sources of error are small. Either a dry or a water spirometer may be used. I am accustomed to both, with a preference for the latter; it seems to me to be rather more accurate and less likely to become disarranged. As illustrative of this part of the subject, I give the lung capacity of thirteen consumptives with more or less advanced disease.

| | |
|---|---|
| A, male | 145 cubic inches. |
| B, male | 115 " |
| C, male | 76 " |
| D, male | 50 " |
| E, male | 75 " |
| F, male | 70 " |
| G, male | 75 " |
| H, male | 132 " |
| I, male | 103 " |
| J, male | 102 " |
| K, male | 95 " |
| L, male | 52 " |
| M, female | 85 " |

The average lung capacity for males being 235.7 cubic inches, and for women about 150 cubic inches.

The pneumatometer or pressure spirometer is the instrument used in measuring the so-called strength of the lungs — or the inspiratory and expiratory forces. Under normal conditions, according to Waldenburg, the expiratory force exceeds the inspiratory by 20 to 30 millimetres. In cases of tubercular disease, however, even in the earliest stages, "the inspiratory power is diminished, whilst the expiratory remains normal."[4] Renzi has repeated Waldenburg's experiments, and finds that both the inspiratory and expiratory forces are diminished in tuberculosis of the lungs, but the former more so than the latter and earlier. In emphysema the expiratory pressure is lowered. I have made a large number of observations upon the expiratory force, "strength of lungs" so-called, and I am unable to find that there is any constant ratio between it and the lung capacity. The test has a certain value, however, I think, as a gymnastic

[3] Die Chronische Lungenschwindsucht und Tuberculose der Lunge, Dr. Herman Brehmer, Berlin, 1869.

[3] Pathogenese, Symptomatologie, und Behandlung der Lungenschwindsucht, von Dr. E. De Renzi, Wien, 1894.

[4] Powell: Diseases of the Lungs.

exercise. Waldenburg used a mercurial manometer. I have used what is in common use in the gymnasiums, an ordinary steam-gauge made for recording low pressure. Dr. Denison, of Denver, Col., has also devised a mercurial instrument, which I have here.

In thoracometry two circumferences of the chest are taken, one at the level of the nipples, and the other about two inches below, the "respiratory chest" so-called. These may be taken under three conditions: extreme inspiration, extreme expiration, and in calm breathing. I have been accustomed to take them in calm breathing and extreme inspiration only. The important fact to be ascertained in these tests is the mobility of the chest-walls as a whole. To determine the amount of excursion of the chest-walls antero-posteriorly and laterally we measure these two diameters in repose and full inspiration: this is important, for I have often found that the expansion comes almost entirely from the increase of one diameter alone, as the accompanying charts illustrate. I take them at the level of the nipple, the antero-posterior one, by metal calipers — the self-registering ones I think, are more convenient — and the lateral one either with the same instrument or a pair of wooden slide calipers.

These measurements of the circumference and diameters of the chest taken in repose and inflation tell us of its size and mobility, but not of its shape or of the symmetry or asymmetry of the respiratory movements. It is a fact I have frequently verified that the apparent and real shape of the chest often differs very largely; and further we know that it frequently expands unsymmetrically, the amount of excursion of one side of the chest-walls being larger than that of the other, or the expansion being mostly either anteriorly or laterally. In order to make apparent these facts of shape and variations of expansion we can trace the contour of the chest in repose and inflation, which will still further complete our knowledge of the respiratory chest, its movements and contents. For this purpose we can either make use of a simple band of lead with a rubber hinge as I have done, or the more complicated and accurate apparatus of Démény, of Paris. Generally for the purpose of the clinician the simpler instrument will suffice. The contour of the chest is first taken in repose and charted, and superimposed upon this its shape when fully expanded, thus giving us a representation of the shape under the two conditions. By this method, for example, we can see at a glance if the two sides of the chest expand unequally, as in a case of previous pleuritic trouble.

By these additional methods of physical examination, which I have enumerated and briefly described above, I feel convinced that we can often obtain valuable knowledge of the respiratory chest and its contents in addition to that obtained by auscultation and percussion; and in doubtful cases, as I have said, of suspected tubercular trouble, their evidence will often, I believe, render the diagnosis clearer.

I do not by any means consider all these tests of equal value; indeed, taken by themselves some have very limited value, such as the strength test of the lungs and the tape measure of the chest expansion, but the sum total of them does, I believe, very materially supplement the knowledge obtained by auscultation and percussion, as well as suggest to us possible defects in the respiratory function when all other evidence is negative. Moreover, by an examination of this kind one gets into the habit of looking at his patient from rather a different point of view, a physiological one, if I may so denominate it, in addition to the pathological one. And further, if in an examination of a suspected case we obtain no evidence of disease, we do gain information by these additional methods which we could not obtain, or but indifferently, by auscultation and percussion, namely, how the function of respiration is being performed.

## MEASUREMENTS OF THE CHEST AND LUNG CAPACITY.

TABLE I. — *Chest Measurements.*

| CHEST MEASUREMENTS. | Repose, inches. | Inflated, inches. | Difference, inches. |
|---|---|---|---|
| *Girth, Muscular.* | | | |
| MEN. | | | |
| Average of Dr. E. O. Otis, 1,000 measurements, between sixteen and forty years of age | 34.0 | 36.1 | 2.1 |
| Average of Dr. Hitchcock, of Amherst College, 8,000 measurements | 34.6 | 36.5 | 1.9 |
| Average of E. Hitchcock, Jr., of Cornell College, 15,000 measurements | 34.5 | 36.3 | 1 8 |
| WOMEN. | | | |
| Mt. Holyoke and Wellesley students. Measurements Miss Wood and Dr. Mary Colton | 29.5 | 31.5 | 3.0 |
| *Chest, Respiratory.* | | | |
| MEN. | | | |
| Average of Dr. E. O. Otis, 1,000 measurements | 31.1 | 33.1 | 2.0 |
| WOMEN. | | | |
| Fifty per ct. of 1,500 Wellesley students, Miss Wood | 24.6 | 27.2 | 2.6 |
| *Depth of Chest.* | | | |
| MEN. | | | |
| Average of Dr. E. O. Otis, 1,250 measurements in repose and 362 inflated | 7.5 | 8.3 | 0.8 |
| WOMEN. | | | |
| Fifty per cent. of 1,500 students at Wellesley, Miss Wood | 6.9 | .... | .... |
| *Breadth of Chest.* | | | |
| MEN. | | | |
| Average of Dr. E. O. Otis, 400 measurements | 9.9 | 10.8 | 0.9 |

TABLE II. — *Capacity of Lungs.*

| | Cubic Inches. |
|---|---|
| MEN. | |
| Average of Dr. E. O. Otis, 1,000 measurements | 240.6 |
| Hitchcock, 8,000 measurements | 230.0 |
| Hitchcock, Jr., 15,000 measurements | 236.6 |
| WOMEN. | |
| Mt. Holyoke and Wellesley students, measurements of Miss Wood and Dr. Mary Colton | 145.8 |
| Fifty per cent. of 1,500 Wellesley students, Miss Wood | 150.3 |

TABLE III. — *Comparison of the "Vital" or Lung Capacity and the Amount of Air Expelled after an Ordinary Quiet Inspiration. Average of Dr. E. O. Otis. One Hundred and Fifty Measurements.*

| | Cubic Inches. |
|---|---|
| Vital capacity, or the amount of air exhaled after a full inspiration | 230.5 |
| Amount of air exhaled after an ordinary quiet respiration | 129.3 |
| Difference, or "complemental" or "reserve" air | 101.2 |
| Difference as given by Hermann | 97.6 |

If the vital capacity is low and the expansion poor, we are enabled, by the knowledge of these deficiencies, to warn our patient of possible tubercular trouble in the future encouraged by his faulty habits of respiration, and teach him how to correct them by gymnastic exercises arranged to obviate these deficiencies. As Renzi says, in speaking of spirometry, "One can in some degree form a reliable opinion as to a possible

future lung invasion, and, therefore," he adds, "it is important that this means of examination should be used in the schools and gymnasiums."

These methods of examination are of value also in keeping before one's mind this valuable means of treatment and prophylaxis, namely, lung-expanding exercises, a treatment all too much neglected, it seems to me, but which, when properly arranged and supervised, can produce striking results.

Says Dr. Butler in his conclusions to a recent paper read before the American Climatological Association, upon "The Methods and Value of Supervised Exercise in the Prophylaxis of Pulmonary Phthisis": "Among many therapeutic agencies for imminent or incipient phthisis, one of the most useful is respiratory exercise. . . . Of all methods of obtaining increase of respiratory strength, capacity and nutrition, supervised exercise secures the most permanent and lasting results."

I give, on the preceding page, a table, previously published, of measurements and averages of the chest and its vital capacity. I also present a variety of chest contours with the vital capacity and expansion.

## Medical Progress.

### REPORT OF PROGRESS IN PUBLIC HYGIENE.

BY S. W. ABBOTT, M.D.

#### INDUSTRIAL HYGIENE.

THE Consulting Committee of Public Health of France, in its last annual report,[1] publishes the text of a proposed code of regulations for the protection of industrial labor. The proposed code is divided into two parts, the first pertaining to the health of operatives, and the second to their security from accident and harm. These are to be carried out with penalties under the provisions of an act of June 12, 1893.

The following is a digest of the hygienic regulations: (1) The places used for work, and all their appurtenances are to be kept constantly clean. The floors to be thoroughly cleansed at least once a day before the beginning, or after the closing of work, but never during work. The cleansing to be done by washing unless the character of the work forbids it. The walls and ceilings also to be frequently cleansed and kept in good order.

(2) In establishments where organic materials are used, the floor should be impervious and level. The walls to be either plastered or glazed, or covered with a good coat of zinc paint. Floors and walls to be washed as often as is necessary with a disinfecting solution. In every case a washing with strong alkali should be conducted at least twice a year. Decomposing material must not be allowed to remain in places where work is done, nor should much material be used in the processes of work. It should be taken away, or in case of deposit, should be carefully disinfected.

(4) The air of workshops must be kept constantly free from all emanations from sewers, drains, vaults or other sources of infection. Establishments connecting with a public or private sewer must be provided with an efficient trap on the main drain, to be frequently cleansed and flushed with water at least once a day. Operations in sewers, along gas mains, smoke flues, vaults and similar places likely to contain harmful gases, must only be undertaken after the air has been purified by efficient ventilation. Workmen in such places must be provided with safety-belts.

(4) Water-closets must not be in direct communication with closed places where workmen are employed. They must be provided with an abundant supply of water for flushing. The floor and walls must be of impervious material, zinc paint only to be used and of a light color. There should be at least one closet for each thirty persons, and urinals in sufficient number. No drain, cesspool, or any other mode of sewage-disposal is to be permitted without the proper sanction of the authorities.

(5) Closed places used for work must not be tightly closed. The air-space for each workman must never be less than eight cubic metres (about 280 cubic feet). These places should be well ventilated; and in cases where the character of the work does not allow ventilation, and where the materials used are harmful, artificial ventilation must be furnished, of such sufficiency that each man shall have a minimum of 24 cubic metres of fresh air per hour (about 840 cubic feet). Workrooms, as well as adjoining halls and stairways must be well lighted.

(6) Dust, noxious gases and harmful powders must be forced out-of-doors as soon as they are produced, and must not be allowed to mix with the air of workrooms. In the case of vapors, gases and light dust, connection must be made with chimney-shafts, or some other effectual method must be employed. For the dust powdered by mills, crushers, grindstones and other similar mechanical appliances, blowers must be furnished, connecting with a strong ascending current of ventilation. In the case of heavy gases, such as mercurial vapors, bi-sulphide of carbon, etc., ventilation must be effected by downward currents, each working-table being put in direct connection with the ventilator. Noxious gases and dust must not be let loose into the out-door air; gases and vapors must be condensed or burned, and dust must be carried to furnace fires or into collecting chambers. The powdering of irritating and poisonous substances, and similar operations, such as the sifting and packing of these materials, must always be done by machinery, and in closed apparatus when possible.

(7) During the interruption of work for meals the workrooms should be cleared of their occupants, and the air of these rooms entirely renewed.

(9) Workmen must not take their meals in the workrooms, nor in any of the places used for work. Proprietors of establishments must put at the disposal of their employees the means for ensuring personal cleanliness, and furnish dressing-rooms with wash-bowls, as well as water of a good quality for drinking.

The second division of the code relates to the means of insuring workmen against accidents from falls, revolving machinery, belts, elevators, electric dynamos and wires, sharp tools, the oiling of machines when in motion, etc.

#### QUANTITATIVE DETERMINATION OF THE DUST IN THE AIR.

Dr. Carl Arens, of Wurzburg,[2] has devised a method of estimating the amount of dust in the air of factories,

[1] Recueil des Travaux du Comité Consultatif d'Hygiène publique de France, 1894, June 23, p. 148.

[2] Archiv. für Hygiène.

etc. The apparatus consists of a bellows-like arrangement, capable of holding five litres of air. In place of a nozzle, it has a Y-shaped tube provided with taps, so that the air drawn in by one of the arms may be expelled by the other. To make it air-tight the edges were smeared with soap and water, and the apparatus tested, to see if bubbles escaped.

The end of the Y-tube through which the air is to be expelled, is fixed to a glass tube 8.1 cubic metres long, stuffed with cotton-wool. Two hundred litres can easily be made to pass through the cotton-wool in a half-hour or more, and the difference in the weight of the tube (after drying), before and after the experiment, represents the amount of dust in the air drawn through. He obtained the following results, the figures representing the number of milligrammes of dust per cubic metre of air:

| | |
|---|---|
| Dwelling-room | .1 |
| School-room | 8.0 |
| Horse-hair manufactory | 10.0 |
| Sawmill | 17.0 |
| Woollen factory | 20.0 |
| Snuff-factory (during working-hours) | 72.0 |
| Cement factory | 224.0 |

The author has also devised a contrivance to catch the dust in a horse-hair factory, consisting of a box in the air-shaft, containing overlapping ledges stretching diagonally from side to side, covered with flannel. These ledges are kept wet with a small stream of water. The dust sticks to the moistened flannel, and the air freed from dust passes through.

### THE DUST OF DIFFERENT TRADES AND ITS EFFECTS ON THE WORKMEN.

Dr. Wegman[3] contributes a paper on the dust of different trades, with reference to its shapes and mechanical action on workmen. The paper is fully illustrated with plates showing the microscopic appearance of different sorts of dust. The effect of dust upon the eyes, skin and lungs are portrayed. The author believes that consumption caused by inhaling dust differs materially from tubercular consumption, although it undoubtedly predisposes to a condition of the lungs which makes them eventually succumb to the tubercle bacilli. Removal from an atmosphere of dust will allow the lungs to recover in a great measure, and lungs which have become black with inhalation of soot will, if the exciting agent be removed, gradually recover their normal condition, even after a year of inhalation. The dangers of dust-inhalation are diminished if we lessen the amount of dust in the air, or if, for varying periods, the dust in the room is diminished in quantity. He mentions the following prophylactic measures:

(1) Dust can be prevented in many industries by moistening or wetting the materials to be worked, as for instance, in the substitution of wet grinding for dry in the case of metal, glass and stone.

(2) The introduction of machinery instead of hand labor.

(3) Unavoidable dust to be dealt with, and led away at its source by special fans.

(4) Protective personal measures on the part of the workmen, as, for instance, by wearing spectacles, sponges, respirators, etc.

(5) Shortening the hours of labor, or introducing pauses in the work.

(6) Passing laws dealing with the subject of dust.

[3] Archiv. für Hygiène.

### EXPERIMENTS UPON SEWAGE FILTRATION.

Sidney R. Lowcock, C. E., contributes a paper to the Proceedings of the British Institution of Civil Engineers,[4] in which he gives the results of experiments upon sewage filtration with a filter tank, seven feet six inches square and four feet deep, filled with different filtering materials at different successive experiments. The object of the experiments was to determine the possibility of constructing and working a filter which should follow the operations of nature, and promote the growth of the nitrifying organisms and the consequent purification of a sewage effluent, when working continuously.

After giving a *résumé* of the earlier experiments in this direction, and commenting upon the importance and value of the more extended experiments of the Massachusetts Board of Health at Lawrence, he considers that the following conclusions have been established:

(1) That filtration is not only a mechanical but also a chemical and biological process, when it is properly carried out and when sufficient aeration is provided for.

(2) That no practicable chemical process yet devised will, alone, do more than remove the suspended matters in sewage, and a very small portion of the dissolved impurities.

(3) That dissolved impurities can only be removed by the action of micro-organisms, that is, by nitrification; and this can only be effected subsequently to the decomposition of the organic matter and the formation of ammonia, and in the absence of undecomposed organic matter.

(4) That organic matter cannot be destroyed or converted into plant food until it has been dissolved.

(5) That, as nitrification proceeds far more rapidly in a moistened and aerated porous soil than in a liquid, and as the nitrifying powers of soil are capable of cultivation, the process should be carried on by means of filtration, so that the organisms can be cultivated and be supplied with food in the filter.

(6) That the most important factor in the processes of decomposition and nitrification, and the subsequent preservation of the nitrates formed, is an ample supply of air.

(7) That the suspended matters in sewage should not be allowed to pass on to the land or filter-bed, as they clog the surface and have to remain until they are decomposed before they can be destroyed.

*(To be continued.)*

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. G. MUMFORD, M.D., SECRETARY.

Regular Meeting Monday, January 24, 1895, Dr. C. J. Blake in the chair.

Dr. Goldthwait showed

A SECTION OF A SPINE

from a patient of forty-five, who had had a malignant tumor of the breast removed four or five years previously.

[4] Vol. cxv, p. 297.

Dr. Warren: I have here

A FIBROID TUMOR OF THE UTERUS,

which I temoved on Friday. The specimen is interesting partly from its size, and partly from the peculiar attachment of the growth. The specimen and the uterus are also enlarged, and a smaller additional fibroid tumor attached to it weighed about sixteen pounds.

The first thing of interest in opening the abdominal cavity was the appearance of a congeries of large varicose veins and lymphatics. They were tortuous and greatly enlarged, many of them having the calibre of the little finger. It was apparent that they belonged to the omentum owing to the thinness of the membrane in which they ramified. With some difficulty several of them were tied, and the hand passed through in order to examine the tumor which occupied the greater part of the abdominal cavity; and after trying to tie them separately, I came to the conclusion that the best way was to deliver the tumor, adhesions and all, the omentum being everywhere adherent to it. It was lifted out of the abdominal cavity more easily than I expected, and was found attached to the fundus of the uterus by a narrow pedicle, the tumor obtaining the greater part of its nourishment from the omentum, the vessels of which had been enlarged evidently for the purpose of nourishing the tumor. The omentum and the pedicle of the tumor were tied, and the tumor quickly removed. The uterus was afterwards removed, and the stump was sewed in beneath the peritoneum, and everything left in a satisfactory condition; but in the middle of the night the patient suddenly failed and in spite of infusion did not rally. At the autopsy it was found that hemorrhage took place from some of the large vessels in the omentum. It seems to be an illustration of one of those cases of separation of a fibroid from the uterus, so that in a comparatively short time it might have floated off in the abdominal cavity.

Dr. Whitney: As Dr. Warren has said, the especial interest is in the condition of the lymphatics which are so enormously distended in this veil of omentum which passes over and is adherent to the tumor. It is perhaps easy to understand why a vein should enlarge, but I do not see why the lymphatics should to such an extent. We know that fibroids have enormous lymph spaces in them at times, and some of them have cavities as big as a walnut which contain this clear serous fluid evidently of lymphatic character. This tumor is very solid and has very small lymph spaces. I do not remember to have noticed in other uterine fibroids enlargement of the lymphatics of the broad ligament.

Dr. F. G. Morrill reported

THE SUCCESSFUL USE OF ANTITOXIN IN CHECKING AN ENDEMIC OF DIPHTHERIA AT THE CHILDREN'S HOSPITAL.

Dr. E. G. Cutler read a paper on

HEMORRHAGIC PANCREATITIS.[1]

Dr. J. W. Elliot followed with an article on the

SURGICAL TREATMENT OF PANCREATITIS.[2]

Dr. W. F. Whitney then considered the

PATHOLOGICAL ASPECTS OF PANCREATITIS.

[1] See page 354 of the Journal.
[2] See page 361 of the Journal.

Dr. Warren: Cases of pancreatitis seem to be sufficiently numerous to make this disease one of practical interest to the surgeon. At first I think it was generally supposed that it was very rare indeed and certain symptoms only were associated with it. Perhaps that accounted for the fact that many cases went unrecognized. The acute hemorrhagic type I presume was the type first recognized, and was associated with severe pain and sudden death. I have had three cases of pancreatitis. I think all of them have been alluded to, and two of them reported before.

One was a case connected with injury, and I think it has been reported by Dr. Fitz,— traumatic pancreatitis. The condition was discovered only at autopsy; and numerous injuries had been inflicted on the individual.

One of the cases I saw was certainly interesting from the surgeon's point of view of operative interference. It was the only one that seemed to hold out any chance of improvement by operation. This case has been reported by Dr. Whitney and Dr. Bush already. It may be of interest perhaps to the members to have me say something about the case in a general way. I saw the case after it had been previously seen by another consultant, and the trouble had existed already for perhaps ten days. The feature of that case was intense pain in the epigastric region; no large amount of fever; no symptoms of general peritonitis, but a severe pain. There was also vomiting of greenish vomitus. The question of an exploratory operation was raised, but as the patient stoutly refused to have it considered, it was not pursued with any vigor on our part. No diagnosis was made. There was a sense of resistance in the left hypochondrium extending to that region from the median line and some dulness and evidence of a tumor in that region. The patient improved a good deal in the next few days, and I saw nothing of the case for over a week. I was then called again, the patient being in a state of collapse and approaching a moribund condition, and it seemed that operative interference would be useless at that time. The autopsy was performed by Dr. Whitney, and the specimen is here this evening. The interesting features brought out at autopsy were that there was no peritonitis, but a large pus-cavity existed containing about two quarts of pus, in the middle of which the pancreas floated in a gangrenous condition. Here was a case in which, if the peritoneum had been stitched to the abdominal wall and an opening made, this cavity could have been readily drained. Whether the patient would have lived without any pancreas, having gone through such a severe ordeal as that I am not able to say, but in the light of the two cases of which Dr. Elliot speaks it seems possible.

The last case occurred a few weeks ago at the hospital. It was seen by quite a number of surgeons and physicians. The opinions of these gentlemen were that there was disease of the liver. The symptoms in this case were in the right hypochondrium. There was dulness and tenderness; also vomiting. The patient was seventy-four, of temperate habits, and had been well up to the time of this illness, with the exception of about a month before, when he was doing some work in the cellar he had felt faint and had to sit down. He was helped up stairs. The condition passed away and was forgotten, but was recalled by his wife in his last illness. He went to town as usual. He was taken suddenly with pain and nausea and

took a drink which he threw up and went home. We saw him at the hospital about a week after the beginning of the sickness. Most of the surgeons thought it disease of the liver. I thought it was likely to be a cancer of the hepatic flexure. That was Dr. Homans's diagnosis, and I inclined to that. The peculiarities of this case were its somewhat chronic course, and the absence of any very severe pain in the epigastric region, but as I have heard the cases reported to-night the presence of severe pain does not seem to be a *sine qua non* for the diagnosis of pancreatitis. At the autopsy Dr. Whitney found the hemorrhagic condition which has been described this evening, and then a burrowing of it along the root of the mesentery, and what finally seemed to carry the patient off was perforation through the mesentery into the lower portion of the abdominal cavity. I will read what is said by Dr. Whitney about the peritoneum.

I think discussions of this kind are of value as they will call the attention of the profession to this disease, and it is possible that here and there a case may be found capable of being saved. I ought to add that in this last case the question of pancreatitis was considered. In regard to the second case and also the last two cases which I alluded to, the specimens are here, and Dr. Whitney, I think, might perhaps show the one of abscess of the pancreas which is distinctly different from the others, and might be interesting to look at.

DR. CUTLER: Pancreatic hemorrhage is a thing that occurs so suddenly, sometimes so violently, that the patient usually dies at once, and the physician who is called to see it is able to make the diagnosis by exclusion. The hemorrhagic pancreatitis lasts longer and has a set of symptoms in common with quite a number of other conditions, and these conditions may be such that a man may not be able to differentiate and make anything more than a probable diagnosis. The kind of case which Dr. Elliot and Dr. Warren spoke about, is accompanied by the presence of tumors and definite conditions which aid very materially in the diagnosis. Such cases last longer than the ones I have spoken of. It seems to me the most difficult to diagnosticate is the hemorrhagic form of pancreatitis because there are so many other things which may exist which have symptoms in common with the condition.

DR. M. H. RICHARDSON: I have no doubt that there are more cases of acute disease of the pancreas than we suspect, because of the large number of deaths following acute abdominal symptoms in which no diagnosis can be verified by exploration, either before or after death. We can all recall cases of this kind in which a rapidly fatal end has followed the onset of acute abdominal pain.

My experience with the diseases of the pancreas has been limited to cysts, either congenital or acquired. The pancreatic cyst, even if purulent, seems to be too far removed from acute pancreatitis, both as to etiology, as to treatment, and as to prognosis, to be properly discussed this evening.

The question of probable inflammation of the pancreas always arises in the course of acute abdominal symptoms in which most other and common conditions can be excluded. I can recall several cases in which the question has been fully discussed, but in which, unfortunately, the exact condition must always remain obscure. Epigastric tumors containing pus, even if they have appeared some weeks after the initial pain, always suggest the possibility of a pancreatic source. I recall one case in particular in which such a tumor slowly appeared after the onset of acute pain at the pit of the stomach. The patient, a young girl, had been in the habit of swallowing daily the rubber gum she had been chewing. She was finally seized with acute pain, with fever, in the epigastrium, where I found some weeks later a boggy tumor. I supposed that the gum had formed a ball in the stomach, and that nature was taking this way for its expulsion. Deep exploration of the tumor down far enough to feel the abdominal aorta, failed to reveal anything but an infiltrated, boggy mass containing small cavities of pus. No foreign body was detected. The pancreas was never thought of as the possible source of the tumor, yet I dare say the trouble may have originated there.[2]

The diagnosis of acute pancreatitis in the stage of operable abscess seems to me necessarily obscure. An acute inflammation, to be positively made out, must be explored in its early stages, before the involvement of the secondary parts conceals effectually the exact origin. A localized abscess that is reached by separating the omentum, and that is found situated in the exact region of the pancreas, may fairly be said to be of pancreatic origin, in the absence of a stomach or of an intestinal perforation. In the case of a perforation of the posterior wall of the stomach, one would expect to find a very extensive collection of foul-smelling pus filling the lesser cavity of the omentum.

Perforations of the intestine in the immediate region of the pancreas, the posterior wall of the transverse colon, perforation of the third portion of the duodenum, or of the beginning of the jejunum — these might simulate septic collections from the pancreas so closely that no positive differentiation could be made out.

The subject is of extreme interest to the surgeon as well as to the physician and to the pathologist. It needs careful attention on the part of those who see these cases in the beginning, for early interference may be rewarded by as brilliant results as are now obtained in the early hours of appendicitis.

We have only to recall the early discussions in appendicitis, in which no one could report a successful case of removal of the gangrenous appendix, to express the hope that one day we may report as favorable progress in acute pancreatitis.

DR. CUTLER: I should like to ask Dr. Mallory if as pathologist at the City Hospital he has seen cases of this kind of late. During seven years in which I was pathologist I think a single case only occurred.

DR. MALLORY: Personally I have never seen a case at the City Hospital. I believe they have had one case in the last year. I have seen one case in private which was diagnosticated as hemorrhagic pancreatitis, but which proved to be an ulcer of the

[2] March 12, 1895. Another case more suggestive of the pancreas has come to my notice since Dr. Elliot's paper was read. Mrs. B., aged fifty, a patient of Dr. C. S. Cahill, of Cambridgeport, was taken six weeks before February 19th, with what she called a bilious colic and a sharp diarrhea. For two days she had nausea and vomiting. Dr. Cahill first saw her February 17th. She then had a temperature of 102°, and a pulse of 120, with respirations at 34. There had been no jaundice. She was a very stout woman. I found a large, hard, smooth, tender tumor in the epigastrium, rather to the right than to the left of the median line. Aspiration showed very foul, fecal-smelling pus. I took her to the Massachusetts General Hospital, and two days later explored the tumor. It contained superficially several ounces of fetid pus. By carefully exploring with the finger, I came upon a very considerable cavity in the depths of the epigastrium, directly towards the pancreas. She has made a good recovery. In this case the possibility of a pancreatic source was first suggested by Dr. Elliot after the operation. The more I think of the case the more likely the explanation seems. The foul odor to the contents of the abscess suggests also some intestinal contamination.

duodenum extending round the pancreas. Fat necrosis was present.

Dr. Whitney: The necrotic and gangrenous forms of pancreatitis seem to be sequelæ of the hemorrhagic. In all such cases I have always found indications of more or less hemorrhage about or in the region of the pancreas, in the form of black clumps of pigment or black shreds of necrotic tissue. The subject is a very interesting one, and aside from those of anemic necrosis of the cells of the pancreas I have not seen evidences of an inflammation of the parenchyma of the organ. The changes have always been in the interstitial tissue. The hemorrhage is always primarily, as far as I have seen, between the lobules of the pancreas and has extended from there into the cells of the pancreas, and when not necrotic these have always stained well. It is possible that disturbances of circulation play a more important rôle than has been assigned to them, in producing at first small areas of hemorrhagic infarction in the interlobular fat tissue, on which the pancreatic juice acting in some way forms a toxine, which acts as an irritant and causes necrosis of the fat tissue. It has been argued that this fat necrosis cannot be dependent on pancreatic juice because it is found scattered all throughout the peritoneal surfaces and not in lines extending out from the pancreas. I do not see why if there is a chemical irritant formed it may not be selective in its action, just as toxines of certain bacteria produce necrosis only in certain spots although present everywhere in the blood.

## NEW YORK ACADEMY OF MEDICINE.

### A SYMPOSIUM ON ANTITOXIN.

At a crowded meeting of the New York Academy of Medicine, held April 4th, Dr. Joseph E. Winters, Professor of Diseases of Children in the University Medical School, made an elaborate and violent attack upon the use of antitoxin in the treatment of diphtheria, as well as upon the bacteriological department of the Board of Health. The occasion which afforded him the opportunity to give vent to his bitter invectives was a sort of symposium on antitoxin which had been arranged by the authorities of the Academy.

The discussion was opened with a paper by Dr. Hermann M. Biggs, entitled, "Experiences in the Production and Use of Diphtheria Antitoxin," in which he described the good effects of the remedy in its use at the Willard Parker Hospital under the control of the Board of Health. He had personally observed the effects of antitoxin in 252 such cases. In 30 cases in which it was applied on the first day after the appearance there were but two deaths; in 77 cases in which it was first used on the second day after the appearance of the disease there were seven deaths; in 67 cases in which it was used on the third day there were 11 deaths; in 31 cases in which it was used on the fourth day there were seven deaths; and in 46 cases in which it was used on the fifth day there were 13 deaths. His experience went to strongly confirm the opinion generally held that the more promptly the agent was resorted to the more efficacious it would prove. The antitoxin treatment of diphtheria, he said, was now conceded to be the greatest discovery of the century in therapeutics.

Dr. William H. Park read a paper describing the method of producing antitoxin through the inoculation of horses with diphtheritic virus.

Dr. C. H. Peck, of the county branch of the New York Infant Asylum, at Mount Vernon, described the good results obtained from antitoxin in a recent serious outbreak of diphtheria in that institution.

Drs. George P. Biggs and Ira von Gieson, of the Board of Health service, followed with short papers describing the method employed and the good effects obtained, together with the results of autopsies on the bodies of children who had died at the Willard Parker Hospital after being treated with antitoxin.

There then followed a general discussion, which was participated in by Drs. Winters, George L. Peabody, L. Emmett Holt, W. P. Northrup, W. L. Somerset, and others, most of whom agreed with the previous speakers as to the efficacy of the antitoxin treatment.

Dr. Winters said, in part: "Some months ago I hoped and expected, in company with the rest of my associates here, that a specific for the toxine of diphtheria had at last been discovered. My experience of the past three months, a personal experience dealing with 150 cases at the Willard Parker Hospital, has been a sad — an extremely sad — disappointment. I am here as the result of that experience — and I regret extremely to say it — to oppose the antitoxin treatment of diphtheria. I have watched for three months, and I say that not a single case of septic diphtheria has shown one sign of improvement under antitoxin treatment. I have asked Dr. White at the hospital — and he is here and will bear me out — not to use any treatment in this case and that case, saying the patients would recover without it. And they did recover. Statistics seem to be the principal part of the papers here to-night, but I wonder if you have noticed that a larger part of the statistics consist of elimination. 'We exclude this and we except that,' they say. Dr. Biggs did not tell you that in December we had eight consecutive recoveries in diphtheria without antitoxin. I can show you by the records that Dr. Biggs has, that in a group of eight cases two were given the first injection on the eighth day, and they recovered. Two more were given the first injection on the fourth day, two on the fifth day, and two on the sixth day; and they all died. I can show you further by the record that the stronger the dose, the worse the result; the weaker the dose, the better the result.

"I have daily examined every case sent to the Willard Parker Hospital for three months. I have seen many cases on the list which Dr. Biggs quoted in which there was not the slightest clinical evidence of diphtheria. . . . There are more than a score of cases of that sort. There may have been the bacteria of diphtheria, but not the clinical evidence of the disease. Almost every case examined bacteriologically comes back from the Board of Health as diphtheria. This is the general statement made to me by physicians in every part of the city. The statements made here to-night are absolutely worthless — they show nothing. . . . There is a difference between individuals in their susceptibility to the same quantity of the same drug. But we have assumed that we are treating animals — that the serum will act on all alike. This difference in susceptibility explains the unfortunate death of Miss Valentine, of Brooklyn. It explains the deaths in all the fatal cases I have alluded to. When a bacteriological diagnosis, in the absence of

any clinical diagnosis, can force the poor and unfortunate into a contagious disease hospital, then I say that such a diagnosis becomes a crime. Antitoxin is dangerous in its immediate effects on the kidneys and the nervous centres, dangerous in its effect on the blood, dangerous to life."

Dr. Winters then proceeded to describe in detail the unfavorable effects of antitoxin as they have come under his observation — the great rises in temperature, the unnatural position of the head, the severe pains in the joints, etc. — and mentioned several deaths which he believed were due to the remedy and not to the disease for which it was employed.

In reply, Dr. Biggs characterized many of the statements and inferences made by Dr. Winters as distinctly untrue, and stated that no cases of diphtheria were sent to the hospital which were not reported to the Board of Health by practising physicians as diphtheria. He said, in part: "He (Dr. Winters) has omitted to explain why the mortality from diphtheria is still 10 per cent. lower in this city than it was last year. How and why are diphtheria epidemics milder all over the world this year than ever before? Why has the mortality been reduced in every city in the civilized world?"

At this meeting of the Academy of Medicine a fine oil-painting of the late Dr. Valentine Mott was presented to the Academy by his daughter, Mrs. Isaac Bell, the presentation speech being made by Dr. A. H. Ely. A resolution, proposed by Dr. Wm. M. Polk, was adopted providing that the first meeting of the Academy in May should be devoted to memorial exercises in honor of Dr. Mott. On this occasion addresses will be made by Dr. L. A. Stimson, Chancellor McCracken, of the University of the City of New York, and Ex-Mayor Abraham Hewitt.

Resolutions, presented by Dr. Smith, were also passed, asking the Legislature to divide the present Department of Charities and Correction into two separate departments.

---

At the last meeting of the Section on General Medicine of the New York Academy of Medicine, the paper of the evening was by Dr. Louis F. Bishop, entitled

A REVIEW OF THE PRESENT STATE OF OUR KNOWLEDGE OF GOUT, AND A DISCUSSION OF ITS COMPARATIVE FREQUENCY IN AMERICA.

In it he expressed the opinion that the disease was infrequently met with here in comparison with its prevalence in England. One reason for this he believed was because the country was so much younger, and another was the comparatively small amount of sour wine consumed here. "Unfortunately," he said, "the drinking of sour wine is becoming more frequent with the growth of American vineyards and the manufacture of native wine."

In the interesting discussion which followed the paper Dr. William H. Draper spoke on the theory of the nervous origin of the disease which had been referred to by Dr. Bishop. Although it was as yet very incomplete, he considered it of very great importance, and thought this must be admitted by every one who has seen much of the gout. It seemed to him that there was a very striking analogy to a purely nervous disease in the mode of attack, especially its suddenness. He thought that the importance of the uric-acid theory was possibly exaggerated, and that there was a tendency on the part of many to draw too sweeping conclusions from chemico-pathological examinations. Personally, he had met with many persons who had an inordinate amount of uric-acid in their blood, and yet who did not suffer from gout; and other persons whose systems contained very little of it, who did suffer from the disease.

The gouty habit, he remarked, was a constitutional vice. This he believed was clear, because it was hereditary — just as hereditary as form and feature. Another characteristic of the habit was that it was apt to be associated with one other important disease in the same individual, not often in members of the same family. This disease was diabetes, which he considered to be unquestionably a gouty affection.

As to the treatment of gout, he said he was not in accord with the popular notion as to the efficacy of abstinence from meat diet. He had met with numerous cases in which a meat diet proved to be the best. At some future time he supposed it would be discovered why persons who ought not to eat animal food, but do eat it, cannot take the carbo-hydrates, which they ought to eat. As to the use of alcoholic beverages, it was his experience that gouty patients find that if they drink spirits they meet with no inconvenience, but if they take malted liquors or wine, they suffer. As to the efficacy of various mineral waters which had been vaunted in the treatment of this disease, it seemed probable to him that perhaps, after all, the most effective thing about such waters was the water part. In other words, pure water taken in the quantities that persons who go to the so-called medicinal springs usually drink of mineral water would do just as much good as the latter.

Dr. F. P. Kinnicutt expressed the opinion that gout was considerably more prevalent in America than was generally supposed. As regards the diet for gouty patients, he had found that in some cases animal food and carbo-hydrates did not go well together, but that either kind did well by itself.

## Recent Literature.

*Text-Book of Hygiene.* A Comprehensive Treatise on the Principles and Practice of Preventive Medicine from an American Standpoint. By George H. Rohé, M.D. Third Edition. Philadelphia: F. A. Davis Company. London: F. J. Rebman. 1894.

Dr. Rohé's work comes to us revised and considerably enlarged, and in every way improved. Public and private hygiene receive due attention, the progressive character of preventive medicine is fully recognized, and the book has been made to conform to recent advances in sanitary science.

The book is prepared with a series of questions following each chapter, to adapt the work to class-room use.

The chapters on quarantine and marine hygiene have been revised by Surgeon-General Wyman and Dr. Geddings of the Maine Hospital Service and by Medical Director Gihon of the U. S. Navy. The added chapters upon examinations of air, water and food have been contributed by Prof. Seneca Egbert, as well as that which relates to vital statistics.

## PSYCHOLOGICAL INTERPRETATION OF HYSTERICAL ANESTHESIA.

PIERRE JANET, known for his investigations on automatic states and works on the psychology of the hysterical,[1] has attempted an explanation of hysterical anesthesia accepted by Dutil in his monograph on hysteria[2] as the best yet given. He refers the anesthesia, as well as other of the paralytic stigmata of hysteria, to an enfeeblement of the higher functions of the cortex; in fact, there is now a general consensus in attributing this disease to anemia and malnutrition of the cortical centres. The idea of a narrowing of the field of consciousness, corresponding to the contraction of the field of vision, as the basis of the anesthesia, is peculiar to M. Janet's "interpretation." In brief, his explanation is substantially as follows:

Hysterical anesthesia is a species of *distraction*. In the normal individual under the influence of voluntary abstraction phenomena are witnessed not entirely differing from those which characterize the anesthesia of the hysterical. A person is engaged in his ordinary occupation and does not hear the din of the crowded city or perceive objects or contacts; he is, we say, busy with other things. When the attention is strongly applied to a subject of interest, even violent sensations may fail to elicit any response. Pascal forgot his physical sufferings while endeavoring to solve a problem. Now, hysterical persons have such distractions intensified. It is easy to produce in them by diverting their attention momentary insensibilities which have all the characters of their permanent anesthesias.

At the same time, the permanent *stigma*, the hysterical anesthesia, cannot be altogether likened to a distraction pure and simple. It is more enduring and is more clearly defined. It exists even when the attention of the person is not engrossed by a fixed idea or some external object. It does not disappear when he desires it, as in the case of the transient insensibilities which accompany distraction in the normal individual. The latter, it is true, does not hear the noises of a large city, the ticking of a clock near him, etc., and yet he can hear them if he tries to. There is, then, in hysterical anesthesia, which is a pathological phenomenon, something more than there is in distraction, a normal phenomenon.

In order to understand the differences which distinguish these two states, as well as their resemblances, it is necessary to have well in mind the psychic mechanism of the *perception of sensations*. We may represent this as an operation occurring in two stages. In the first stage various sensory impressions come to the cortex, constituting the elementary psychic phenomena, the consequence of multiple peripheral excitations (tactile, visual, auditory, etc.). These are the elementary sensations — primary states of consciousness. So far the notion of the personality of the subject does not come in. In the second stage a reunion, a synthesis, is effected of these elementary phenomena with the vast notion of personality, that is, with that aggregate of memories, of past sensations, of facts previously acquired, which constitute the idea of personality, the consciousness of the ego. It is this assimilation of new sensations by the conscious personality which enables the subject to recognize, that is, *perceive* them as like or unlike. Janet calls this *personal perception*.

Now the man best endowed is incapable of thus regrouping together, at each instant, in one same personal perception, all the elementary sensations awakened in him by the innumerable excitations which constantly assail his various senses. A great many of these elementary sensations are not included in his personality. They have not passed the threshold, and remain thus, *unperceived* but *real*, in the state of *sub-conscious* sensations. The maximum quantity of sensations which the subject can at a given moment assimilate, re-group in his personal perception, will give the measure of the *extent of his field of consciousness*.

Suppose the case of a normal individual listening to a lecture. He will perceive a certain number of sensations, auditory, visual — the words, the voice of the lecturer, his attitude, his gestures; but all the rest, the tactile, thermic, muscular impressions which he may receive at the same instant, will pass unperceived, and remain in the state of sub-conscious sensations. If instead of listening to a lecture, he undertakes immediately after the solution of a problem in algebra, his field of consciousness will be occupied by another series of sensations and images, all other sensations remaining in their turn in the state of sub-conscious phenomena. But by reason of the alternation of perceptions, as fast as he applies his attention to different objects furnishing different sensations, he will be able at last to perceive all the impressions. By this we can understand what is distraction, simple and normal.

Suppose now the case of a patient whose mental activity is enfeebled, whose field of consciousness is in a certain sense contracted to the point that he can no longer perceive at once more than a very small num-

[1] Pierre Janet: L'état mental des hystériques, etc. 2 vols. Paris, 1894.
[2] Traité de Médecine, t. vi.

ber of sensations; this person will neglect little by little to attend to the sensations which are least important for his habitual duties — the tactile sensations, for instance — applying himself to those, more indispensable, of hearing and of sight. During a certain period he will still be capable of heeding those neglected sensations and of rearranging them momentarily in the field of his personal perception when his attention is directed to them; but at length the "bad psychologic habit" is formed, and the time comes when he no longer can perceive them consciously; we prick his arm and to his surprise he does not feel the prick. After having been "distracted" (*un distrait*) with regard to these sensations, he has finally become anesthetic. The anesthesia of hysterical persons is then a symptom of weakness, of mental torpor; it is the consequence of the narrowing of the field of consciousness. These patients being able to grasp and include within their personality only a very small number of sensations, insensibly accustom themselves to direct their personal perception always toward the same group of sensations, and they come at last to the point where they can no longer apply it to the group of sensations which they have formed the habit of neglecting.

These theoretical considerations enable us to understand why at the onset of their malady, young hysterical patients have no anesthesia. They have only transient insensibilities, mobile at will, which the least distraction brings into being and which a little attention suffices to dissipate; at a more advanced stage, these insensibilities tend to become fixed and permanent. A more forcible appeal to the attention is then necessary to bring back momentarily the personal perception of sensations becoming more and more faint. Those sensations which are not perceived by the personality are nevertheless real; they are not entirely lost. They persist and continue to act in the latent state beneath the horizon of consciousness. In this sub-conscious state they may still have motor effects and influence other ideas. Most hysterical patients under hypnotism recover these impressions which were not consciously experienced during the waking state.

If we apply to hysterical anesthesia these essential notions, we may say that this morbid condition consists in an enfeeblement of the personal perception, which is limited to a certain order of sensations, to the exclusion of others. The other sensations unperceived and remaining in the sub-conscious state are nevertheless real, persist, act, and take part in the automatic functionating of the person's mind. We can understand why these anesthesias are sometimes systematic, elective and mobile; why they disappear temporarily by suggestion, or when by any means the attention of the subject is forcibly directed to certain of these sensations apparently lost; also why these anesthesias are aggravated when the patient is distracted by a reverie, by the obsession of a fixed idea, etc.; why, in fact, since the sensations which seem not to be perceived exist in reality in the sub-conscious state, these anesthesias do not entail grave perturbations in the automatic functions of these patients; finally, why these anesthesias are a matter of indifference to the patients and sometimes exist without their knowledge. Janet thinks that the interpretation which he has proposed of the tactile anesthesias may equally be applied to all the sensorial anesthesias, and that it makes comprehensible the particular characters of hysterical amblyopia. It is quite natural that the patient should neglect from the first the sensations which correspond to the eccentric parts of the visual field, and that he should perceive only the images the nearest the point of fixation. Hence the concentric form of the contraction of the visual field.

## INSPECTION OF MEAT.

Dr. Legge, in a paper entitled "Notes on some Continental Abattoirs," contributes certain valuable information to *Public Health*[1] upon the inspection of meat. He acknowledges that England is about twenty years behind the Continental cities in this matter. It is unnecessary to estimate how much behind some of our own American States would be placed; but the subject has its interest in connection with bills to promote or hinder inspection of food products now or lately before State Legislatures.

In Paris the seizure of meat is considered justified and is made (1) when deprived of all edible qualities; (2) when the eating of it might be followed by injurious consequences; (3) when from some reason or other it has derived qualities rendering its taste repugnant.

Under the first head comes the flesh of animals that have been killed too young, and of those that are either dropsical or cachetic; under the second that of animals affected with disease, such as fever, septicemia, anthrax, tuberculosis, etc.

The signs which guide the inspector in condemning the flesh of cachectic animals are chiefly the wasted condition, the absence of fat about the omentum, and the lack of resistance in the muscular tissue. With regard to animals that have died of inflammatory diseases the signs are: (1) a general tarnished coloration, more or less deep red; (2) a capillary injection of the fat, which in extreme cases is penetrated deeply by it; (3) aborescent markings on, and a tendency to a livid coloration of the serous membranes; (4) a violet tint of the kidneys; (5) a brown or blackish coloration of the spongy bone, seen best in the vertebræ; (6) loss of firmness in the muscular tissue. In Brussels the conditions under which the flesh of tuberculous animals is seized, no matter how good its general condition, are —

I. (*a*) Tubercle having its seat in both the thorax and abdomen. (*b*) Tubercle, whether it be thoracic or abdominal, with presence of tubercles in any other

[1] Public Health, vol. vi., September, 1894, p. 402.

part of the body outside these cavities. (*c*) Tubercle generalized in the following organs: lungs, pluræ, peritoneum, liver or mesenteric glands. (*d*) Tubercle of the lungs or pericardium involving the pleura extensively. (*e*) Tubercle of any organ of the abdomen involving the peritoneum extensively.

II. Tubercle observed in no matter what part of the body, or what the number of tubercles, when the animal is markedly wasted.

No slaughtering can take place in Berlin except at the abattoir, and no meat can be sent away from the abattoir without first being stamped as having passed the expert examination. The inspection is entirely in the hands of veterinary surgeons. They make first a rough inspection of the carcase, and cut into the glands of the neck, especially the retro-pharyngeal. The liver and lungs of every animal must also be cut into by the veterinary surgeon. If the appearances are suspicious, he further examines the spleen and the various glands of the body.

The flesh of all animals affected with tubercle, but not so extensively as to justify total seizure, and of those in which only a few cysticerci are found, is cooked for two hours in boiling water, and twice a week sold to the poor for a trifle.

In Copenhagen, also, a slaughter of animals can take place only at the abattoir, where the veterinary inspection also is made. All the animals are first inspected as they stand in the market, and any animal found with dangerous infectious disease is isolated and slaughtered apart from the others. None of the organs may be removed until the veterinary surgeon has been his rounds. The latter, after a general inspection of the carcase, cuts into the glands of the neck, examines the pluræ, peritoneum, lungs and liver, and should there be nothing wrong with them, allows the meat to be stamped with a blue mark as of good quality. If he finds any inflammation or suppuration about them, he undertakes a methodical examination, not only of those of the neck, but also of the submaxillary, axillary, bronchial, mesenteric, inguinal and lumbar glands. Cysticerci are always looked for by cutting into the muscles at the root of the tongue. Tubercle when generalized, is deemed a sufficient cause for seizure, but not when localized. A black stamp is freely used to mark meat as of second-class quality, which is not considered sufficiently diseased to warrant total seizure.

## MEDICAL NOTES.

EPIDEMIC OF CEREBRO-SPINAL MENINGITIS. — A representative of the Kentucky State Board of Health, who was sent to investigate an epidemic recently prevailing in Floyd County, reports that the disease was cerebro-spinal meningitis. There were twenty-five cases (with twenty deaths) in an area of four miles in a low country between two creeks. The epidemic occurred among a very poor class of people, living under the worst sanitary conditions.

MORTALITY IN THE JAPANESE ARMY. — According to *La Médecine Moderne*, the *Official Gazette* of Japan reports that from July 16 to December 6, 1894, the total number of killed and wounded was about 350, and the deaths from sickness but 430. Although the losses of the navy are not included in these figures, it is not probable that they would bring the total losses for the first five months of the war to a number greater than between 1,200 and 1,300, which is certainly remarkably small, when one considers the magnitude of the scale upon which operations have been carried on. The Japanese disposed of the bodies of their dead by cremation rather than interment.

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, April 10, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 33, scarlet fever 38, measles 215, typhoid fever 6.

A BILL TO PROHIBIT CHILD INSURANCE. — The Committee on Insurance of the Massachusetts Legislature has reported to the House of Representatives a bill to prohibit child insurance in this Commonwealth. The bill is the same as that asked for by the petitioners; it fixes the age limit at ten years, with the exception that a penalty of one hundred dollars is attached for every violation of the act.

MEDICAL REGISTRATION ACT. — The Committee on Public Health reported to the Massachusetts Senate an amendment to the present law relating to the registration of physicians and surgeons by providing that Section 10 shall read as follows: "Whoever not being registered as aforesaid, shall advertise or hold himself out to the public as a physician or surgeon in the Commonwealth, or appends to his name the letters 'M.D.' or uses the title of doctor, meaning thereby a doctor of medicine, shall be punished by a fine not less than $100 nor more than $500 for each offence, or by imprisonment for three months, or both."

### NEW YORK.

DIPHTHERIA ANTITOXIN NOT THE CAUSE OF MISS VALENTINE'S DEATH. — Dr. John M. Clayland, coroner's physician, who made the autopsy on the body of Miss Valentine, of Brooklyn, has made the following report: "Puncture on the left side of the abdomen, not penetrating the cavity; brain congested, lungs normal, blood fluid, left heart empty, right heart containing a small amount of fluid blood, liver and kidneys congested, especially the latter. No edema. Larynx normal. The fauces contained diphtheritic false membrane. Cause of death, convulsion, due to the injection of diphtheria antitoxin." Dr. Wilson, Chief Bacteriologist to the Brooklyn Board of Health, has reported officially: "Speculative theories may be advanced as to the cause of death in this case, the true cause not having yet been determined; but my experiments, conforming as nearly as possible to the actual

condition, demonstrate that the cause was not inherent in the antitoxin." Dr. Wm. H. Park of the bacteriological department of the New York Board of Health, has also reported: "My experiments lead me to express the opinion that the unfortunate results which followed its administration in this specified case cannot be attributed in any way to the antitoxin which was employed."

Anti-Vaccination Leagues. — At one time during the past winter there were a considerable number of cases of small-pox at Newburgh-on-the-Hudson, and unvaccinated children have been excluded from the public schools. The legality of this proceeding was strenuously opposed by the Anti-Vaccination League of Newburgh. On April 3d Judge Barnard refused the application of the League for a mandamus requiring the Board of Education to permit children who had not been vaccinated to attend the schools. The court held that the law of 1893, requiring vaccination, was not repealed by the compulsory education law of 1895. A despatch from New Haven, dated April 5th, announces that Harold Wilson, a Yale student who is a son of the president of the Newburgh Anti-Vaccination League, was ordered by the Faculty to leave college because he refused to be vaccinated after a chamber-maid at the house at which he boarded had been taken down with small-pox.

Saturday and Sunday Hospital Funds. — The Distributing Committee of the Hospital Saturday and Sunday Association met at the mayor's office on April 3d and distributed the undesignated fund of the collection of 1894. The sum distributed (after deducting necessary expenses and exclusive of the special amounts, aggregating $7,314, designated for particular hospitals), amounted to $40,000. The distribution was made, as usual, on the amount of free care bestowed by the various institutions during the year. The sums awarded to hospitals receiving over $2,000 were as follows: Montefiore Home for Chronic Invalids, $4,794; St. Luke's Hospital, $4,783; Mount Sinai Hospital, $4,714; German Hospital, $3,877; Roosevelt Hospital, $3,319; Hospital for Ruptured and Crippled, $2,861.

## Miscellany.

### A SUCCESSFUL CASE OF CARDIOCENTESIS.

Dr. Allan T. Sloan[1] reports a case in which the right ventricle was accidentally tapped during a hurried attempt at paracentesis of the pericardium, on a patient in extreme collapse.

The patient was a woman nineteen years old, in whom a sharp attack of facial erysipelas was followed by acute rheumatism, and finally by pericarditis with effusion. The collapse was so extreme that although there was marked increase of cardiac dulness, it was not thought safe to perform paracentesis. When this condition of things had persisted for two days, Dr. Sloan was hastily summoned by the report that his patient had just died. He found her with a pulse that could not be counted and barely could be felt, the pallor of the skin and expression of the face indicating approaching death. After two subcutaneous injections of ether the pulse and respiration stopped. The rest of the story is best told in Dr. Sloan's own words:

"In the moment of excitement I jumped up, seized the aspirator, and plunged the needle into the fourth interspace, about half an inch to the left of the sternum and a little below the left nipple. To my astonishment, from eight to ten ounces of pure blood flowed rapidly into the bottle of the aspirator and then suddenly stopped, and to my dismay I found I had penetrated a cavity of the heart. As I was slowly withdrawing the canula, regretfully telling the nurse that it was all over, and to close the patient's eyes, to my surprise the heart made first a feeble, irregular movement, then gave a sudden strenuous jump, and finally, like a pendulum regaining its swing or a runner his stride, it started to beat again in the race for life. In moments of intensity, it is difficult to estimate time, but I should say fully half a minute had elapsed between the introduction of the needle and the restarting of the heart-beats. It was an extraordinary sensation to feel the heart beating more and more forcibly against the point of the canula, which was gradually withdrawn so as not to further injure the heart-wall. I was standing thus, with my thumb on the puncture made by the needle, when Drs. Bramwell and Smith made their welcome appearance. My uppermost feeling at first was one of regret that I had converted a patient practically dead into one apparently dying, and sincerely did I lament she had not been left to pass away in peace, for a most pitiful scene was now enacted for an hour. Occasionally there was given a heart-rending shriek; quantities of frothy mucus were half-coughed, half-vomited, and had to be swept out of the mouth with a towel; the blood went ebbing and flowing from the cheeks, which were first ashy-gray then purplish in hue; the pupils were dilated to their fullest extent; the running, following pulse was quite uncountable; and the patient had every appearance of one dying asphyxiated."

To make a long story short, the cardiocentesis was followed by free stimulation with ether given subcutaneously, under the influence of which the patient became maniacal, and required morphia to quiet her. This treatment was soon followed by marked improvement. Under free stimulation with brandy and champagne, the improvement continued, and two days after the operation, the temperature fell to normal and the pulse to 40.

Within two months the patient was well enough to be sent into the country, and six months later was in perfect health.

The cure of a case of acute rheumatism, apparently of septic origin, by draining off ten ounces of blood directly from the heart is certainly a most brilliant therapeutic success. Whether the same favorable result would have followed the tapping of the pericardium, which was the operation actually attempted, of course will never be known. The stimulation of the heart-muscle by the needle puncture probably had more effect in reviving its enfeebled action than the actual abstraction of blood from its cavity. It is an interesting question whether the actual stimulation of the heart-wall by the needle or canula does not contribute

[1] Edinburgh Medical Journal, February, 1895.

perhaps as much to the success of pericardial paracentesis as the relief of pressure by the withdrawal of fluid.

In going over the literature on the subject, Dr. Sloan finds that in 1872 Roger accidentally thrust the needle through the right ventricle while tapping the pericardium for effusion, withdrawing six ounces of blood. The patient (a child) recovered, but died five months later from failure of compensation.

Other cases of cardiac puncture have been reported, some resulting in relief, but none in permanent cure. In view of these facts, and of the numerous reported cases of the survival for a longer or shorter time, and even in rare cases of recovery after wounds of the heart-wall, Dr. Sloan concludes that, in all cases of asphyxia, such as suffocation by drowning, carbonic-acid poisoning, accidental hanging, and chloroform narcosis, after other remedies have failed, this one should be tried. If an aspirator needle is not at hand, puncture with a hypodemic syringe might give surprising results. In all desperate cases of engorgement of the right heart, where death is imminent, even when due to pneumonia or bronchitis, when other remedies have failed, Dr. Sloan thinks that "a possible chance of saving life might be lost if cardiac aspiration were not attempted."

## Correspondence.

### LETTER FROM DENVER.

Commonplace Facts for Prospective Sojourners.

Denver, Col., March 28, 1895.

Mr. Editor: — I read with much interest, in a recent number of the Journal, a communication from Redlands, Cal. Your correspondent touches also upon a point which seems to me much neglected by many physicians in sending their patients to distant health-resorts. The ways and means of living in such places are too often overlooked, even by physicians who are professedly acquainted with various resorts, in favor of a theoretically perfect climate. This oversight is even more marked in the published articles of climatologists, which, valuable as they are in other respects, often fail to tell the facts most desired by the general practitioner. A table of mean temperatures and relative humidity may point to the speedy death of tubercle bacilli, but it may be equally poor diet for a man; and the warmest, dryest air may not compensate for greasy and unsuitable food.

Having had occasion to spend the past winter in Denver, many of the ways of living here have come under my notice. It may be of interest to your readers to know some of these unstatistical, practical facts.

Denver is about twelve miles east of the foothills of the front range of the mountains, and lies domestically, though not municipally, on both sides of the South Platte River, which runs from south to north. In the middle of its way through the city, it trends about thirty degrees to the east. The westerly bank rises in a sharp slope about one hundred and forty feet, while this elevation is not reached on the east till about two miles from the river. The valley along the river is naturally given over to factories and the numerous railroads. The smelter works are about two miles and a half to the northeast and in the river basin. As the prevailing winds are from the south and southwest, they drive the smoke from the increasingly numerous factories, all of which burn soft coal, down the valley through the city. This is ordinary smoke, though plentiful. A change of wind to north or east drives this back, and with it sends the suffocating acrid smoke from the smelters into the city. Clean linen is here a virtue, a struggle and an expense. To get clean fresh air one must live out of the city at least two miles to the east. To the west the quick rise makes a less distance needful, but the west side is not the desirable district for a residence.

Now, accommodations for living in such parts of the suburbs as are free from smoke are not easy to find. There are boarding-houses in abundance, of course, but few suitable for an invalid, as a large proportion of the families who take boarders have members suffering from pulmonary disease. There is consequently the infected air of the house and the depression of sickness.

Aside from the fine residences of the wealthy, most of the houses are small. They rarely have a veranda at all suited for an invalid; and by actual count over many blocks more than half were on the north side of the house. A surprisingly large number of the moderate-sized houses have but one window on the south side and all the chambers on the north. In a country where there is so much strong sunshine this is of less importance but it is still a disadvantage.

Far harder than to find a pleasant house, is it to find fit cooking. There are good cooks in Denver, as I know from kind hospitality; but they do not abound in the homes of those who take boarders, general or "private." Fried and fatty, is the rule. I have personal friends here this winter who have changed from one good "first-class" house to another four times in as many weeks, jumping each time literally from the frying-pan. For a person of limited means it is even more difficult to get good food. It is not the fault of the material, for meats are excellent and cheap, but of the western custom of cooking. This difficulty of getting a good boarding-place is not confined to Denver, and is probably less here than elsewhere; but, where even the best are poor, one should come prepared to spend no short time in getting settled. I was considered exceptionally fortunate in doing so after two weeks' hunt.

Should one desire to keep house, there is less trouble. There are many small houses to be had. A comfortable house of six or seven rooms, in a locality both socially and atmospherically good, rents for from twenty-five to forty dollars a month. All the houses are of brick and few have an air-space between the bricks and plastering. The woodwork, no matter how well done, soon shrinks and pulls away, so that the cracks are many and large. The soil is so dry that few cellars have any flooring. Within the city there is both electric light and excellent gas. Most of the suburbs have electricity, but between them and the city there is a limbo of kerosene twilight.

Domestic service is high and poor. A servant to do general housework for a small family gets twenty or twenty-five dollars a month, and for good help more must be paid. There is the usual difficulty in getting them to live out of town, and help of the ranch variety is hardly trained to cook for invalids.

The subsequent cost of living does not vary much from that in the East. Meats are very cheap and of first-rate quality. Game is plentiful and of low cost. Groceries are higher than in Boston. Vegetables are abundant. The fuel is soft coal and lignite, and costs about four dollars and a half a ton. Anthracite brings nine dollars a ton.

The most important single feature to be sought in choosing a house should be a veranda or balcony sheltered from the wind and with a southerly exposure. On such a piazza an invalid can sit with light wraps for from four to seven hours a day all through the winter, even when the temperature of the air is as low as twenty. Being out of the wind, the thermometer in my south loggia has often been forty degrees higher than the air around. For one who does not succeed in finding such a house, the large and attractive City Park gives opportunity for sitting out-doors away from the street. It is abundantly supplied with *comfortable* seats, and is in the part of the city suited for an invalid.

For occupations the visitor has, first, the street-car rides. They are many and interesting. The cars, run by cable or electricity, are in pairs, one open and one closed; and there are few days in the winter when the open car can not be used. With a rug over one's knees the riding is

no exposure provided it is not windy. For ten cents one can ride fifteen miles in view of the magnificent mountain range. A generous system of transfers allows many changes of route. Horse-hire is cheap, if not taken from large livery-stables. In the outskirts of the city where we are living, I can have a saddle-horse kept for nine dollars a month. At many of the small ranches you can hire a buggy for an occasional drive. At present I have the use of a saddle-horse every morning, as the ranchman uses it only in the afternoon, for a dollar and a half a week. Another member of my family has a much better horse for which we pay thirty cents an hour. Such bargains are readily made if you live away from the city.

Society in Denver itself is delightful, but living away from town here is not like living in Brookline. It means more or less complete isolation, according to the distance. We have one house within half a mile of us, though we live within five miles of the City Hall. The school facilities, for one who has children to bring with him, are most ample and excellent. There are two good libraries whose privileges are generously open to strangers. There is a fine athletic club and the beginnings of a country club.

A few features of the climate are worth mention, though they seldom appear in the climatological schedules. Many days, though warm and sunny and statistically perfect, are far too windy for any but the strong to be out in. While the wind may last but a short time it rises suddenly, and the exposure in reaching home may be great. The dust-storms are less frequent, but more trying. The changes in temperature are marked and sudden, and while they have little effect on the total thermal result of the month, they are a tax on the vitality of an invalid. I do not speak of the extreme cold this winter, which is unusual, but of the alternations on single days which have been called to my attention as typically fine days. It is no safer here than in Boston to go far from home without a wrap. March here is warm, to be sure, but it is blustery.

The attractions of Denver as a city, and the advantages it offers of several suburbs, such as Montclair or University Park, which are entirely free from smoke, make it an excellent headquarters for an invalid. The tables of climatologists tell us the therapeutic value of the climate, but they can give no picture of the charm of continued sunshine and soft dry air, or of the wonder and joy of each successive fine day. They give us few facts beyond the averages of meteorological conditions; and yet these commonplace facts play a large and important part in an invalid's life. It is in hope of being of aid to some prospective sojourner, that I venture to send you so plain a tale.

Yours truly,

CARROLL E. EDSON, M.D.

## IN MEMORIAM. J. M. CHARCOT.

MR. EDITOR: — We wish to call the attention of the physicians of Boston to the fact that a fund is being raised to commemorate by a suitable memorial the remarkable services of the late Dr. Charcot, and that, although no special committee has been formed to receive subscriptions in Boston, the undersigned gladly undertake this office.

Charcot was one of the physicians through whose name and work this century will stand distinguished. Unknown and penniless at the beginning of his career, his industry early gained him the honors of a trained observer, while his genius and imagination enabled him to throw light into the dark corners, not of neurology alone, but of many departments of pathology and medicine.

To his intelligence and energy it is due that the Salpêtrière was transformed from an almshouse unknown to physicians, into a great hospital, to which young men, ready to work hard at original research, were eager to flock, with what results for the progress of medicine we all know well.

We believe that the physicians of our city will be glad of this opportunity to honor the memory of a great man and a great physician.

The amount subscribed here, however, is still considerably less than that subscribed in New York and Philadelphia.

Subscriptions have been received from the following gentlemen, in sums varying from two to twenty dollars: R. T. Edes, G. L. Walton, George B. Shattuck, H. P. Bowditch, Walter Channing, James J. Putnam, J. B. Ayer, H. B. Howard, F. B. Greenough, F. C. Shattuck, P. C. Knapp, and the Medico-Psychological Society.

Dr. C. A. Herter, of New York, is Secretary of the Committee having charge of the subscriptions in this country.

The memorial will consist in part of a statue, to be placed in the Salpêtrière.

JAMES J. PUTNAM, M.D., 106 Marlboro' St., Boston.
PHILIP COOMBS KNAPP, M.D., 33 Marlboro' St., Boston.

## VIVISECTION: A REPLY TO H. C. WOOD, M.D.

BOSTON, April 8, 1895.

MR. EDITOR: — Although most physicians might deem themselves competent to act without advice in the matter of replying to the temperate appeal of the American Humane Association, words of wisdom and solemn warning addressed to us in a judicial spirit by those eminent in the profession should be treated with consideration and due deference. In his communication in the last number of the JOURNAL, Dr. Wood does not fail to appreciate that he has assumed a somewhat delicate task; and the preliminary excuse which he deems it incumbent to offer for tendering gratuitous counsel, though not very flattering to our self-pride, may upon the whole be accepted, and perhaps in a spirit of thankfulness. He should certainly be encouraged in all reasonable efforts to guard us from committing indiscretions such as might make us appear eccentric or ridiculous in the estimation of the laity. When, however, he makes delinquencies upon the part of distant colleagues a pretext for observations not strictly in harmony with facts, he must not be surprised if we subject him to a little catechising.

Does he really believe that New England physicians are likely to be taken in by allegations which involve the "wildest fanaticism?" If not, what emergency then calls for this unsolicited advice?

Dr. Wood, who is an erudite and experienced teacher and writer, understands that novel, sweeping assertions should be backed by some well-authenticated evidence, especially when addressed to medical men upon scientific questions; and he therefore begins by putting forward a proposition designed to meet just this requirement. But, strangely, in the single paragraph cited to reinforce his philanthropic appeal, and which, by the way, I have searched for in vain in the documents mailed to me, he utterly fails to designate an erroneous or even inaccurate statement. It is perfectly true, precisely as stated in the paragraph quoted by him with unqualified disapproval, that in most of our States scientific experimentation has not yet been hampered by restrictive legislation; and for the reason most creditable to our profession, that vivisection has been practised, as I believe, humanely with intent to minimize suffering. Hence attempts at prohibitory or restrictive legislation have generally been ineffective; and Dr. Wood, who writes not without premeditation or careful preparation, does not advert to a single State law directed against experiments upon animals. Indeed, shying from this point, he falls back with tinsel logic upon the general laws against cruelty which are not under consideration.

Now, is it not possible that this advocate of decorum has underrated our intelligence when he expects us to acquiesce in his declaration that "the college instructor or student is just as liable to punishment as is the carter or huntsman who abuses the horse or dog?" For why should we not know, just as well as he knows, that while all are indeed *amenable* alike to general laws, there can be no comparison between the liability to apprehension and punishment for

acts of manifest brutality committed in public, and cruelty, perhaps legitimate and justifiable, inflicted by physiologist or students in pursuit of scientific investigations and within the walls of the private laboratory?

From the tenor of the circulars issued, and in view, moreover, of the high standing and intelligence of many who have seen fit to identify themselves with this organization, I can conceive of no ground for the unsympathetic imputation of present or future dishonesty or bad faith. Over-enthusiastic reformers, as well as some officious counsellors, are too apt to base their extravagant protests upon fictitious reports or perhaps a misapprehension as to essential facts, and thereby unwittingly furnish ammunition to the adversary. All such emotional effusions, whether emanating from reckless agitators or distinguished scientists, may with propriety be treated with indifference, as the product of a morbid psychological state forming one of the manifold manifestations of hysteria. In the exceptional instance of the circular in question, the object appears to be an honest attempt to elicit from medical men a recorded expression of opinion in a matter concerning which they are especially qualified to judge and in which their views may therefore carry more than ordinary weight.

Yours with respect,

ARTHUR H. NICHOLS, M.D.

## A REPLY TO PROF. H. C. WOOD.

CAMBRIDGE, MASS., April 6, 1895.

MR. EDITOR: — It is not in accord with my ideals of professional honor and veracity, to quote from a printed document, a garbled extract, and — omitting all mention of the proofs that immediately follow on the printed page — to boldly denounce it as a "lie." That offence Prof. H. C. Wood has unfortunately permitted himself to commit in the letter which appeared in your issue of this week. I shall not follow his example, and call his untruths by the Saxon word "lies," because falsehood implies deceitful intent,— and Professor Wood is a member of the medical profession, to which I have the honor to belong. It is more probable, I fancy, that, blinded by the white heat of his well-known enthusiasm for that unbounded liberty which led Magendie and Claude Bernard into infamous cruelty, he forgot, in his zeal, that as an apostle of science, his first duty was absolute accuracy and fidelity to fact; and that no skill in the laboratory excuses forgetfulness of the decencies of debate. Still, "it is astounding, that even the wildest fanaticism" should permit a man of his standing to be guilty of perversions so easily detected and so absolutely unfair.

(1) Professor Wood makes no quotation from either of the two circulars issued by the *American Humane Association*, though he speaks of their "positive false statements." The slip from which he prints an incomplete extract is simply a letter from the President of the Association, and it formed no part of the general investigation.

(2) *His quotation from this letter was garbled.* "To garble," says Webster, is "to pick out such parts as may serve a purpose," and that is what he did. Permit me first to quote the few words which so unduly inflamed him, and to follow them with that proof of their accuracy which Professor Wood most carefully omitted in his letter to you:

> "While State laws generally prohibit cruelty, yet, *in the great majority of cases, there is no law, no college rule, or regulation even*, preventing the infliction upon living animals of the utmost conceivable torture, *so long as it is done within the walls of the college laboratory and by permission of the instructor.*"

This statement Professor Wood stigmatizes as false. But why did he omit and evade the evidence on which it rested, and which immediately follows?

> "*The proof of this statement rests upon replies made by different college presidents to letters of inquiry.*
>
> "President Harper of the University of Chicago writes: 'We have not thought it wise to place any restriction upon experimentation involving prolonged or severe pain.' President Patton of Princeton said: 'The College of New Jersey has not defined or limited the extent to which living animals may be subjected to pain.' President Dwight of Yale, answered: 'We have had no occasion to lay down any definite restrictions as to the matter to which your refer.' President Jordan of Stanford University, going still further, says: 'I am decidedly of the opinion that *no restrictions should be put upon the student*, except those which the professor may lay upon him.' The idea finds wide acceptance that infliction of extreme pain is simply a question for the instructor to decide. 'We have felt that the matter could be safely left *to the discretion of the preceptor*,' says President Rogers of the Northwestern University. President Carter of Williams College states that 'the principle has always been to *trust the professor wholly* unless there seemed reason for distrust.' 'We leave the decision *to the judgment of the investigator*,' says President Day of Syracuse University. These quotations by no means exhaust the list, but they indicate the freedom that now exists."

So far from being false, the *one* statement to which Professor Wood specifically objected is absolutely, accurately true. When he asserts that a college student or instructor "guilty of cruelty," would be amenable to the laws of the land, he fights windmills; for who has ever doubted it? How does the law of the State affect in any way the bungling experimentation of a student, on the nervous system, by permission of his superior and in the privacy of the laboratory?

Apparently Professor Wood assumes that I am an anti-vivisectionist. He is wrong. Not only do I believe in vivisection within certain limits, but I have practised it. Of the four statements presented by the American Humane Association, I have signed with slight alterations — the one favorable to vivisection restricted by utility to mankind. What, then, have I opposed for the last fifteen years? *The introduction into America of the foreign ideal of scientific research*; the widening opportunity for abuse. Does one say that at the hands of a learned and expert scientific investigator "abuse" is impossible? Permit me to quote from a letter received but yesterday from a Massachusetts physician and one of your subscribers:

> "When I was studying medicine in Paris, it was the custom of a distinguished physiologist to illustrate his lectures by operations on dogs. Some of these dissections were not very painful, but others were attended with excruciating, long-continued agony; and when the piteous cries of these poor brutes would interrupt his remarks, with a look of suppressed indignation, he would artistically slit their windwipes, and thus prevent their howling! Curiosity prompted me to inquire of the janitor, whether after this period of torment, these creatures were mercifully put out of misery, and I ascertained that such animals as did not succumb to the immediate effects of their mutilations were consigned to a cellar, to be kept, unattended and unfed, until wanted for the following lectures, which occurred on alternate days. . . . I never noticed the slightest demonstration of sympathy in their behalf, except on the part of a few American students. These dogs were subjected to needless torture, for the mere purpose of illustrating well-known, accepted facts, capable of being taught satisfactorily by drawings, charts and models. . . . I entertain no doubt that barbarous cruelty was practised at that time in all the Parisian physiological laboratories, though it is probable that for novel and horrible experiments, none could rival the infernal ingenuity of that master-demon, Claude Bernard."

Who was this "master-demon?" The most renowned physiologist in Europe; a man honored with prizes by the French Academy, with a public funeral at the cost of the government, and for whose monument subscriptions were asked in England and America. But for one, much as I love scientific truth, I do not believe in methods like these, nor in that secrecy which makes them possible in American laboratories. And when Professor Wood denies that abuses occur in this country, permit me to refer him to the editorial pages of *The Therapeutic Gazette*, a journal with which he is familiar: "Vivisection is grossly abused in the United States. . . . We would add our condemnation of the ruthless barbarity which is every winter perpetuated in the medical schools of this country. History records some frightful atrocities perpetrated in the name of religion; but it has remained for the enlightenment and humaneness of this century to stultify themselves by tolerating *the abuses* of the average physiological laboratory — all conducted in the name of Science." (August, 1880.)

I am, sir, etc., ALBERT LEFFINGWELL, M.D.

## METEOROLOGICAL RECORD.

**For the week ending March 30th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—**

| Date. | Barometer | Thermometer. | | | Relative humidity. | | Direction of wind. | | Velocity of wind. | | Weather. | | Rainfall in inches. |

| Newburyport | 14,073 | — | — | — | — | — | — | — |
| Amesbury | 10,920 | 4 | 0 | 25.00 | — | — | — | — |

Deaths reported 2,112: under five years of age 706; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 228, acute lung diseases 402, consumption 250, diphtheria and croup 103, measles 27, scarlet fever 40, diarrheal diseases 19, cerebro-spinal meningitis 12, erysipelas 9, whooping-cough 8, typhoid fever 6, malarial fever 2, small-pox 2.

From measles New York 14, Brooklyn 7, Cincinnati 3, Springfield 2, Boston 1. From cerebro-spinal meningitis New York 6, Somerville 2, Boston, Fall River, Pittsfield and Amesbury 1 each. From erysipelas New York 8, Boston 1. From whooping-cough Brooklyn 3, New York 2, Boston, Worcester and Salem 1 each. From typhoid fever New York and Boston 2 each. Cincinnati and Lowell 1 each. From malarial fever New York and Nashville 1 each. From small-pox Cincinnati 2.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 30, 1895, TO APRIL 5, 1895.

The following named officers are detailed to represent the Medical Department of the Army as delegates at the annual meeting of the American Medical Association to be held at Baltimore, Md., May 7 to 10, 1895: — LIEUT.-COL. WM. H. FORWOOD, deputy surgeon-general; MAJOR CHARLES K. WINNE, surgeon; MAJOR WALTER REED, surgeon, and CAPT. HARRY O. PERLEY, assistant surgeon. They will proceed from their respective stations in time to reach Baltimore on May 7th, and upon the adjournment of the meeting will return to their proper stations.

The following named officers are detailed to represent the Medical Department of the Army as delegates at the annual meeting of the Association of Military Surgeons of the United States, to be held in Buffalo, New York, May 21 to 23, 1895: — LIEUT.-COL. DALLAS BACHE, deputy surgeon-general; MAJOR PHILIP F. HARVEY, surgeon; CAPTAIN DANIEL M. APPEL, assistant surgeon. They will proceed from their respective stations in time to reach Buffalo on May 21, 1895, and upon adjournment of the meeting will return to their proper stations.

CAPTAIN RUDOLPH G. EBERT, assistant surgeon, relieved from duty at Fort Huachuca, Arizona, and ordered to Fort Columbus, New York, for duty at that post.

CAPTAIN PAUL SHILLOCK, assistant surgeon, relieved from duty at Fort Wingate, New Mexico, and ordered to Madison Barracks, New York, for duty at that post, to relieve CAPTAIN ROBERT B. BENHAM, assistant surgeon.

CAPTAIN BENHAM on being relieved by CAPTAIN SHILLOCK, will report in person for duty at Fort Wingate, New Mexico.

The leave of absence on account of sickness, granted LIEUT.-COL. JOSEPH R. GIBSON, deputy surgeon-general, is still further extended six months on surgeon's certificate of disability.

Leave of absence for three months, to take effect on the expiration of his present sick leave, with permission to leave the United States, during May and June, 1895, is granted CAPTAIN WILLIAM C. SHANNON, assistant surgeon.

## SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library on Monday evening, April 15th, at 8 o'clock.

Dr. J. A. Tanner will report "A Case of Spontaneous Perforation of the Heart, with Obscure Symptoms."

Dr. W. T. Whitney, Dr. H. F. Vickery, Dr. J. Homans and Dr. F. B. Mallory have been asked to take part in the discussion.

Dr. E. E. Jack will present a paper on "Ophthalmoplegia Externa, total, bilateral." Discussion opened by Dr. M. Standish.

JAMES G. MUMFORD, M.D., *Secretary.*

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene, will meet at 19 Boylston Place, on Wednesday evening, April 17th, at 8 o'clock.

Dr. A. K. Stone: "Clinical Notes from Hospital Service."

Dr. Edw. Wyllys Taylor: "A Case of Tabes Dorsalis with an unusual Complication."

JOHN L. AMES, M.D., *Secretary.*

## RECENT DEATH.

DR. PETRONIO, Professor of Surgical Pathology and Teacher of Surgery in the University of Naples, died on March 1st at the age of fifty-five. He published several works, including "A Guide to Clinical Surgery." He was Director of the Hospitals della Pace and Pellegrini, and of the lunatic asylum. He also took an active part in politics, and was Radical deputy for Caserta.

## BOOKS AND PAMPHLETS RECEIVED.

Proceedings of the American Microscopical Society, Seventeenth Annual Meeting held at Brooklyn, N. Y., August 13, 14 and 15, 1894.

Cylindroma Endothelioides of the Dura Mater causing Localizing Symptoms and Early Muscular Atrophy. By L. Bremer, M.D., and N. B. Carson, M.D., of St. Louis, Mo. Reprint. 1895.

Left Hemiplegia followed by Loss of the Deep and Superficial Reflexes, Considerable Muscular Atrophy, Marked Anesthesia in the Distal Portions of the Limbs, Loss of Faradaic Irritability and Reaction of Degeneration of the Muscles on the Paralyzed Side. By J. T. Eskridge, M.D., Denver, Col.; with remarks by Frederick Peterson, M.D., New York. Reprint. 1895.

## METHODS OF TREATMENT OF EMPYEMA.[1]

BY S. G. BONNEY, A.M., M.D., DENVER, COL.,
*Visiting Physician to St. Luke's Hospital.*

IT is generally recognized among the members of the medical profession, that the treatment of empyema in all cases should be that of surgical interference, and yet there exists a wide diversity of opinion as to the best methods of operative procedure. To afford a study of these various methods, as advocated by men of authority, to compare their relative advantages, and to note the peculiar conditions, under which each is applicable, or contraindicated, is the object of this paper.

A not unimportant preliminary consideration is the influence of the etiology upon the prognosis and treatment of the disease.

Modern investigations in bacteriology have demonstrated the development of intrathoracic pus-accumulations to be occasioned by the presence of pyogenic micro-organisms; that the bacterial agents vary in their nature and properties, and in the character of the changes induced by their presence in the pleural cavity.

The principal microbes involved are the pneumococcus, the streptococcus, the saprogenic organisms and the tubercle bacillus.

The pneumococcus is recognized as the most benign organism, and occurs almost exclusively in the empyemas of children, and in the effusions following pneumonia in adults. These cases are, therefore, the most amenable to treatment, responding frequently to the simplest measures.

The streptococcus, which is present in more than half the cases in adults, and occasionally in children, is associated with a decidedly destructive tendency, progressive in nature, and giving rise to a condition requiring more positive interference.

The saprogenic organisms produce foul-smelling accumulations of pus, and furnish the necessity of still more radical measures.

Save in extreme cases, a general tubercular infection never contraindicates an operation, from which satisfactory results are frequently obtained.

The value or the recognition of the precise micro-organism involved in any instance, would seem to be more theoretical than practical. Even the effort to approximate a diagnosis of the exact species, by the gross appearance of the pus, as suggested by Germain Sée, possesses little of clinical value. The important practical thought to be emphasized in this connection, is the recognition of the existence of several species of bacteria in the exudate, endowed with varying properties, and possessing marked differences in their virulence, that the most benign of these characterize the empyemas of children and the meta-pneumonic pleurisies of adults, and thereby furnish to the physician a justification for not resorting immediately, in all instances, to the more radical and mutilating measures of treatment. In a very considerable number of cases, however, absolute certainty of diagnosis established by an early exploratory puncture with an irreproachable needle, commands the observance of the following generally accepted therapeutic indications:

(1) Prompt and thorough evacuation of the pus.

(2) Prevention of a reaccumulation by means of free and continuous drainage and by the maintenance of asepsis.

(3) The final obliteration of the pus-secreting cavity through adequate provision for the expansion of the lung and the collapse of the chest-wall.

In but few instances in medical practice, can the responsibility in case of delay be greater. The recognition of the occasional absorption and encapsulation of the pus, renders the demand for operative interference no less imperative.

The choice of the precise method of surgical procedure involves a careful consideration of all factors having a possible bearing upon the prognosis, namely, the age of the patient, the history of the case, the recent or remote origin of the disease, the existence of complicating affections, the probable degree of atelectasis resulting from prolonged compression, the presence or absence of old adhesions, the general character of the pus, and anatomical conditions of the chest-wall, such as the flexibility of the ribs and the width of the interspaces.

A conscientious estimate of the relative significance of the preceding considerations should enable the physician to choose wisely from the following general methods of treatment: simple aspiration, aspiration with irrigation, permanent drainage through a canula or rubber tube, drainage through two openings, syphon drainage, pleurotomy, thoracotomy, and thoracoplasty.

*Simple Aspiration* provides merely for the fulfilment of the first indication, the removal of the pus, ignoring the necessity for further interference. The knowledge of its theoretical and clinical insufficiency, and the realization of the disastrous results of delaying the adoption of more rational means, combine to impose much responsibility upon him who makes use of this method, except under certain conditions and limitations.

Aspiration is applicable to the early treatment of the empyemas of children, in whom a much more favorable result may be expected than in adults, both on account of the comparative benignity of the bacterial organism involved and the greater absorptive power of the system.

That there exists in children a natural tendency toward recovery, following aspiration, by means of the greater faculty of absorption, has been remarked by Godlee, Garland, Cabot, Matas and Huber. A justification of their conclusions is found in the experience of Holt, who reports 23 cases cured by aspiration in early life, out of a total of 121.

Jacobi, Branthomm, Blake and many other clinicians have recorded a considerable number of successful aspirations in children.

The simple nature of operation, the avoidance of an anesthetic, and the slight degree of shock experienced, may be urged in its favor.

It is my opinion, however, that there are three distinct objections to the indiscriminate adoption of this method:

(1) The difficulty of the complete removal of the effusion. A protracted period of convalescence is thus established during the absorption of the residue, and in the event of its inspissation the patient is exposed to a possible focus for future tubercular infection.

(2) The opportunity offered for the formation of firm pleuritic adhesions, thus preventing the fullest

[1] Read before the Colorado State Medical Society in Denver, June 20, 1894.

expansion of the lung and rendering the conditions less favorable in the case of any subsequent operative measures.

(3) The frequent reaccumulation of the pus, thereby necessitating indefinite repetitions of the operation and meanwhile subjecting the child to the manifold dangers of delay.

Authorities differ as to the number of times it is advisable to repeat the aspiration. Successful cases are reported following an astonishing number of operations, the largest of which we have cognizance being 122. This reflects great credit upon the patient. It is the consensus of opinion that recourse should be had to the more radical measures not later than the second or third unsuccessful aspiration. I am impressed with the conviction, however, that it is unjustifiable to resort to this method more than once in children, and never in adults, unless to be followed immediately by more radical measures.

It is interesting to note in this connection the views of Ashhurst, contained in a paper recently read before the American Surgical Association at Washington. He states, "No operation is justifiable unless the presence of pus is certain, unless thorough treatment by medical agents, blisters, etc., has failed, or unless the symptoms, dyspnea, etc., are so urgent as to demand immediate relief."

He objects to the preliminary use of the aspirating needle for diagnostic purposes, for fear of thereby converting a serous effusion into a purulent one. Not until the development of urgent or dangerous symptoms, does he consider it justifiable to confirm the diagnosis or to involve the aid of surgical measures.

He remarks: "The first operation should consist of simple aspiration, with antiseptic precautions. This tells us whether we have made a mistaken diagnosis or not, and if so, prevents an open operation. There is no less danger from the use of the exploring or hypodermatic needle, and we should therefore always use the aspirator."

Again, he states: "When the fluid has partially reaccumulated, as it almost certainly will do if purulent, incision and drainage should be practised, which is much better than frequent tapping, which exhausts the patient without giving much, if any, permanent relief."

It is very apparent from the foregoing statements that his choice of simple aspiration is not based upon any faith in the adequacy of the measure to effect a cure, but is made with an aim to afford temporary relief from the urgent symptoms and at the same time to establish a diagnosis, admitting that the purulent nature of the effusion, particularly in adults, almost invariably demands subsequent operative measures.

In view of the facts, namely, that absolute certainty of diagnosis can be obtained only by means of an exploratory puncture, that this, under antiseptic precautions, presents but slight risks of converting a serous effusion into a purulent one, and that the delay of operative interference, until the advent of distressing symptoms, affords additional elements of danger, it is my strong preference to make use, strictly according to the principles of asepsis, of an early exploratory puncture, to be followed, if the effusion be purulent, by the prompt and thorough evacuation of the pus, in accordance with methods to be described. To accomplish the immediate removal of the effusion however, the temporary employment of simple aspiration, preliminary to more radical measures, is recommended by Senn [3] and others.

*Aspiration with irrigation*, although considerably in vogue for a time, is now virtually obsolete, and requires but brief mention to demonstrate its impracticability. Its employment has been largely limited to children. The injection of the various antiseptic solutions through an aspirating needle following the removal of the pus, was presumably designed to prevent the reaccumulation of the effusion by the action of the irrigating fluid upon the pus-secreting surface. A consideration, however, of the mechanical and therapeutical principles involved, coupled with the observations and experience of others in regard to the employment of this method, has led me to the following conclusions, namely, that irrigation performed in this manner is exceedingly incomplete, that it is usually superfluous, and that it is frequently attended with certain dangers. I refer to the possibility of shock, and the sudden onset of nervous disturbances to be mentioned more in detail later, as well as to the liability of poisonous absorption, on account of the extreme susceptibility of the child, and the difficulty of entirely withdrawing the fluid injected.

*Permanent Drainage through a Canula or Rubber Tube.*— The underlying principle in this as well as in several of the succeeding methods to be described, is based upon the observance of the second indication, the prevention of a reaccumulation, and consists in the adoption of measures to promote a free and continuous discharge. The degree of success attained, with a few rather insignificant exceptions, is directly commensurate with the sufficiency of the drainage. The general recognition of the manifest incompleteness of the discharge effected by the introduction into the chest of a trocar with canula or rubber tube, precludes anything here beyond a simple reference to the method.

*Drainage through Two Openings*, in different portions of the chest, has been revived by the endorsements of Michael and others, who have employed this method with frequent success. A single fenestrated rubber tube enters the pleural cavity through the upper anterior orifice, and emerges lower down from the posterior opening, the object being to induce freer drainage than by a single puncture and to secure more thorough irrigation. This plan has not received general commendation, however, on account of the imperfect evacuation of the cavity affected, the irritation of the pleura produced by the tube, and the additional opportunities offered for the development of sepsis.

*Syphon Drainage* has received much attention, and is worthy of more extended consideration. Various forms of apparatus based upon this principle have been devised, the best known and most popular of which are perhaps those of Potain and Bülan. Potain's method consists in passing a rubber tube about thirty cubic metres in length, and filled with an antiseptic solution, through the canula into the chest, until the end of the tube touches the wall of the cavity. The canula is then withdrawn over the tube, which remains firmly held in place by the contraction of the soft parts around it. A clamp is placed upon the tube near the opening in the chest, and another at the end, which is immersed in water. A branch tube, connecting with the portion entering the chest, is used to introduce within the cavity the various irrigating solu-

[3] Principles of Surgery.

tions, which are subsequently withdrawn by the syphon action in the lower tube.[3]

I cannot conceive, however, that any practical benefit is to be derived from the opportunity thus ingeniously offered for the washing out of the cavity, for in simple cases the irrigation is unnecessary, and in the more aggravated cases with odorous discharges, more radical measures are demanded.

Bülau uses a long single tube in like manner as the above, provided with clamps and connected with a glass tube, which passes through a rubber stopper to the bottom of a bottle filled with an antiseptic solution. If rendered necessary by the presence of clots in the tube, suction can be made by means of a glass mouthpiece inserted through the stopper.

Immerman, an ardent advocate of this method, states that "the patients are soon able to go about, carrying their bottle with them."[4] At the Ninth Congress of Internal Medicine, held in Vienna in 1890, he reported 49 cases directly cured by this method, out of a total of 57. Upon the same occasion Curschman reported 63 excellent results out of 75 cases.[5] Eberle has since recorded generally satisfactory results from an experience of 19 cases.

The aim to be obtained in all methods making use of this principle has been to secure the proper continuous drainage without permitting the entrance of air to the pleural cavity. By this means it was designed to produce the fullest expansion of the lung and favor the obliteration of the pus-cavity by restoring the parts as fully and as quickly as possible to their normal conditions. The application of this theory, however, has been demonstrated by experience to be exceedingly disappointing and the method does not, therefore, meet with general favorable acceptance. Its chief disadvantages are the occasional entrance of air around the tube, destroying at once the syphon action; the necessarily slow and imperfect drainage accomplished on account of the weak aspirating force employed; and the liability of the occlusion of the tube by large masses of coagula.

Even Immerman, the most enthusiastic advocate of the measure, admits that "this method gives good results only in recent empyemas, in which the pus is not too thick."

Matas concludes that "the syphon method may be adopted only in recent cases, in which the expansile power of the lung is not lost, and in which a preliminary aspiration reveals the presence of a thin, liquid, inodorous pus, free from large flocculi of fibrinous masses."[6]

I would suggest, however, that it is well nigh impossible to demonstrate the presence of those fibrinous masses in the exudate by the preliminary use of the aspirating needle, and also that it is in cases of precisely this class with organic *débris* or coagula, as well as in the more simple conditions, that are exhibited the most satisfactory results of the method to be next considered.

*Pleurotomy* consists in the free opening of the pleural cavity, and provides for the immediate and thorough evacuation of its contents. A complete exit is offered to the clots and organic *débris*, and perfect facilities for a continuous discharge.

It is my opinion, that this method is indicated as an initial procedure in the treatment of all cases of empyema, excluding only the use of the single aspiration in children previously alluded to. It is admitted that pleurotomy alone, will not always suffice for the later treatment of old protracted cases, owing to the existence of certain complicating conditions.

Were this method, however, more frequently employed in the early stages of the disease, before an opportunity be given for the development of unfavorable conditions, the necessity for recourse to the severer operative procedures would result far less frequently.

It was Küster's wise motto, "Never allow an empyema to grow old."

The opening by incision into the pleural cavity may be accompanied in some instances, if necessary, by the resection of a small portion of a single rib. This should be distinguished from the multiple rib-resection, which of itself, constitutes a separate method, is subject to different principles, and indicated by other conditions. The prime object of the resection of a single rib is to enlarge the opening.

This is indicated when the ribs are too near together to otherwise allow a sufficient orifice for the escape of the pus. An additional indication is the presence of a putrid accumulation, as revealed by the aspirating needle, in which condition the provision for the discharge must be perfect.

Jacobson[7] remarks, "It cannot be too strongly insisted upon that fetor calls for a freer opening, not for washing out."

While there can be no doubt of the justification of resorting to resection in all cases associated with an offensive discharge, there may occasionally be room for discussion as to its universal expediency under other circumstances; thus in children, although the rib-spaces are narrow, I would seriously question the wisdom of invariably performing resection, although such has been the sanction of high authority. I should not consider the operation indicated in such cases until it is ascertained that a moderate-sized, soft-rubber tube will be compressed between the ribs to such an extent as to seriously interfere with drainage.

Garland states that, "when an inch of rib is removed, the cut ends immediately drop together, so that no more space is left than previously existed, and a broken rib is added to the other casualties of the case."[8]

The performance of pleurotomy, with or without resection of a rib, should be accompanied by an observance of strict antiseptic precautions, the skin, the hands of the operator and the instruments demanding most scrupulous attention. Upon the antiseptic details of the operation and of the subsequent dressings, will depend to a great extent the degree of success attained.

An important consideration is the choice of an anesthetic. Although the condition of the patient is never too desperate or extreme to preclude the question of operation, or even to justify delay, it may in some instances positively contraindicate the administration of an anesthetic.

In adults a sufficiently local anesthetic effect may frequently be secured by the employment of cocaine hypodermically, or by a spray of ether or rhigolene. If the patient is excessively nervous, however, a general anesthetic is desirable, in the absence of any specially contraindicating condition.

[8] Treatment of Pleurisy and Pneumonia, page 44.

In children, profound general anesthesia is usually necessary. Chloroform should be preferred to ether, if the condition of the patient is such as to justify its administration; it is more agreeable, more rapid in its action, possesses less danger of dyspnea from abundant secretion of mucus, is less irritating to the bronchial mucous membrane, and is not associated with a period of excitement or violent intoxication.

The coughing and strangling, incident to this stage of ether anesthesia, complicating the condition of distended pleura, and crowded or displaced organs, furnishes a source of danger too obvious to be ignored, the rupture of a bronchial tube. Two fatal accidents of this nature have been recorded by Holt. Upon the other hand, the dangers are apparent of the full anesthetic effect of chloroform upon a heart whose action is already embarrassed by compression and displacement. It is manifestly true that while a large number of cases satisfactorily undergo the anesthesia, its general employment is nevertheless attended with assured possibilities of exceedingly disastrous results.

The site of the operation is a subject of much interest, involving a consideration of certain anatomical and mechanical conditions. It is frequently urged that the incision be made in the more dependent and posterior portion of the chest, in order to secure as perfect drainage as possible. The fallacy of this is rendered clear by the appreciation of the fact that the pus does not escape *solely* in accordance with the law of gravity, but owing as well to the constant action of the intra-thoracic forces, the expansion of the lung and the pushing of the diaphragm impelling it in the direction of the least resistance. The positive objections to opening the lower portion of the chest are: the danger of wounding the diaphragm, which rises higher in children than in adults, the irritation of the diaphragm produced by the incessant rubbing of the end of the tube, and the possible occlusion of the orifice, subsequent to partial evacuation, by the ascent of the diaphragm which returns to its normal position more readily than the lung.

In view of the preceding, and in the absence of specially contraindicating signs, I should prefer the fifth or sixth space in the mid or posterior axillary line.

In this region the chest wall is thinner, the intercostal spaces are wider and the ribs are more fixed, offering less opportunity for their approximation.

The mode of performing the operation will necessarily vary somewhat according to the nature of the anesthesia and the thickness of the chest-wall. The incision, about two inches in length, should be made as nearly as possible in the centre of the interspace, parallel with the ribs.

A single plunge of the knife is hardly advisable. The use of the grooved needle devised by Cabot, which is inserted into the cavity and serves as a guide to the knife, affords a rapid method of opening the chest, particularly adapted to those cases in which local anesthesia is used. I should generally prefer, however, the most careful method of incising quickly through skin, subcutaneous and muscular tissues, forcing an entrance into the pleural cavity by means of a sharp-pointed instrument, and dilating the opening by an aseptic finger, the flow being occasionally interrupted in order to secure the gradual escape of the pus.

Drainage may be effected by the insertion of two soft-rubber tubes, of as large size as may be admitted between the ribs. These should be only of sufficient length to project slightly within the cavity.

Irritation of the pleura in the event of the subsequent expansion of the lung, may be avoided by withdrawing the tubes a little, and cutting the ends. Care should be taken to prevent the tubes from slipping within the chest. This mishap may be avoided by piercing the tubes with one or two large safety-pins, separated from the skin by a small plate of rubber or oil-silk. The use of an external continuous shield, designed to prevent the inward escape of the tube, necessitates the complete withdrawal and subsequent replacement of the tube, in order to effect its shortening.

*Irrigation of the Pleural Cavity* has attained exceeding popularity, and is being used extensively under the sanction of eminent authority, either as a simple initial procedure following evacuation, or as a regular part of daily routine.

Gaston remarks: "It is evident from the numerous reports of cases in which medicated irrigation has been resorted to during the past year, that it is growing in favor with the medical profession in different parts of the world."[9]

It is my conclusion, however, drawn from a comparative review of the experience and observations of many, that this measure, unless subject to certain limiting conditions, merits much criticism. It should never be recommended except in cases exhibiting much fetor, which exists notwithstanding an abundant provision for drainage. Save under such conditions, the injection of various sterilized and antiseptic solutions into the cavity should be discountenanced as superfluous, and positively contraindicated as possessing certain elements of danger.

Owing to the admirable drainage usually incident to pleurotomy, the liability of toxic absorption from the use of the more powerful antiseptics is indeed slight, although disastrous results have occasionally followed their use.

A much more serious development from the irrigation is the occurrence of shock, which is sometimes fatal, and the sudden onset of severe nervous manifestations resulting from irritation of the pleura.

Sears has called the attention of the profession in this country to the experience of Jeanselme in a series of forty-five cases of this nature.[10] A great variety of disturbances of nervous origin was noted. He mentions the occurrence of syncope, convulsions, hysterical and epileptic attacks, monoplegia and hemiplegia, delirium, vaso-motor or trophic changes, strabismus, disturbances of vision and inequality of the pupils, the latter being a premonitory symptom. These manifestations took place regardless of the nature of the fluid injected and rendered a necessarily grave prognosis, as over half the cases proved fatal.

The prevention of shock during irrigation, may be assisted somewhat by proper attention to the temperature of the fluid and to the manner in which it is injected. Extremes of heat or cold are to be avoided, a temperature of about 100° being the most desirable. Only the slightest degree of force should be employed in the introduction of the solution, preference being given to the gentle steady flow from a fountain-syringe or syphon.

From among the numerous antiseptic fluids recom-

[9] Annual of Universal Medical Science, 1893, vol. iii.
[10] Boston Medical and Surgical Journal, August 31, 1893.

mended for injection, my choice would be either solutions of boric or salicylic acids in sterilized water, or a dilute solution of peroxide of hydrogen, to the exclusion of carbolic acid, corrosive sublimate or iodoform.

The correct application of the dressings after pleurotomy requires the observance of strict antiseptic precautions. The demand for the most scrupulous care in this respect remains continuously and rigidly in force till the final closure of the wound.

An adherence to these principles during each subsequent dressing should prevent the pus-cavity from assuming the condition of sepsis.

An appropriate dressing may also be of material assistance in favoring the distention of the lung. It is very desirable that the lung be made to expand as quickly as possible and to the fullest extent.

Should the lung become bound down by the formation of pleuritic adhesions, when in a state of only partial dilatation, its subsequent expansion is rendered extremely difficult if not impossible.

By reviewing the mechanical principles involved in the process of lung-expansion, it becomes apparent that one function of the dressing should be to provide for the ready passage of the air from the pleural cavity, and to obstruct as far as possible its re-entrance.

The possible valve-like action of the dressing has been ably discussed by Dr. Cabot[11] who recommends the employment, external to a thick layer of antiseptic gauze, of mackintosh, sufficient in size to project upon the skin in every direction, to which it is held closely applied by the elastic pressure of the outer dressings, consisting of more gauze, carbolated cotton and a flannel bandage.

He explains: "When air is forcibly driven out of the chest by a cough, or other effort, it lifts the edge of the rubber and escapes, but as the elastic outside dressings immediately press the mackintosh again to the side, the air which could lift it from within cannot get beneath it from without. It acts, in short, as a valve, and with the aid of the movements of the chest, pumps the fluid and air from the pleural cavity. Under this form of dressing, if the lung is not already tied up, so that it cannot expand, we may look for its rapid dilatation and the quick closure of the cavity."

While several other theories have been presented to explain the expansion of the lung after entrance of air to the pleural cavity, their elucidation involves a consideration of the principles of dynamics, which does not fall within the scope of this paper.

It is sufficient for my purpose to show that at least one element among the several that may combine to promote rapid lung-expansion is the application of an appropriate dressing. The use of the mackintosh, as described, commends itself highly in theory. It may be properly questioned, however, if a generous occlusive aseptic dressing may not answer quite as well.

In the after-treatment, systematic "lung gymnastics" may be of considerable service in aiding the distention of the previously compressed lung.

Osler[12] recommends the use of the James method, which consists in the transfer of water from one large Wolff bottle to another by means of the expiratory effort of the patient.

It occasionally happens, however, owing either to the presence of firm adhesions or to the result of an unduly long period of compression, that the lung does not expand sufficiently to fill the chest. In this condition, the further obliteration of the cavity may be aided to a greater or less extent by the retraction of the chest-wall. The realization of this is particularly simple in children, in whom the flexibility of the ribs is well known. In later life, however, when the parts have become more stiffened and rigid, the shrinking in of the chest-wall and the consequent approximation of the pleural surfaces of the cavity, can only be affected by radical surgical measures.

It is under these conditions that *Thoracotomy*, the multiple resection of ribs, is indicated. This method, with which the name of Estländer is frequently associated, consists in the removal of portions of several ribs with an aim to produce a collapse of the wall of the chest. While attempting no detailed description of the technique of the operation, a few points of practical interest may be considered.

The rapidity with which the operation may be performed by expert surgeons, renders possible the use of simple local anesthesia, as almost invariably employed by Abbe and Beck of New York. The latter states,[13] "Resection of the rib itself is by no means painful, and the whole operation can be done in two or three minutes." He also remarks, "I have had but little trouble from the patient or his friends, regarding the performance of the operation without an anesthetic. It has come chiefly from the objections of the attending physician."

Notwithstanding this, it would seem that the operation as usually performed, would suggest the advisability of the employment of a general anesthetic unless specially contraindicated.

The determination of the precise number of ribs to be resected, as well as the length of each section, should be made with reference to the depth and extent of the cavity. Should the cavity be covered by several ribs, resection should be made of a variable portion of each overlying rib, the largest section removed corresponding with the point of greatest depth of the cavity. The operation may include the resection of from two to eight ribs according to the conditions present, the portions of bone removed from each varying from one to eight inches in length.

While it is frequently the custom to make use of several horizontal incisions, parallel with the ribs, a preferable method is the employment of a single subaxillary vertical incision extending from the upper to the lower rib involved.

The ribs having been exposed and stripped of the periosteum, resection is readily accomplished by means of a bone-forceps.

The pleura may be freely opened to provide for the removal of fibrinous masses and *débris*, which are scraped away, if necessary, with a blunt spoon. In some cases the condition of the cavity renders advisable a systematic curetting, coupled with an antiseptic irrigation and followed by a light packing with sterilized gauze.

A question of some importance is the length of time that should be allowed to elapse after an unsuccessful pleurotomy before recourse be had to this method.

Estländer advises against an early operation in order that sufficient opportunity be given the pleural surfaces to become transformed into "thick, firm, connective tissue."

[12] Practice of Medicine, page 871.
[13] Post-Graduate, February, 1894.

Berger has shown, however, that the most satisfactory results have attended those cases in which an early operation was adopted.

In accordance with this view, Matas recommends that thoracotomy be delayed not longer than three or four months after pleurotomy in the absence of signs of healing. It is evident that the operation should be performed, provided the general condition of the patient is favorable, as soon as the natural forces applied to produce an obliteration of the cavity have become exhausted.

Complete *Thoracoplasty* is a truly heroic method of treatment, advocated by Schede and Tillmans. As this provides for the removal of the entire chest-wall, with the exception of a skin-flap only, its general application is contraindicated, and its justification in special cases very exceptional.

My conclusions may be briefly summarized as follows:

Absolute certainty of diagnosis by an exploratory puncture with an aseptic needle; use of a single aspiration in children, followed in the event of a reaccumulation, by open incision and drainage; no justification for aspiration in adults, except as a mere preliminary to pleurotomy; the performance of pleurotomy in all recent cases, excluding only the employment of aspiration as an initial procedure in children; avoidance of general anesthesia when practicable; a single opening for drainage, not located in the most dependent portion of the chest; double drainage-tubes to extend but slightly within the cavity; the resection of a small portion of a single rib in case of a fetid discharge, or of marked approximation of the ribs; no irrigation of the cavity, unless in the presence of considerable fetor, the irrigating solutions to be introduced slowly, of proper temperature, and non-poisonous in nature; observance of scrupulous asepsis during each dressing from the beginning to the end of the case; adoption of multiple rib-resection in the event of an unduly prolonged continuance of the pus-cavity; number of ribs resected and size of section to correspond with the depth and extent of the cavity; exceedingly rare justification for the employment of complete thoracoplasty.

## REPORT OF CASES OF CASTRATION FOR THE RELIEF OF PROSTATIC HYPERTROPHY, WITH REMARKS.

BY FRANCIS S. WATSON, M.D., BOSTON.

SINCE Prof. J. William White, of Philadelphia, experimented on dogs, as to the effect of castration on the prostate, in December, 1892, and reported June 1, 1893, as the result, that rapid atrophy of the prostate followed the operation, and upon these results, and upon the well-known effect of oöphorectomy on certain forms of uterine fibroids, based the suggestion that atrophy of the senile hypertrophy of the prostate might reasonably be expected to follow castration, and urged that the experiment be tried, his suggestion has been carried out; first by Ramm of Christiania, then came reports of cases from Haynes of Los Angeles, Smith of St. Augustine, White of Philadelphia, Moullin of London, and of others from Dresden, etc. During the last year experience has been steadily increasing; and now, so far as I know, the number of reported cases is 18. The uniformity of the results in these cases is so striking that while it is as yet too early to form a final judgment as to the value of the operation, it is at least very suggestive and of great interest, and if their promise should be fulfilled, old age will have been robbed of one of its most distressing infirmities.

In regarding this claim to practically uniform success of a new surgical step, our attitude should be, as in other similar cases, critical, rather than credulous or sceptical. One thing that is noticeable is, that the record of reported cases does not contain a single failure, and that the reports do not come from one individual or one locality, but from widely separated places, such as Christiania, California, Florida, Philadelphia, London, Dresden, etc.; also that the reporters are all surgeons of high standing and are not men who are likely to record hasty judgments. I must say that when I read the report of Dr. Smith's case last year, in which he described the condition of the patient, an old man, who had had for a considerable time serious symptoms due to urinary obstruction from a typical senile hypertrophy of the prostate, and who at the time of operation had cystitis, sepsis, and beginning uremia, and was in a very dangerous condition, and in whom very speedy relief of most painful symptoms and prompt subsidence of the grave conditions (sepsis, etc.) followed the operation, and who fifteen weeks later had gained forty-five pounds in weight, urinated freely and spontaneously, and had no urinary symptoms whatever, I was strongly inclined to be sceptical with regard to this almost magical result.

The first case in which I had the opportunity to watch personally the effects of the operation was that of a patient operated on by Dr. Gavin, who has kindly offered me the opportunity of showing him here to-night, and whom I am going to ask to give you his own impression of what the operation did or did not do for his relief. [The report of this case is reserved for publication by Dr. Gavin in the Boston City Hospital Reports. I will only say that the result was brilliantly successful.]

Since Dr. Gavin's case I have operated on three patients; the opportunity to do so I owe to the kindness of my colleague, Dr. H. L. Burrell. The observations of these cases were confirmed by Drs. Thorndike, Dwight and others.

CASE I. The first patient was fifty-eight years old, he had suffered from symptoms of urinary obstruction for several years. One year ago he had retention of urine, and again three months ago. Since then he has used the catheter more or less regularly. Previous to doing so, he was threatened with attacks of retention from time to time. There was gradually increasing frequency of urination, and pain attending the act. After beginning the use of the catheter these symptoms were not relieved, but, on the contrary, became gradually worse, until during the three weeks preceding his entrance to the hospital he became an example of the most suffering form of the malady, having a painful desire to urinate every fifteen minutes day and night. This state was, I think, in part due to friction of the deep urethra by his catheter which had become roughened; but it is certain that it was not wholly referable to this cause, since well-marked symptoms of urinary obstruction had been present for several years before he had ever used a catheter, and had already reached a distressing stage.

[1] Read before the Boston Society for Medical Improvement, February 4, 1895, but now printed with changes and addenda.

When the patient entered the hospital he was unable to pass the catheter, and had retention. Between the times of passing the instrument he had been voiding a few drops of urine every fifteen minutes or so, with much straining and vesical tenesmus, and was beginning to show constitutional exhaustion from the effects of sleeplessness and pain. The urine contained a considerable quantity of blood and mucus, but was not foul, nor did it show evidence of disease of the kidneys. The patient was kept in bed and regularly catheterized five times daily with a proper instrument, and the bladder was washed with a hot solution of boracic acid at the same time. During the five days at the hospital which preceded the operation, he was unable to void spontaneously more than an ounce or two of urine in the twenty-four hours, and that only a few drops at a time, and with great pain. No benefit followed the palliative treatment, and castration was done on the sixth day. [Continuous drainage of the bladder by a catheter in the urethra was not tried before operating.]

*Operation*, January 3, 1895. The condition of the prostate, as noted by rectal examination, was as follows: The upper border of the prostate could not be reached by the finger. Both lateral lobes were markedly hypertrophied, and were both, the right more than the left, exceptionally dense and hard; this was especially marked in the lower half of the gland. The surface of the right lobe was somewhat uneven; and in the course of the vas deferens there was a hard, round body of the size of a pea, which was movable. The prostate did not project very prominently into the rectum, nor was it tender to the touch. It was unquestionably a typical example of senile hypertrophy of the gland, and had nothing whatever of an inflammatory character. Castration was performed through two incisions, one over each testicle, the operation being somewhat prolonged by the presence, on one side, of an encysted hydrocele of the cord, which was dissected out carefully in order to preserve it intact as a specimen. There was no constitutional disturbance whatever after the operation, and the wounds united by first intention.

All treatment, including the use of the catheter, was omitted immediately after the operation, in order not to confuse the result. Previous to the operation retention had followed immediately if the catheter was omitted. In the first twenty-four hours, although the bladder filled up considerably, it did not become overdistended, and the patient during this time voided at each urination more than he had done previously. There was no change in the frequent or painful desire to urinate; and at the end of thirty-six hours, however, he had an interval of one hour and a half without either pain or desire to urinate, and during the second night after the operation he slept undisturbed for two hours. On the sixth day he passed from two to four ounces at each urination spontaneously; there began to be much less pain on urination. Since then he has passed from four to six ounces at each urination. On the tenth day he was entirely free from pain, and the urine contained less pus and mucus. The patient slept two hours at a time at night, and the intervals between urination were from an hour to an hour and a half in the daytime; the residual urine was but three ounces.

Three weeks from the time of operation there was but an ounce and a half of residual urine, and the urine was almost free from pus; the patient's general condition was excellent. At this time a distinct diminution in the size and hardness of the prostate was for the first time noticeable. Within the next nine days the atrophy advanced much more rapidly; the left lobe then was smaller than normal, was flat and soft, and the right was but a little larger than normal; the gland throughout was much softer and the intervals of urination had lengthened to two and a half hours in the day and to three at night.

At this time Dr. H. W. Cushing examined the patient by rectum for the first time, and the statement I have just given of the contour and condition of the prostate is that which he made to me after he had done so. The patient was again examined two months from the time of operation. The prostate was distinctly smaller than normal. There was but one ounce of perfectly clear residual urine. The patient slept five hours at a time undisturbed. In the daytime the calls to urinate are but once in three or four hours. The patient states that he feels ten years younger, and that he can work at his trade (that of a stone-cutter) as hard as he ever could in his life. This case is another example of the complete success of the operation.

CASE II. This patient, sixty-nine years old, I operated upon January 21st, removing both testicles through a single median incision, which was suggested to me by one of my students. This incision seems to me to make a neater and quicker operation than the double one usually practised.

There was but very moderate hypertrophy of the lateral lobes; the catheter passed nine and a quarter inches before entering the bladder. This patient had been using the catheter regularly for a year previous to the operation, and had had symptoms of urinary obstruction for three years. The flow of urine as it passed through the catheter was very feeble. For the past six months he had been suffering a good deal of pain, which could not be relieved by palliative treatment; the catheter could not be omitted without producing retention; the patient could pass but a few drops at a time, spontaneously. The obstruction in this case was due to hypertrophy of the median portion of the prostate. The urine contained a considerable amount of pus, but was acid, of good specific gravity, and there was no evidence of renal disease. The patient was losing flesh, strength and appetite.

After the operation the catheter could not be omitted, the wound did perfectly well, and the patient made a rapid recovery from the operation. There has been less pain, but no other improvement in the urinary symptoms, up to the present time, forty-four days after the operation. There is no perceptible change in the size of the prostate, the character of the urine remains the same, the general condition of the patient is unchanged; so that, *so far*, the second case is a failure. It is too soon, however, to judge of the final result.

CASE III. Patient, aged seventy, entered the hospital with retention of urine. He had had symptoms of urinary obstruction for several years, and an overflow bladder for several months. He was beginning to be uremic, and his condition was critical. Operation was postponed for several days, during which time he improved somewhat.

*Operation*, February 21st. The patient had double inguinal hernia of long standing. The gut was easily reducible, but the sacs were very thick and so closely

adherent to the testes and cords that it was impossible to separate them. The sacs were therefore divided and tied, the gut being retained within the rings by firm bandages and pads. The patient was slightly delirious before the operation, and continued to be so afterward. The prostate in this case was much enlarged; the sulcus between the lateral lobes could not be reached by the tip of a very long finger in the rectum; the lateral lobes projected prominently into the rectum. There was constant and painful desire to urinate, and at times violent bladder tenesmus, the urine being expelled involuntarily, a few drops at a time, with much force; there was also frequent dribbling of urine in spite of the regular use of the catheter; palliative treatment had failed to give any relief.

During the night following the operation, the patient tore off his bandages, got out of bed, and in a violent fit of coughing forced down the hernias, distending the scrotum, and putting the wounds on the stretch. On the following day when this condition was first discovered, it was found to be impossible to reduce the hernias. The patient's uremic symptoms became more marked during the next few days; and on the ninth day he died. At the time of operation the testes were examined for spermatozoa, but none were found. There was decided relief of bladder tenesmus and pain from the third day.

*Autopsy.*— The autopsy showed very marked enlargement of the lateral lobes of the prostate, and a small median enlargement. The hypertrophy was in the form of distinct fibro-adenomatous tumors, each lateral lobe containing within a much thickened capsule, a growth about the size of a large horse-chestnut. So far as could be judged, no atrophy of the prostate had occurred. The vesiculæ seminales contained no spermatozoa. The bladder was the seat of chronic cystitis. The ureters were much dilated, as were also the pelves of the kidneys, and there was an extensive pyelonephritis of both kidneys.

In closing this short note upon this new and most interesting subject, let me say that it is, of course, of great importance for the future of the operation that these earlier cases should be carefully discriminated and thoroughly examined before and after operation by two or more competent observers. Special care should be taken not to confuse cases of inflammatory, tuberculous or cancerous enlargement with those of true senile hypertrophy, and to select for operation patients in whom the symptoms are due to this cause alone and not to other complicating conditions.

It will be interesting to see, as the number of operations increases, in which special classes of cases it is to prove successful and in which it is to fail; whether, for example, it will succeed better when there are distinct fibroid tumors imbedded in the substance of the prostate — a condition, that is, resembling that of an intra-mural uterine fibroid — than when there is a more diffuse form of growth; whether the presence of spermatozoa in the testes, indicating functional activity, or their absence, will affect the result; whether median hypertrophy will atrophy as readily as lateral hypertrophy, etc. And, finally, it will be important to note whether or not there will result later any consequences injurious to the patient that can be referred to castration *per se*.

The length of time after operation at which atrophy begins varies very much in different cases. The relief to the distressing symptoms, however, is often very rapid, sometimes beginning within twenty-four hours; this is presumably due to local circulatory changes.

The question of whether unilateral atrophy of a bilaterally enlarged prostate occurs after the removal of one testis, and if so, whether that operation may not so modify in some cases the form of the gland in such a way as to allow of the free passage of urine, has been recently raised — there is evidence both for and against the view that this may occur. The author has seen the destruction of one testis by an acute suppurative process, followed by atrophy of the lobe of an hypertrophied prostate, on the same side, and the power of partial voluntary urination restored, in one case.

## CASES OF RETRODEVIATION OF THE PREGNANT UTERUS, INCLUDING A CASE OF PREGNANCY IN AN INCARCERATED CORNU AND A CASE COMPLICATED BY AN OVARIAN TUMOR; WITH REMARKS.[1]

BY W. L. BURRAGE, M.D.

I PRESENT brief histories of six cases of retroversion of the pregnant uterus and fuller histories of two other cases that have come under my observation during the last five years, eight in all. The diagnosis of pregnancy was well established in every case.

The first five cases were treated as out-patients, and their subsequent histories are necessarily incomplete.

There were five cases (I to V) of uteri about two months gone and in the second or third degree of retroversion; four were treated by replacement by means of bimanual manipulation, or by packing and a pessary. There was one case (V) of an incarcerated uterus three and a half months pregnant, that, having been replaced, carried the fetus to term. Two years later the woman appeared with the uterus in the third degree of retroversion and two months pregnant. Of the two cases reported in full, Case VII was pregnancy of three months' developing in the incarcerated right cornu of the retroflexed uterus. In this and in the following case it was necessary to give ether to make clear the diagnosis and to replace the uterus. Case VIII was a retroflexed and incarcerated uterus four and a half months pregnant, with prolapse of the cervix at the vulva, and an ovarian cyst the size of a cocoanut. It was treated by bimanual replacement of the uterus and by ovariotomy, with the result of an uneventful convalescence and a living child at term.

CASE I. S. B., twenty-seven, married eighteen months, sterile. First seen June 1, 1891. Complained of vomiting every morning, and weakness for two months. Last catamenia March 20th. Diagnosis: retroversion, third degree; pregnancy, two months. The uterus was replaced by means of traction on the cervix with a tenaculum, and pressure on the fundus with a finger in the rectum. June 4th, a Thomas soft-rubber retroversion pessary was fitted. July 16th, the uterus was high up in the pelvis, and the pessary was removed.

CASE II. L. C., twenty-five, married eight months, sterile. First seen May 19, 1892. Last catamenia May 5th. Diagnosis: retroversion, uterus somewhat enlarged. She was packed for fourteen treatments, twice a week. Vomiting of pregnancy began June 1st, and continued. July 18th, there was no question as

[1] Read before the Obstetrical Society of Boston, Jan. 12, 1895.

to diagnosis of pregnancy. August 11th, the vomiting had ceased, and the uterus was so high in the pelvis that no support was necessary.

Case III. A. O., thirty-two, married twelve years; one child, two and a half years old; no abortions. First seen March 12, 1894. Catamenia irregular for the last two months; constant pain in the right inguinal region for the last week. Catamenia always regular until two months ago, and since then has flowed one day about every week. Diagnosis; retroversion, third degree; pregnancy, two months. The fundus uteri was replaced bimanually. March 19th, the uterus was again replaced, with the patient in the knee-chest position, and a Thomas soft-rubber retroversion pessary fitted. Patient not seen again.

Case IV. A. E., twenty-one, single. First seen March 15, 1894. No catamenia for two months; morning sickness and pain in the breasts. All the signs of pregnancy. Diagnosis: retroversion, third degree; pregnancy, two months. Not treated.

Case V. A. C., thirty-eight, married fourteen years; six children, the youngest four; two abortions. First seen May 23, 1890. Last catamenia, February 8th. Complained of difficult micturition and pain in the small of the back for two months. Diagnosis: retroversion and incarceration of uterus; three and a half months pregnant; lacerated cervix; cystocele and rectocele. The cervix was high up under the pubic arch, and the fundus jammed in the hollow of the sacrum. With the patient in the knee-chest position the uterus was replaced. April 28, 1891, she reported that she had carried the child to term, and that it had been removed dead (by version probably). The uterus was in good position.

March 17, 1893, she again came under observation. The uterus was then in the third degree of retroversion and two months pregnant. It was treated by replacement and packing for six treatments, and then it remained in place without artificial support.

Case VI. K. McC., twenty-eight, married seven weeks, sterile. First seen Dec. 6, 1894. Backache for a year, associated with dyspepsia and constipation. Leucorrhœa. Catamenia regular, of four to five days' duration, using six to eight napkins but accompanied by increased backache. Last catamenia October 26, 1894. In November flowed slightly one day. Backache very bad since marriage, also almost constant nausea and indigestion. Pains in stomach and breasts. Unable to work. Diagnosis: retroversion, axis of vagina; pelvic inflammation; cervix long and soft; uterus large, immovable and tender; breasts, suspicions of pregnancy.

She was treated by light packing with ichthyol and glycerine cotton for five treatments. Pain somewhat relieved by bromide. December 31st, the uterus being free from adhesions and having increased in size to that of two months' pregnancy, it was replaced by traction on the cervix with a tenaculum and lifting the fundus out of the hollow of the sacrum with a finger in the rectum. A little bimanual manipulation then restored it to a normal position. Cervix very soft. Discoloration of vagina. No question as to diagnosis. The uterus being so large, it was thought that there was little danger of its becoming reincarcerated and no pessary or packing was used.

January 3d, she returned and the uterus was again wedged in the pelvis in retroversion. It was again replaced, the patient being in the knee-chest position, and an Albert Smith retroflexion pessary placed. She is now wearing the pessary with comfort, and the uterus is in good position. She has been partially relieved of her nausea.

Case VII. M. X., twenty-six, wife of a physician, married three months. First seen November 23, 1893. Last catamenia September 8th. Catamenia usually regular and painless. Suffered with severe pain in left ovarian region on September 29th, after getting her feet wet. Nausea and vomiting began the latter part of October, and had persisted with great severity up to the time when I saw her. Early in November, after she had been vomiting persistently for ten days and was losing flesh and strength very rapidly, her husband introduced a bougie four inches into the uterus, and left it there over night. Next day he put in another. As a result, there was some flowing (one napkin) for a day, and relief from the symptoms for a week. A week before my visit the vomiting began again with renewed force. She could keep nothing on her stomach, vomited froth and bile every few moments, had lost fifteen pounds in weight and was becoming very weak.

Dr. X. made use of a large number of drugs without much avail. Morphine and bromide controlled the vomiting for a short time, but were poorly tolerated. November 21st, he dilated the cervix with a Palmer dilator to a one-inch spread of the blades. Since then there had been slight flowing, but no relief of the symptoms. The urine was negative. Temperature 100°.

When I saw Mrs. X., two days later in consultation, I found a tall, well-developed, dark-complexioned woman of a neurotic type. The abdominal walls were reasonably lax, so that the bimanual examination was as satisfactory as is usual in nulliparæ who are not too fat. There was some mucus and blood in the vagina. The uterus, which was enlarged to the size of three months' pregnancy, was retroflexed in the second degree and immovable. In the cul-de-sac to the right there was a mass the size of a hen's egg, that I took to be a cystic right ovary, or an extra-uterine pregnancy. The cervix appeared to be very long and the os was patulous.

It seemed best to me to give an anesthetic, in order to make a more thorough examination. Ether was given accordingly. With the aid of the anesthetic I was able to determine that the mass in the cul-de-sac to the right was not the right ovary, nor the products of extra-uterine fetation, but the enlarged right horn of the uterus that had somehow become incarcerated in the bottom of the pelvis. After considerable vigorous bimanual manipulation, I succeeded in rocking the large horn by the promontory of the sacrum, and put the uterus into its proper position. Then it was possible to map out the asymmetrical uterus and also both ovaries normally placed and of normal size. Diagnosis: pregnancy at three months in cornu; retroflexion and incarceration. A half-grain suppository of morphine was put in the rectum, and the patient put to bed.

The relief from symptoms was marked. With the exception of a slight relapse to vomiting on November 30th and December 1st, pregnancy was from this time uncomplicated; and Mrs. X. was delivered of a living girl baby, weighing five and three-quarters pounds, on April 28, 1894. I saw Mrs. X. again August 31, 1894. The uterus was then symmetrical, in good

position, and of normal size. Left ovary small. No evidence of rudimentary uterine horn.

CASE VIII. D. H., twenty-six, married two years; one child, thirteen months; no abortions. First seen October 25, 1893. Had an attack of flowing in August, 1892, two weeks after her baby was born and had not flowed since until she had a normal menstruation of five days, May 10, 1893. Was in labor five days; ether and forceps used; baby weighed ten pounds and a quarter; in bed three weeks after labor; nursed child. She noticed prolapse of the parts at the vulva as soon as she got up, and the condition persisted in spite of treatment by her doctor with packing and a ring pessary.

Early in September she thought she might be pregnant, being unable to eat her usual articles of diet, and having cravings as at her previous pregnancy. Accordingly she weaned her child. She noticed at this time that the womb came outside the body; and she suffered with dysuria and was unable to sit or walk with comfort. She also suffered from constipation and from pain above the pubes, that had been increasing in severity ever since. She complained chiefly of this pain when I saw her at the Carney Hospital, October 25, 1893. I found the cervix uteri enormously elongated, with as much as an inch and a half projecting from the vulva; deep laceration of the perineum; pelvis filled with a semi-solid tumor, apparently the retroflexed uterus about four and a half months pregnant. Above and on the right, lying on the pelvic brim, was a tumor of indefinite outline and the size of a cocoanut.

By forcible bimanual manipulation I was able to partially dislodge the pelvic tumor, and the patient was kept in bed until six days later, October 31st, when she was given ether and a thorough examination made. Dr. F. W. Johnson kindly saw the case with me in consultation. We found the fundus uteri out of the pelvis, and the cervix high; and we also made out a cystic tumor apparently of the right ovary, the size of a cocoanut.

On account of the limited space in the abdomen, and the rapidly growing uterus, it seemed best to remove the cyst by abdominal section. Having allowed a sufficient time to elapse after the etherization to prevent all fear of miscarriage, I performed ovariotomy November 10, 1893. The patient made a normal convalescence, and was delivered of a living child March 23, 1894. I saw her and her child at my office May 9th, and the uterus was then in good axis but low in the pelvis, which was justo-minor to a slight degree. I shall report the case in more detail at some future time.

In looking over the literature of the subject of retrodeviations of the pregnant uterus, I got the impression that the condition is of fairly common occurrence, and also that its early detection and treatment are of much more importance than one would be led to expect from the cursory manner in which the subject is treated by the text-books.

The most recent and most complete work on this subject that I have found is an article by Dr. Sigmund Gottschalk, of Berlin,[2] "Zur Lehre von der Retroversio uteri gravidi." Gottschalk contrasts a statement made in the last edition of Schroeder's text-book, to the effect that retroversion of the pregnant uterus is seldom found, and that most cases right themselves during pregnancy, with a statement of Chrobak's that in his (Chrobak's) experience the retroverted pregnant uterus only seldom rights itself, whereas the retroflexed gravid uterus, in a vast majority of cases, does not right itself at all.

Gottschalk makes a strong plea for the distinction of retroversion from retroflexion, and sides with Chrobak in his views as to the spontaneous righting. He thinks that it is only those uteri that were retroverted before becoming pregnant that we can expect to right themselves, and with them there is much doubt. Those becoming retroverted or flexed during pregnancy have a much more unfavorable prognosis.

To show the gravity of the condition he collected sixty-seven cases of death due to retrodeviation of the pregnant uterus; the causes of death including uremia and exhaustion, gangrene of the bladder, tearing of the bladder, peritonitis in consequence of gangrene of the bowel, and occlusion of the bowel from torsion of the uterus on its axis.

I have found a case of hemichorea in pregnancy caused by acute retroflexion of the gravid uterus, the chorea disappearing on the replacement of the uterus.[3] Also, a case of pregnancy in a retroverted uterus, with distension of the bladder and sloughing of the vesical mucous membrane, in which the patient miscarried at five months; recovery.[4]

W. S. Stewart reported before the International Medical Congress at Washington, in 1887,[5] the history of a case of retroflexed pregnant uterus, first seen when two and a half months along, which was allowed to go to term. The uterus was replaced during labor; after the os was dilated it fell back, but was again replaced, and the woman was finally delivered of a living child, and made a good recovery.

This case is to be contrasted with one reported by Wenning,[6] of dextrotorsion of the pregnant uterus simulating extra-uterine pregnancy, in which he did celiotomy at the sixth month, and the patient aborted and died of sepsis; and also with a case reported by Gottschalk,[7] where there was acute obstruction of the bowels due to a retroflexed pregnant uterus at four months. He performed celiotomy when the patient was practically moribund, and she died in twelve hours.

It is plain to my mind that retrodeviation is a complication of pregnancy that is very likely to endanger the mother's health, or even her life; and the earlier in pregnancy it is diagnosticated and treated, the better the prognosis.

As to treatment, one must distinguish clinically between the retrodeviations (1) *non-incarcerated*, and the uterus that has grown so large that the fundus cannot rise by the promontory of the sacrum, or the (2) *incarcerated*.

As to the first class, it is admitted that a retroverted and pregnant uterus, although firmly adherent, may rise up into the pelvis without artificial aid, such is the softening effect of pregnancy on adhesions. That is to say, it is possible it may not enter Class 2. It is seldom that the attending physician is able to diagnosticate a retrodeviation occurring during pregnancy from one originating before pregnancy. When seen in the early months, especially when adhesions are present, the presumption is that the malposition antedates the

[7] Loc. cit., p. 361.

pregnancy. Such a distinction is, to my mind, of no importance as far as treatment is concerned.

I contend that it is safer and that the danger of abortion is less, to treat all retroverted pregnant uteri as soon as diagnosticated, with packing and pessaries until such time as the organ has become so large that it cannot fall backward into the pelvis. This will be between the third and fourth month.

I think that there is a belief in the profession that pregnant uteri should not be treated by vaginal packing, and that packing the vagina causes abortion. This I believe to be erroneous. Certainly such treatment did not cause abortion in the cases I have reported. When the uterus is replaceable and has been replaced, it should be held in the normal position by a suitably-fitted pessary. It is well to leave out packing during the times that would be the menstrual periods.

As regards Class 2, the incarcerated uteri, the treatment is to dislodge the fundus and put it in its proper position as soon as possible. To this end ether may be necessary, although in a majority of cases the replacement is readily performed by placing the patient on her back with knees drawn up, seizing the cervix with a tenaculum and pulling downward on this, and at the same time pushing the fundus up with one or two fingers in the rectum.

When the fundus is emerging from the pelvis, I let go with the tenaculum and pushing the cervix backward with a finger in the vagina, massage the fundus forward, with my other hand on the abdomen. When this method proves unsuccessful, I put the patient in the knee-chest position and repeat the procedure.

In Case VIII, which exhibited a most unusual combination of pathological conditions, the uterus was so large, being four and a half months pregnant, that very forcible manipulation succeeded in only partially dislodging the fundus. Several days later, however, it was found in its proper position.

The small size of the child in this case is of interest. It seems probable that the surgical interference and the cutting off of the ovarian artery on one side was accountable in a measure for this. It is safe to say that had the case been allowed to take its course without surgical aid, she would either have aborted or had a difficult labor.

In Case VII, it occurs to one as strange that the introduction of two bougies four inches in the uterine cavity and subsequent dilatation of the cervix did not produce abortion. The explanation is found in the fact that the products of conception were located in the uterine horn and were not reached by the bougies.

Cases VII and VIII are striking instances of the great tolerance of the pregnant uterus; and their happy outcome, as well as the results of my investigation of the literature of the subject, confirm me in my belief that all retrodeviations of the pregnant uterus should be treated by replacement as soon as diagnosticated.

Symptoms of exaggerated backache, dysuria, intractable nausea and vomiting, or pelvic pains occurring during early pregnancy, should lead at once to a bimanual examination, and the physician should satisfy himself that the uterus is in proper position.

Sulphur from Ireland. — Sulphur was once a lucrative product of Ireland, and mines were worked at Ballymontagh in the County Wicklow. It is now believed that the mines can still be worked on profitable terms, and it is likely that they will be re-opened.

## Clinical Department.

### A CASE OF EMBOLISM OF THE RIGHT FEMORAL ARTERY APPARENTLY FROM CARDIAC WEAKNESS.[1]

BY SAMUEL L. ABBOT, M.D.

The patient was a middle-aged married woman, in comfortable circumstances, who up to the time of the attack was in fair health. There was no history of previous rheumatism or influenza. Her health had not been robust at any time, but she was not an invalid. She was in the habit of drinking beer moderately every day.

The first intimation of the attack was a moderate pain in the right foot, coming on in the afternoon. Towards night the foot became very white and extremely cold. The next morning while walking across the room the patient's leg gave way under her and she turned her right ankle painfully. There was some purple discoloration above the ankle, and the leg below the knee had become quite cold. She was still able to walk with some difficulty. The following morning, on coming down stairs, she was seized with a very acute pain in the outer cords of the popliteal space, which led her to suppose that she had ruptured something at this spot. From this time she was unable to walk. On this day I saw her for the first time, and found the outside of the leg from the knee down of a deep purple color, exactly like that of a venous clot, and there were several spots of purplish ecchymosis on the inside up to the knee. The whole leg from the knee down was extremely tender to the touch and considerably enlarged from edema; the circumference at the calf of fourteen and five-eighths inches, being two inches greater than that of the left calf. The outer hamstring tendons and the popliteal space were exquisitely tender to the touch, but no evidence of special local injury could be detected. Pain was felt on movement from the knee to the toes. Except for the local trouble the patient considered herself to be in her usual health. Her appetite was natural and her skin was cool. Her temperature, on the only occasion on which it was taken was 100°.

No pulse could be felt in the femoral artery at the groin, nor in that of the left groin. The left leg was apparently in its normal condition.

On examination of the heart its action was found to be extremely weak, pulsation 160 beats to the minute. There was a distinct want of emphasis to the second sound, and it was nearly as long as the first, the rhythm being very like that of the fetal heart. There was no abnormal cardiac murmur, no local tenderness or enlargement of the organ. At the wrist the pulse was extremely weak.

The leg was kept flexed at the knee as extension was extremely painful. Warm foot-baths were prescribed, the limb in the intervals being wrapped in several thicknesses of cotton wadding. A pill of one-thirtieth of a grain of sulphate of strychnia was prescribed, to be taken every two hours, with one minim of a one-per-cent. solution of glonoin. Five-grain tablets of Dover's powder were prescribed, to be taken, *pro re nata* for sleeplessness.

On the next day the limb was perfectly cold from two or three inches above the knee down, and the swelling was increasing upwards. The leg was not

[1] Read before the Boston Society for Medical Improvement, January 7, 1895.

painful when at rest, and was considerably less tender to the touch and somewhat less cold. The pulse had fallen to 120, but was somewhat intermittent, although stronger. The patient ate her usual amount of food with relish. The dose of strychnia was increased to one-twentieth of a grain and the solution of glonoin to two minims.

On the fifth day of the attack there was considerable edema of the *left* leg, extending half way up to the knee, without pain or discoloration, or apparent reduction of temperature. The ecchymosis of the right leg was increasing and passing around to the calf on the inside. Pulse 111, stronger and more regular. The heart-sounds were also stronger, and the rhythm was much better. There had been no uncomfortable feeling in the head from the glonoin, and the dose was increased to three minims of the solution, with five minims of the tincture of digitalis; the strychnia was continued.

On the next day the pulse had risen to 132; temperature 100°. Ecchymosis extended above the knee, with swelling and tenderness. Below the knee the leg was somewhat smaller, apparently from a constant exudation of bloody serum from behind, the cuticle being somewhat detached, perhaps owing to hot applications to the part at the outset of the trouble. The patient had had a good night under the influence of thirty grains of Dover's powder in divided doses. Her appetite was good and she had eaten a chop for breakfast.

On the seventh day there was a little twitching of the tendons of the wrist, and the strychnia was directed to be given at intervals of four hours. Pulse 102, a little irregular. Sole of foot warm. The next morning the patient was moribund, there being no pulse at the wrist.

I am led to report this case, as it must be one of great rarity. It is only the second that I have seen in a long professional experience. The first was under my care in the Massachusetts General Hospital and occurred in a patient affected with malignant endocarditis. In that case there was evidence of obstruction at the mitral valves, probably from a thrombus. In the course of the case embolism of the right femoral artery occurred, with disappearance of the cardiac souffle and the pulse in the right femoral artery at the groin. Under the use of glonoin the pulse returned to the groin, the embolus evidently being forced down the artery from the increased freedom of the circulation below, and the spots of venous ecchymosis turned to a raspberry color from the increased force of the circulation. In this case also the patient died.

In the present case there was no autopsy, and the only probable cause of the symptoms seems to have been the heart weakness. There was no gangrene in either case.

## CANCER OF RIGHT KIDNEY; NEPHRECTOMY; NO RECURRENCE AFTER EIGHTEEN MONTHS.

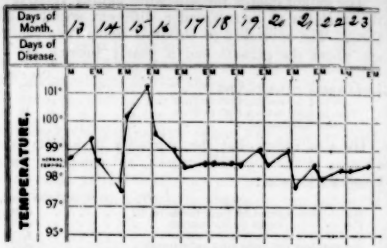
BY WILLIAM N. SWIFT, M.D., NEW BEDFORD, MASS.

A. G. T., forty-seven years old, butcher. No history of malignant disease in the family. Three sisters died of phthisis pulmonalis. Well until two years before, then began to run down. No definite symptoms until spring of 1893. Began to have night-sweats, and noticed a bunch in right side of abdomen.

I saw him in June, 1893. The patient was anemic, but showed no other symptoms except a tumor in right side of abdomen, about the size of a small cocoanut. It was just below the ribs, and extended back to the loin. Was slightly movable and somewhat tender on pressure. The patient complained of distress in the region of the tumor, but no sharp pain. Also distress in the right side of back, most marked when stooping over. Could not lie on left side at night, as it increased distress. Micturition frequent and little at a time. Marked sagging feeling in both testicles, and at times some pain in right testicle. The patient complained of weakness and profuse sweating. Urine normal in quantity, but contained small amount of urea. No albumin or abnormal deposit.

A diagnosis of probable tumor of the kidney was made, and operation advised. The patient decided to wait.

During the summer his weakness and sweating became more marked, and also the distress in his side.



*Operation*, September 13, 1893, at St. Luke's Hospital. An incision, five and a half inches long, was made over the middle of the tumor three and a quarter inches from the median line. The tumor at once presented. It seemed to contain fluid, but a needle showed it to be a solid growth. It was enucleated without difficulty, and was found to come from the lower part of the right kidney. The kidney and tumor were removed. The ureter was tied, and its free end touched with strong carbolic acid. The vessels were tied with silk by transfixing the pedicle. The abdominal wound was sewed up in layers with catgut. Every precaution was taken to make the operation aseptic. No antiseptic solutions were used except for washing the patient's skin and operator's hands.

The tumor was as large as a good-sized cocoanut. It originated from the lower and outer part of the kidney, and was completely encapsulated. Microscopic examination showed it to be a carcinoma.

The patient did perfectly well, and left the hospital on the twenty-third day.

The amounts of urine passed on the days following

the operation were: September 13th, 12 ounces; 14th, 16 ounces; 15th, 16½ ounces; 16th, 22 ounces; 17th, 15 ounces; 18th, 28 ounces; 19th, 22 ounces; 20th, 30 ounces; 21st, 36 ounces; 22d, 31 ounces; 23d, 31 ounces.

After the operation the patient at once began to gain, and now considers himself in perfect health. He has driven a butcher's cart all winter, and has not missed a day's work. His urine at present is normal in quantity, contains a normal amount of urea and no albumin or abnormal deposit.

## Medical Progress.

### REPORT OF PROGRESS IN PUBLIC HYGIENE.

BY S. W. ABBOTT, M.D.

(Concluded from No. 15, p. 360.)

#### THE SANITATION OF THE ROMAN CAMPAGNA.[5]

THE malarial character of the Pontine marshes has been known for centuries. The region has become deserted on account of its poisonous exhalations, due to imperfect drainage, and the peculiar character of its undulating volcanic soil. Soon after the unification of the Kingdom of Italy, the reclamation of this region began to receive careful consideration from the government, and various measures were proposed to remedy the evil. At one place plantations of eucalyptus trees were made, which proved a failure so far as an effectual amelioration of the miasma was concerned.

The drainage of the soil finally was believed to be the proper remedy, and the work was entered upon soon after the enactment of a law of 1878 providing for the carrying out of the scheme.

The basin, fringing the ancient, but now disused southern arm of the Tiber estuary, on which once stood the city of Ostia, contains a low-lying tract having the following area:

| | Acres. |
|---|---|
| *a.* Permanently submerged | 1,690 |
| *b.* Inundated in winter | 768 |
| *c.* Saturated and useless | 2,608 |
| *d.* Higher ground, fairly dry | 227 |

A total of 4,693 acres, or about 7 1-3 square miles.

The upper levels are to be drained by gravitation, and the lower areas by pumping. The high level drains comprise a total length of nearly 79,000 feet. Two engines pump the water of the low levels. The pumps were started in December, 1889, with the water about twelve inches above the marshes; and after 116 hours of intermittent working, the water-level was reduced over the whole marsh 19½ inches.

[5] Giorno del Genio Civile 1893, p. 265.

After this the work was continued at different times till the water-level was reduced six feet lower. The average working period is 1,200 hours per year.

The cost of the whole works, including working expenses and maintenance has been about $115 per acre.

The reclamation of the whole area has now been effected; the district is becoming repopulated, and plentiful crops of wheat, barley and oats are now raised upon the land.

#### MUNICIPAL SANITATION.

In the literature of sanitary science one of the most noted papers of the half-century nearly closed, was the report of the Chief Medical Officer of the Privy Council of England,[6] in which it was shown that a marked decrease in the mortality of certain English cities was coincident with important improvements in municipal sanitation, consisting mainly of the introduction of pure water-supplies, systems of sewerage, disposal of offal, etc.

A discussion has recently occurred in the Berlin Medical Society, in which similar facts were brought out in regard to the effect of the magnificent works now in operation in that city upon the health of its inhabitants. One writer (Zadek) had attempted to prove that this improvement or decrease in the death-rate was due to a decrease in the birth-rate and to changes in social conditions, and not to sanitary improvements. Dr. Oldendorff answers him very fully in a paper bristling with figures, proving very conclusively, the fallacy of Zadek's views, and taking a similar position to that which Dr. Farr had taken many years earlier in regard to the decline of the death-rate of London.

Dr. Oldendorff[7] shows that the improvement in the health of Berlin is chiefly manifest in the decline of infant mortality in the past ten years. This decrease is a measure of the improvement in the health of the city and is shown not only among the children of the poor but among all classes.

He presents a table, in which the general death-rates, the death-rate of children under one, as compared with the total population, and with the births for each of the thirteen districts of the city, are given for the four years, 1876, 1880, 1885 and 1890; and in each and every instance the decrease is shown.

The two decades, 1871–80 and 1881–90, are then compared with each other with reference to the mortality per 10,000 from each of ten causes of death, showing an improvement in all except measles and whooping-cough. The figures are as follows:

MORTALITY PER 10,000 OF THE POPULATION, FROM CERTAIN DISEASES, IN BERLIN.

| Causes of death. | 1871–80. | 1881–90. |
|---|---|---|
| Measles | 2.3 | 3.1 |
| Scarlet Fever | 5.7 | 3.5 |
| Small-Pox | 0.1 | 0.1 |
| Typhoid Fever | 7.3 | 2.0 |
| Dysentery | 2.0 | 0.6 |
| Diarrhœa and Cholera Morbus | 48.1 | 32.8 |
| Diphtheria and Croup | 16.0 | 14.3 |
| Whooping-Cough | 3.2 | 3.3 |
| Phthisis | 35.3 | 32.3 |
| Acute Lung Diseases | 17.0 | 16.1 |

[6] Ninth Report of the Privy Council, 1866. Report by Dr. Buchanan on the results which have hitherto been gained in various parts of England by works and regulations designed to promote the public health.

[7] Die Sterblichkeitsverhältnisse Berlins mit besonderer Berücksichtigung der Verhandlungen der Berlin. Med. Gesellschaft uber den Einfluss hygienischer Massnahmen auf die Gesundheits Berlins. Von A. Oldendorff. Centralblatt für Allgemeine Gesundheitspflege, xiii, 1894, p. 327.

Comparing Berlin with the sixteen Prussian cities having over 100,000 inhabitants, it had advanced from the twelfth rank in relation to mortality in 1876, to the sixth place in 1891.

When compared with the 92 cities of over 20,000 people it had the twenty-eighth place in relation to the general mortality, and the ninth in regard to the mortality of infants under one year.

While, in Berlin the mortality of infants had decreased by 34 per 100 births, in the surrounding province of Brandenburg it had increased 12 per 1,000. The greatest improvement in infant mortality had been in the decrease of deaths from diarrhea and cholera infantum.

There has also been shown a very marked decrease in the death-rate from typhoid fever — from 6.3 per 10,000 living in 1876 to 0.9 in 1890.

One of the most convincing of the many tables presented is that which gives the mortality, after the introduction of a thorough system of sewerage, of the inhabitants living in houses connected with the public sewers as compared with those which were not thus connected. The houses are divided into three groups, according to the number of tenants; and the improvement in health, of the well-sewered houses is distinctly shown.

The author concludes that the improvement of the health of Berlin is mainly due to the introduction of these great public measures; the well-filtered water-supply, and the removal of the sewerage by the radial system to irrigate fields outside the city.

## INFANT MORTALITY.[8]

In a paper upon the maintenance of helpless infants, Dr. Krisowski gives many facts relating to infant mortality in general. He quotes a summary of Wappaeus and Oesterlen of from fifteen to sixteen million deaths in all Europe — in which it is stated that the mortality of infants under one year averages 20 per cent. of the total mortality in the whole of Europe, the extremes being 10.4 per cent. in Norway and 36 per cent. in Würtemberg.

The average mortality of children up to the third year of life for all Europe is, according to the same author, 33⅓ per cent. of the total mortality.

The following table from the official Prussian statistics gives the mortality of infants and children up to five years of age, expressed as a percentage of the mortality of the first five years of life:

| | Per cent. |
|---|---|
| First day of life | 2.9 |
| Second " | 1.7 |
| Third " | 1.1 |
| Fourth " | 0.7 |
| Fifth " | 0.6 |
| Sixth " | 0.7 |
| Seventh " | 0.8 |
| First week of life | 8.5 |
| Second " | 4.5 |
| Third and fourth weeks of life | 7.0 |
| First month of life | 20.0 |
| Second " | 10.0 |
| Third " | 6.0 |
| Fourth " | 5.0 |
| Fifth " | 4.0 |
| Sixth " | 3.5 |
| Seventh " | 3.0 |
| Eighth " | 2.7 |
| Ninth " | 2.6 |
| Tenth " | 2.4 |
| Eleventh " | 2.3 |
| Twelfth " | 2.3 |
| First year of life | 65.0 |
| Second year of life | 16.5 |
| Third " | 8.5 |
| Fourth " | 6.0 |
| Fifth " | 4.0 |
| | 100.0 |

The author quotes the following figures relative to the mortality of infants under different social conditions. The mortality of children under one year of age where the parents had a yearly income of

| | Per cent. |
|---|---|
| Less than 600 marks, $145 | 29 |
| 600 to 1,500 marks, $145 to $360 | 25 |
| 1,500 to 3,000 marks, $360 to $720 | 18 |
| Over 3,000 marks | 15 |

He also shows that the mortality of infants from diseases of the digestive organs, as compared with living births, was:

| | Per cent. |
|---|---|
| For children nursed by their mothers | 0.74 |
| For children nursed by wet-nurses | 0.77 |
| For children fed upon cows' milk | 4.21 |
| For children fed upon milk substitutes | 6.77 |

Illegitimacy also has a marked effect on infant mortality, the percentage of deaths of legitimate and illegitimate infants, as compared with births, being as follows according to Uffelmann:

| | Legitimate. | Illegitimate. |
|---|---|---|
| In France | 14.0 | 30.0 |
| In Austria | 22 9 | 35.1 |
| In Sweden | 14.4 | 24.8 |
| In England | 14.0 | 35.0 |
| In Bavaria | 39.6 | 45.0 |

These figures differ considerably from those of factory towns in England. Dr. C. Porter, of Stockport, England, gives the following as the result of five years' observation (1889–93) in that city:[9]

"The number of deaths on the *first day of life* is three times greater than that on any succeeding day, and considerably exceeds the combined total of the deaths in the remaining days of the first week. On the second day, mortality falls to one-third of its previous height, and then continues to decline rapidly.

"The deaths during the *first week of life* constitute more than half of the deaths in the first month of life. The rate of mortality in the first week is such, according to the registrar-general, that if maintained uninterruptedly, every infant born would die long before completing its first year of life. In the *second week*, however, mortality falls to less than one-third of its previous height.

"The infant mortality of the *first month*, is nearly double that of any other month, and amounts to about one-fifth of all such deaths. In the second month it falls to about one-half its previous height. In the third month there is but little diminution; but thereafter the mortality decreases gradually, except in the eighth month."

The foregoing figures apply to a manufacturing town of about 150,000 population, and hence might be considerably modified by a longer experience and a large number of city populations.

In summing up the causes of the high rate of infant mortality in Stockport, Dr. Porter mentions, as the diseases or causes of death certified: (1) prematurity and low vitality at birth, (2) respiratory diseases, and (3) diarrheal and digestive disorders. As other and important causes, he mentions, primarily, the employment of young married females away from home, the ignorance of working mothers as to infant-feeding, the administration of opiates, illegitimacy and infantile in-

[9] Public Health, vol. vii, January, 1895, p. 138.

surance. (62.8 per cent. of all the children in Stockport who died under five year of age were insured.) Another cause is the attendance *of ignorant and unqualified midwives*, a class whose advent at the bedside is fraught with danger, both to the mother and the child.

In the discussion which followed this paper prominence was given to the subject of the employment of married women away from home, and further statistics were given relative to Blackburn, a city of 200,000 inhabitants, supporting the same view.[10]

### COMPARATIVE MORTALITY FROM PHTHISIS IN ENGLAND AND IN MASSACHUSETTS.

The mean annual death-rate per million inhabitants living in ten-year periods is shown in the following table:

| | England. | Massachusetts. |
|---|---|---|
| 1851-60 | 2,679 | 3,993 |
| 1861-70 | 2,475 | 3,495 |
| 1871-80 | 2,120 | 3,280 |
| 1881-90 | 1,780 | 2,935 |
| 1891-93 | ..... | 2,360 |

Other tubercular diseases are not included in this summary.

The death-rate from consumption, per ten thousand of the population living at each age-period in Massachusetts is given below:

| Ages. | 1863-90. | 1890. |
|---|---|---|
| 0 to 5 | 17.25 | 14.62 |
| 5 to 10 | 3.23 | 3.24 |
| 10 to 15 | 6.49 | 6.62 |
| 15 to 20 | 31.75 | 27.77 |
| 20 to 30 | 50.25 | 48.23 |
| 30 to 40 | 43.83 | 43.31 |
| 40 to 50 | 36.74 | 35.88 |
| 50 to 60 | 36.51 | 30.24 |
| 60 to 70 | 48.00 | 33.85 |
| 70 to 80 | 60.22 | 33.72 |
| Over 80 | 44.48 | 33.51 |
| All ages | 31.67 | 25.09 |

### LEAD-POISONING CAUSED BY THE USE OF SUGAR OF LEAD IN REPAIRING A MILLSTONE.[11]

In November and December, 1893, several persons living at Lang-Göns, near Giessen, were attacked with lead-poisoning. It was assumed that the illness was caused by lead enamel in the family cooking-utensils. An examination showed that the utensils were free from lead. Attention was then directed to the food; and it was found that the flour came from a grist-mill to which the farmers took their grain to be ground. Out of eleven samples of flour and four of bread made from it, seven of the former and three of the latter contained lead, the amount varying from .013 to .068 per cent. of the ash. It was a matter of interest to discover whether it existed in the metallic state or as a salt. It was found to exist as a soluble salt.

Analyses of fragments of the mill-stones of the suspected mill, and of substances used to repair the same, showed that a grayish-white substance was used to fill up gaps and cavities in the top stone which, according to the miller's statement, was "alum." But analysis proved it to be acetate of lead. The question, how the miller came to use this poisonous substance was submitted to a court trial, but the result was not stated.

[10] It is undoubtedly due to the same cause that the relative mortality from cholera infantum in Fall River for a period of twenty years surpassed that of any city or town in the State, being nearly double that of Boston. It was also true that the percentage of married women employed in the mills, as compared with the total population of the city, was higher than that of any other city or town.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. G. MUMFORD, M.D., SECRETARY.

REGULAR Meeting, Monday, February 4, 1895, DR. C. J. BLAKE in the chair.

### A NEW CANULA.

DR. BRIGGS showed a new self-retaining drainage canula.

DR. F. S. WATSON read a paper on

### CASTRATION FOR HYPERTROPHIED PROSTATE,[1]

and showed a patient on whom this operation had been performed by Dr. M. F. Gavin.

The patient, in answer to questions, said: "This trouble commenced six years ago. There was frequent desire to pass water, which increased until a year and a half ago; I had to pass water every hour or two. Indeed, the stream almost entirely stopped. The pain in the penis was terrible when trying to pass water; and the only way I could succeed was by the application of hot water. After applying hot salt water for fifteen to thirty minutes I could pass one-half to one teacupful. Then the condition grew worse, so that I could pass only a tablespoonful at a time, and with most terrible pain through the penis and neck of the bladder. That condition persisted up to the time of the operation. I was able to sleep only a little owing to pain, and I became very much used up. I lost about thirty pounds in weight. Since the operation, October 3, 1894, I have gained thirty-five pounds, and I never felt better in my life. I suffer no pain now. The water is clear, and I think I empty the bladder. I find that my mind works quicker than before the operation."

DR. CABOT: This subject is one of the new and interesting questions in surgery, and the immediate good effect of the operation is certainly attested by the cases that Dr. Watson has reported, as well as by a considerable number of previously reported cases. I am also cognizant of a few cases which have not yet been reported, some of which are favorable, but one or two of which are not so favorable. The effect of castration in reducing the size of the chronically hypertrophied prostate is undoubted. A sufficient number of cases have been reported to show that. Whether this operation has any decided effect upon prostates which are filled with fibroid tumors, which are therefore in a condition analogous to that of the uterus with its fibroid tumors, is as yet doubtful. We have not sufficient information in regard to cases of that sort.

I think that one point which ought always to be taken into account before much is promised from the operation, is the condition of the bladder. A bladder which has been long distended behind a hypertrophied prostate, which therefore contains a good deal of residual urine and has lost its muscular contractibility, cannot be expected to recover its functions and provide for normal urination as completely as a bladder which, always striving against an hypertrophied prostate, has itself become hypertrophied. A concentrically hypertrophied bladder would naturally provide power for urination where a dilated and thinned bladder would not. So much for the local question.

[1] See page 378 of the Journal.

In regard to the more general question of the effect of castration upon these patients, I think we have everything to learn.

The operation is one of no danger, takes but a few minutes, and confines the patient to the bed, usually, but for a few days. If so simple an operation will save the patient all the discomfort of an hypertrophied prostate, it is an enormous advance in our means of treating this class of cases. We should not lose sight, however, of the possible disadvantages which the operation may entail, and in regard to which we are as yet so much in the dark. We know but little of the functions of the testicles as possibly affecting the nervous system, and sufficient time has not elapsed since this operation has been practised to supply us with information upon this point. We know that after thyroidectomy had been practised for some years with good success, it was discovered that certain very serious changes in the patient sometimes followed the operation. Whether any similar serious results will follow the operation of castration in men who are already entering upon old age, we cannot yet tell. We know, however, that many men, prominent in the treatment of nervous diseases, are using testiculin as a remedy in certain grave nervous disorders and are reporting good results from its use. This fact may well lead us to reserve our opinion as to the final place of this operation. It may be necessary to wait for considerable time before we can ascertain whether castration is followed by any decided diminution in vitality, or whether senility comes on more quickly after loss of the testicles. Certainly, many patients will demand knowledge on these points before consenting to undergo the operation. One patient discussing the question of submitting to the operation, asked whether it would have any effect upon his voice, as he had to do a great deal of public speaking. This is another point which may need time to clear up, although the probability is, that no such effect will be produced in a mature voice.

DR. WATSON: In regard to the senility of which Dr. Cabot spoke, one of the points I meant to make was that it was important to know if any changes injurious to the general health of the patient would occur after the operation. But we must remember the stage of the disease in the one to whom we give that advice. To the man who is going to die in a few weeks the question of general injurious results, if any, that might follow the operation, does not concern us so much as the possible immediate benefits. I think that is a very important point Dr. Cabot has made, however, as to our being able to urge the operation at an early stage of the disease.

DR. CABOT: I agree with Dr. Watson, that in patients who are in a desperate condition the operation is a perfectly proper one, and one that I am recommending and using in such cases. If, however, the removal of the testicles is to have no deleterious effect, the operation should have a much wider applicability than to these desperate cases. If there are no objections to its use, patients with commencing trouble from their prostates, might, by resorting to it early, save themselves from any of the secondary effects in the bladder and kidney which lead to such serious consequences.

DR. BRADFORD asked if there was any accurate evidence as to the value of testiculin. The fact that it had been used in tabes is hardly of sufficient value to justify its acceptance as a therapeutic agent, as so many various measures have been tried in that affection.

DR. H. P. BOWDITCH: I suppose that the doctor is aware of the fact that the French journals have a good many cases of reported success in treating a great variety of cases with testiculin. I do not know how much allowance is to be made for French enthusiasm. A gentleman who came home from Paris a year or two ago said about half the members of the French Academy were taking the treatment.

THE MUSCLES OF EXPRESSION.

## THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., BOSTON.

THIRTY-FOURTH Annual Meeting, January 12, 1895, the President, DR. CHARLES M. GREEN, in the chair.

DR. EDWARD REYNOLDS reported

CASES OF RETROVERSION OF THE PREGNANT UTERUS.

DR. W. L. BURRAGE reported

CASES OF RETRODEVIATION OF THE PREGNANT UTERUS, INCLUDING A CASE OF PREGNANCY IN AN INCARCERATED CORNU, AND A CASE COMPLICATED BY AN OVARIAN TUMOR.[1]

DR. A. D. SINCLAIR said that incontinence of urine from overflow of a distended bladder was a symptom he had noticed in several cases of retroversion of the pregnant uterus. In one case he withdrew 106 ounces of urine and then had no difficulty in replacing the uterus.

DR. F. H. DAVENPORT said that he had seen a case where the only complaint made was inability to pass urine. He found an incarcerated retroverted uterus. Packing relieved the symptoms and later a pessary was used. He referred also to a case, where the uterus formerly retroverted without symptoms, resumed the normal position as soon as the patient became pregnant.

DR. G. H. WASHBURN spoke of a case where the patient was said to have had two "false conceptions" at three months. She again felt the same symptoms coming on after three months amenorrhea. He found a retroverted pregnant uterus, which he held in position with packing and the patient went to full term. After delivery the uterus returned to the retroverted position and she again became pregnant. The same conditions demanding the same treatment occurred as before and everything went well.

DR. C. M. GREEN was especially interested in these cases from the absence in all of bladder trouble, meaning by that either retention or difficulty in passing urine. After an unfortunate experience resulting from packing, he has never dared to pack the vagina in pregnancy for fear of producing abortion. He was, therefore, interested to learn that some of these cases had been packed without harm.

DR. J. R. CHADWICK said he wrote a paper some twelve years ago incorporating eighteen cases of this affection. He entitled the paper "Pregnancy of the Retroverted Uterus," as he considers that the state of affairs, and not that the normally placed pregnant

[1] See page 380 of the Journal.

uterus becomes retroverted. He rarely used ether in his cases. In two cases he failed to raise the uterus without ether, but the uterus in both cases returned later of itself to the normal position. He also found that putting in a ring pessary with the uterus still retroverted gradually brings the uterus into place. He has been generally disappointed with the knee-chest position and prefers to correct the displaced uterus with the patient standing erect. This causes the uterus to descend and a little pressure will make the uterus fall forward. If the uterus stays in place after reposition he feels sure it is pregnancy, if not it might be pregnancy or might be fibroid.

Dr. Edward Reynolds said he had used ether in four cases mainly if not wholly for diagnosis; but with ether reposition is easy, while without it it is often difficult. The papers to-night certainly showed the importance of examining a pregnant woman as soon as she complained of pelvic pains.

Dr. A. D. Sinclair confirmed Dr. Chadwick's observation that it was often easy to replace the uterus in the erect position.

Dr. W. L. Burrage reported orally

A CASE OF FIBROID OF THE UTERUS,

and showed the specimen. The patient was thirty-nine years old, single. The tumor was growing very rapidly. He performed laparotomy and found that the tumor came up under the peritoneum from the region of the internal os, pushing the uterus into the right iliac fossa. The tumor when removed weighed ten and one-quarter pounds. The patient made a good recovery.

Dr. A. D. Sinclair spoke of a case he had followed for ten years. In the last six months it had grown very rapidly and was removed by operation.

Dr. A. Worcester reported

A CASE OF RUPTURE OF THE MEMBRANES IN THE SIXTH MONTH.

The patient, a multipara, was put to bed, and for eight weeks the liquor flowed away, delivery not taking place till the end of this time, which was within three weeks of full term. The liquor was caught on pads and weighed, fifteen pounds being collected in this manner. The infant weighed six pounds, was apparently well, but died suddenly on the second day.

Dr. C. W. Townsend spoke of a case he had attended two years ago where the membranes ruptured four weeks before the birth of the child which occurred about one week ahead of time. Six or eight napkins were soaked daily with liquor. The child lived.

## Recent Literature.

*A Manual of Hygiene.* By Mary Taylor Bissell, M.D. New York: The Baker & Taylor Co. 1894.

This manual was, as the author states, primarily written for medical students, as a text-book of hygiene adapted to American conditions, for use in the class-room.

The different topics embraced under the head of public and individual hygiene, are treated in twenty chapters, with marked clearness, and with sufficient fulness of detail for the purposes of the general student, either in the professional schools or in the higher grades of schools and colleges.

## ON HEREDITARY CEREBELLAR ATAXIA.

Under the name of "Hereditary Cerebellar Ataxy" (*Hérédo-Ataxie Cérébelleuse*) Dr. Pierre Marie has recently called attention to a morbid syndrome resembling Friedreich's disease, and which seems to claim a place apart in nosology.[1] Marie's description is based on sixteen cases, two of which are furnished by Fraser,[2] three by Nonne,[3] eight by Sanger Brown, and three by Klippel and Durante.[4]

Since the publication of Marie's paper, Dr. Paul Londe, editor of the *Annales de Médecine*, has reported three carefully observed cases (in collaboration with Drs. Brissaud and Robin); has also collected a series of cases published prior to Marie's researches, apparently belonging to the same group, and has embodied the results in an excellent monograph just issued by Battaile et Cie., Paris.[5] From a study of these publications, we draw a brief *résumé* of the principal characteristics of the disease in question.

By its symptomatology, cerebellar heredo-ataxy resembles Friedreich's disease. There is the same staggering gait, the same pains and numbness in the lower limbs. The knee-jerk, however, is not lost; it is, on the contrary, exaggerated. At a later date, the arms become affected with incoördination; arms and head tremble; vertigo is a frequent, not constant, symptom; Romberg's sign is always absent; the patient has no difficulty in walking with the eyes shut.

On observing the gait of a person afflicted with cerebellar heredo ataxy, one cannot but notice the two principal symptoms — the disorder of equilibrium, especially manifest in the staggering and in the difficulty which the patient experiences in standing; and the incoördination of movements of the lower limbs. The titubation disappears when the patient lies down,

[5] Paul Londe: Hérédo-Ataxie Cérébelleuse, p. 248, Paris, 1895.

but in typical cases the muscular incoördination persists.

The ataxia of the upper extremities (a late symptom) is accompanied by certain trembling movements which only exist during the performance of acts of volition, and resemble the "intentional trembling" of multilocular sclerosis. Choreiform convulsive shocks, exaggerated contractions of the muscles of the face and ataxia of speech have been noted by several of the authors. The utterance of the patient, says Londe, is slow, jerky; the words are sometimes spoken in a precipitate, explosive manner, as if there was ataxy of the articulatory muscles. There is especial difficulty in the enunciation of certain letters, as labials and palatals. The voice is often indistinct and guttural. There is a peculiar rotatory trembling of the head during emotion or during standing, which is very characteristic.

It might be supposed that the disorder of equilibrium was due to abolition of the muscular sense; but this, says Londe, is not the case; for in all the observations where it has been tested, the muscular sense has been found intact. The muscular force is not greatly diminished.

These heredo-ataxics suffer greatly from sensations of fatigue, especially marked in the morning, often accompanied by headache and backache, numbness and cramps in the limbs, twitchings, and other symptoms essentially neurasthenic. There is a *stolidity* about the countenance of these patients when asleep (relaxation of the muscles of the face), and an aspect of amazement when they are awake (excess of contraction) quite characteristic, and remarked by both Sanger Brown and Londe.

The symptoms of psychical enfeeblement shown by these ataxics (irritability, diminution of the faculty of attention, hebetude, failure of memory) are sufficiently pronounced, but the ocular troubles are the most marked. These are: (1) atrophy of the papilla, generally bilateral, often slight, sometimes complete; (2) a consequent contraction of the visual field and diminution of visual acuteness; (3) disorders of the external ocular muscles, manifested by "nystagmiform or choreiform shocks" (not by true nystagmus). Many of these cases, says Marie, have presented a degree more or less pronounced of paralysis of the external rectus; Nonne observed paralysis of the rectus superior; Sanger Brown, an incomplete ptosis "giving to the countenance a singular expression of intense emotion."

The term "hereditary cerebellar ataxy" expresses the three fundamental characters of the disease. The ataxy we have above considered — there is both ataxy and titubation, and the latter, as Londe remarks, is strikingly suggestive of cerebellar disease. The hereditary nature of the disease is seen in all the instances in which it has been noted; in the observations of Londe, Marie, Nonne, Klippel and Durante. Sanger Brown's cases show five generations attacked successively, and numerous persons affected in the same family. It is oftenest a disease of early adult life, of females rather than of males.

As for the principal seat of the morbid lesions, the data which we possess respecting the pathological anatomy of the disease are confessedly rather meagre, since in reality they are founded on only well-conducted autopsies, the one of Fraser, the other of Menzel, the third of Nonne. In all these cases, the cerebellum was markedly atrophied. This organ weighed in Fraser's patient 81 grammes, in that of Nonne, 120 grammes, the normal weight being from 150 to 170 grammes (a diminution of one-quarter of the normal weight). Fraser remarks that it was principally the gray substance of the cerebellum which was reduced in volume. Both Fraser and Menzel also noted the disappearance of a great number of the cells of Purkinje; those that remained were altered. The spinal cord, examined by the microscope, exhibited no alteration; macroscopically, there was in Nonne's case a simple diminution in size. The lesions are, it will be seen, quite different from those which characterize Friedreich's disease. In the latter, we find also a notable diminution in the volume of the cord, but there are also degenerative lesions of great extent, involving Burdach's column, the column of Goll, the direct cerebellar tract, the crossed pyramidal column, and the cells of Clark.

The anatomical proofs of the cerebellar origin of this form of heredo-ataxy are reinforced by physiological considerations. An interesting part of Londe's treatise is the demonstration that experimental suppression of the cerebellum produces markedly similar functional troubles. If we take into account only the symptoms of deficit, we find that in both experimental and hereditary ataxia, there are astasia, titubation, and incoördination. The head and the upper limbs manifest the same instability during voluntary movements, and present at times oscillations having the character of intentional trembling. The gait of the mutilated animal and of the heredo-ataxic person is the same when the eyes are open and when they are closed; and if the phenomena of deficit are characterized by asthenia, there is certainly absence of paralysis. Luciani compares cerebellar asthenia to the asthenia of convalescence. To him, the cerebellum is *par excellence* the organ from which emanates muscular energy; the titubation is simply a manifestation of weakness. Londe denies that there is any marked diminution of muscular force in heredo-ataxy; there is a lack of coördinating energy; the titubation resembles that of drunkenness.

Cases of so-called atrophy of the cerebellum are few. Nothnagel has collected eight cases, in all of which there was one constant predominant symptom, uncertainty in the movements of the lower extremities, often also in those of the upper extremities. In almost all the cases, the speech was slow and jerky, and there was marked intellectual enfeeblement.

The visual phenomena of heredo-ataxia are ex-

plained by the connections of the cerebellum with the peduncles and the corpora quadrigemina.

With regard to the diagnosis of this disease, the resemblance to tabes dorsalis is slight. Cerebellar ataxia, says Londe, results from the suppression of the equilibrating function of the cerebellum; the muscular sense is intact. The tabetic has lost the muscular sense, but equilibrium can be maintained by the visual and auditory (vestibular) sensations which he receives. But the titubation is sufficiently characteristic of itself. Heredo-ataxy has the nearest resemblance to multilocular sclerosis, as there is hardly a symptom that is not common to the two diseases. In both we may have incoördination of movements of both lower and upper extremities, vertigo, ocular troubles such as diminution of the visual field, dyschromatopsia, diplopia, nystagmus, etc.; in both articulation may be jerky, and even explosive. But the hereditary and family nature of *sclerose en plaques* has not yet been proved, and the trembling of heredo-ataxia is seldom witnessed in the former disease. Marie has devoted nearly a whole lecture to the differential diagnosis between cerebellar heredo-ataxia and Friedreich's disease, the main points of which will be seen in this rapid enumeration of the principal distinctive characters of the former malady; the more advanced age of the patient when the disease first appears; conservation and even exaggeration of the patellar reflexes; frequence of spasmodic phenomena; the visual troubles; absence of cyphoscoliosis, absence of talipes.

With regard to the course of the disease — it begins in adolescence, or in adult life, with cerebellar ataxia; the lower limbs are first affected. If there are prodromic symptoms, they are those of ordinary neurasthenia: headache, backache, fatigue, etc. A traumatism, or strong emotion may usher in the morbid syndrome. It never results from infection or from syphilis. The disease is slowly progressive; it is not amenable to any real improvement, or to notable remissions. When the disease is declared, the standing posture and locomotion without assistance are impossible; confinement in bed eventually becomes necessary. The intentional trembling, and the ataxia of the head and upper members become noticeable and pronounced during the second period, or period of impotence. There is a third period, or period of absolute impotence, in which the ataxia is most marked, and in which there is permanent contracture of the legs, in flexion at a right angle. The duration of this disease may be very long. One of Sanger Brown's patients, and Fraser and Nonne's patients lived more than twenty-five years after the onset of the disease. The helplessness of the last stages becomes extreme.

Londe emphasizes the fact that the visual disturbances (ocular, motor, sensory) on which Marie lays stress, do not constitute an essential feature of the disease, and that in typical cases the symptom-picture may be reduced to its simplest expression: general incoördination with conservation or exaggeration of the reflexes.

## THE EMANCIPATION OF THE HORSE, AND ITS DANGERS.

When the curative effect of antitoxin serum had been demonstrated in the diphtheria of animals, and the question arose of its application to the human subject, it was found necessary, in order to obtain a sufficient supply, to choose an animal of large size, capable of losing large amounts of blood without injury to its health. The horse was chosen, as furnishing in the highest degree the characteristics of size, cleanliness and docility. It has been found that the slight attacks of diphtheria which the horses have had to undergo during the process of immunization, and the abstraction of blood for the production of antitoxin serum, do not injure the health of the animal. On the other hand, the horses, which, of course, are provided with the best of food and care, and regularly exercised, actually improve in condition under the treatment. The horse is transformed from a beast of burden, fed and trained with the idea of getting out of him the largest amount of hard work at the least expense, to a sort of pet upon whose care no expense is spared which may help to get him into the pink of condition. Instead of hard work he is given regular exercise, care being taken not to fatigue him unduly, for the animal whose blood is to be mixed with that of children must be free even from the taint of fatigue. It is doubtful if any of the several hundred horses now undergoing the immunization would exchange his present lot, where the only drawback is the occasional prick of the hypodermic needle, or the lancet which opens the vein, for his former life of the lash and burden.

When we consider the tremendous prospects of the antitoxin treatment, if, as is at least possible, it shall be found applicable to all forms of bacterial disease, and that, as in diphtheria, the horse will probably be called upon to furnish the chief supply, the value of the horse to mankind increases beyond computation. With the successive advent of steam, electricity and the bicycle as means of transportation, the importance of the horse for these purposes has steadily diminished, so that the possession of horses and carriages is rapidly becoming, except in special lines of business, more of a luxury than a necessity. It is interesting that at just the time the horse as a beast of burden and as a means of transportation is decreasing in value to mankind he should be called upon to fulfil the nobler function of an agent of healing.

The success of the serum treatment in diphtheria, however, brings with it the danger that "horse serum" will be vaunted as a cure for all the ills that flesh is heir to, and enthusiastically accepted, perhaps, before a thorough trial has been made. Such premature acceptance, however, cannot fail in the future as in the past to result in disappointment and chagrin. From St. Louis comes the report that Dr. Paul Paquin, Professor of Bacteriology in the State University of Columbia, having convinced himself that the horse is naturally immune against tuberculosis, has argued that the serum of healthy horses can be em-

ployed without artificial immunization in the treatment of tuberculosis in man. Although the serum is said to have been employed in fifty cases with results almost uniformly successful, the chronicity of the disease, and its proved susceptibility to temporary improvement under the most various modes of treatment, render it simply impossible to prove any treatment of value by its application to so small a number of cases, over a time of less than a year.

The possibility of a serum-therapy for syphilis, founded upon a venereal disease in the horse which is said to bear the strongest resemblance to syphilis in man, has been recently suggested by Dr. Duncan Manzies, of Gibraltar. The fact that syphilis has never been transmitted from man to the horse has suggested to Dr. Manzies the possibility of a kind of antagonism between the two diseases, upon which a method of serum-therapy might be founded.

In considering the horse as a possible source of supply for the healing agent of various diseases, it is to be remembered that he was not chosen because his serum had more antitoxic effect than that of other animals, but because the requisite amounts could be obtained from him more conveniently. It is, at least, probable that for curative effect in other bacterial diseases, as in diphtheria, the toxin must be obtained in the first instance from the human subject, and the immunizing and curative effect be tested by patient experimentation before practical results are reached. The fact, if proved, that tuberculosis or syphilis are not transmitted from the human subject to the horse may be due to other conditions of the blood than those which would give it power to immunize or cure a human subject.

It is necessary for the medical profession to remember that it is the antitoxin serum, and not serum of the horse alone, that cures diphtheria, in order not to be led into accepting "horse cures" for various diseases without sufficient investigation. A more minute investigation of the "sacred horse" which the ancient Trojans believed would bring them victory in their battles with their besiegers, would have saved them a good deal of subsequent trouble. Modern physicians would do well to profit by their example, and not accept a horse consecrated by fanatical enthusiasm and ill considered argument without most careful investigation, as an aid in their battle against disease. Because horses had proved themselves excellent animals to draw the chariot of Hector to battle, furnished no particular reason for exalting a horse as a talisman who was in some manner, "not previously determined by experiment," to give the Trojans a general success against the Greeks. Let us beware lest we find, as they did to their cost, that the conditions are different.

## MEDICAL NOTES.

An Exposition of Hygiene. — An International Exposition of Hygiene will be held in the Palace of the Liberal Arts in Paris, from the 15th of next May to the 15th of September.

The Medical Association of Georgia. — The Medical Association of Georgia will hold its forty-sixth annual session in Savannah, April 17th to 19th, inclusive.

Beri-Beri at Delaware Breakwater. — It is reported that a vessel recently arrived at Delaware from the Phillipine Islands whose entire crew is affected with a disease thought to be beri-beri.

A Warning to Obdurate Examiners. — At a recent examination in anatomy conducted by Professor Weichelbaum, a student who was plucked for the second time is reported to have prostrated himself at the feet of the professor, kissed his hand, and begged him to allow him to pass. On the professor's refusal he seized a scalpel, and threatened to commit *hari-kari*. Fortunately he was seized and held in time to prevent the consummation of his purpose.

The Antitoxin Treatment of Diphtheria. — Risel reports in the *Deutsche. med. Wochenschrift*, of March 7th, 114 cases of diphtheria treated in the city of Halle between November 11, 1894, and January 15, 1895. Of these, 89 cases were treated at their own houses, and 83 recovered; 70 of the 89 cases showed no involvement of the larynx and trachea, and of these 68 recovered. Of 19 laryngeal cases 15 recovered. Of the 114 cases 25 were treated at hospitals, with 23 recoveries. In 10 of these, in which there was no involvement, there were no deaths. Of 15 laryngeal cases there were three deaths. Out of the total of 114 cases, therefore, there were nine deaths, or 7.89 per cent. Thirty different physicians were concerned in the treatment of these cases, and bacteriologic examination was made in but a small number of them.

The Murder of Thomas Patton in Kansas. — Later and more accurate information tends to show that, in common with others, we were unnecessarily disturbed about the acquittal of McDonald and the conviction of Gray in the Kansas Supreme Court at Topeka, April 7th, for the murder of one Patton, on the ground of the employment of hypnotism. The facts seem to be that Patton was murdered, that McDonald shot and killed him in cold blood and without provocation, and that Gray, who had a motive for wishing Patton out of the way, incited McDonald to the act. Hypnotism was mentioned during the trial casually, but was not an active factor in the conviction. As we now understand the subject, Gray was convicted of murder in the first degree, and McDonald escaped, although he actually committed the murder. Whether this was a judicious conclusion of the trial, our legal friends and the community immediately concerned must decide. Our interest in the trial ceases with the disappearance of hypnotism from the case.

Ingenious Simulation. — *La Médecine Moderne* (March 2, 1895) gives interesting instances of the ruses adopted by French soldiers in order to deceive medical inspectors and escape disagreeable duty. Among them are smoking hay or straw to whiten the

tongue, and macerating an earthworm in brandy, and taking a piece of it to the major as a segment of tapeworm. The following ruse deserves mention. For some years there has been at Val-de-Grace the portrait of an artilleryman whose knee was swollen and presented the appearance of a traumatic hemarthrosis. On aspiration of the knee a black fluid flowed out, mixed with a little blood, but peculiar looking, and bearing no resemblance to any known pathological product. The discovery was finally made that the man had been injecting ink into his knee-joint.

THE DISCOVERY OF HELIUM. — The recent announcement of the discovery of a new element, argon, in atmospheric air, by Lord Rayleigh and Professor Ramsey, is already followed by the announcement by the latter that in his experiments with the mineral clevite, for the purpose of discovering a compound of argon, in which clevite was treated with sulphuric acid, argon was evolved, but associated with some strange gas. This turns out to be helium, the lightest of all the elements, the existence of which had already been inferred from the line $D_3$ in the solar spectrum. The existence of the new element was in a few days confirmed by Professor Crookes, who identified its spectrum. The discovery of an element whose existence had been previously inferred on theoretical grounds, is certainly a most remarkable vindication of chemical theory. The mineral clevite was supposed to yield nitrogen when acted upon by sulphuric acid. The evolvement in its place of a mixture of argon and helium, suggests the introduction of new and extremely complicated factors into the already complicated chemistry of the nitrogen compounds.

SCAVENGERS OF THE SEA. — Our British *confrères* continue to be agitated over the "typhoid oyster," and the columns of their lay and professional press are flooded with communications on the subject. The effect has been to injure the oyster trade very seriously, and all manner of suggestions are made as to the future regulation of this industry. It is not quite clear, however, that what an Ann Arbor professor calls these "scavengers of the sea" are really responsible *per se* for the manifold ills attributed to them. That an oyster shell may hold typhoid-polluted water is probably true; so also may a glass vessel. Of themselves, oysters have been proved to be destructive of pathogenic bacteria. Mrs. Percy Frankland furnishes a note to *Nature* recalling some of the experiments of her husband, the professor, as well as those of De Giaxa, on this subject. In the greater bulk of experiments made with oysters and some varieties of mussels replaced in sea water after inoculation through a hole in the shell, which was afterwards sealed up, the pathogenic microbes entirely disappeared in six hours; in only two instances were they detected in small numbers at the end of twenty-four hours, and in no case were they identified after forty-eight hours. It is the transplanting of oysters to sewage-contaminated waters or their storage where such contamination ensues, which is responsible for the recent attacks on the good name and fame of these succulent morsels. — *Journal of the American Medical Association.*

DEATH IN CONSEQUENCE OF AN URETHRAL INJECTION OF COCAINE. — In the *Centralblatt für Chirurgie* of March 10th, is an abstract of an account published in *La France Médicale* of a case of sudden death following the injection of six drachms of a five-per-cent. solution of cocaine into the urethra. At the autopsy the urethral mucous membrane was found intact, and there was pronounced arterio-sclerosis. The safety with which cocaine solutions of low strength and in small quantities may be used in minor surgery, brings with it the danger that the drug may be inadvertently employed in a dangerous strength and quantity. A dose as large as that reported to have caused death in this case is never necessary to secure the local effect of this valuable drug, so that it would seem that in a moment of excitement or inadvertence the piston of the syringe had been pushed beyond the point intended. A syringe of a capacity of six drachms should under no circumstances be used in the employment of cocaine solutions of the strength of five per cent. The weaker the solutions, the larger the syringe which it is safe to employ. Operations such as gastrostomy or herniotomy have been repeatedly performed with a drachm or less of a one-per-cent. solution as a local anesthetic. In the use of cocaine for urethral anesthesia, a few drops of a three-per-cent. solution may be made perfectly effective by very gradually pushing the piston of an Ultzmann syringe as its beak is withdrawn slowly through the urethra from the membranous portion. This is certainly a much safer method than squirting in from a large syringe, four or five drachms of a solution a good part of which may perhaps pass the triangular ligament, enter the bladder and be rapidly absorbed.

## BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, April 17, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 36, scarlet fever 26, measles 168, typhoid fever 8.

THE BACTERIOLOGICAL DIAGNOSIS OF DIPHTHERIA. — The health officer of Stamford, Conn., offers to make bacteriological examinations without expense in cases of suspected diphtheria in that city. Stamford is thus the second city in Connecticut to take this step, Hartford having been the first.

THE REGULATION OF MEDICAL PRACTICE IN MAINE. — An Act to regulate the Practice of Medicine and Surgery has been passed by the Maine Legislature. The bill received the approval and support of the Maine Academy of Medicine, and its passage was largely due to the character and influence of prominent members of the Academy. In the judgment of the *Journal of Medicine and Science*, the organ of the

Academy, the bill is not an ideal one, but is a better one than the first passed by most States and Territories. The passage of this law alone is a most successful result of organized action on the part of medical men; and the Maine Academy may well be proud of such marked success so early in its career. The agitation for a medical practice law was begun in the first number of the *Journal of Medicine and Science*, appearing in December, 1894, and noticed in our own editorial on December 20th. As to the securing of an ideal registration law, the Academy must have an exalted opinion of the Maine Legislature to even dream of the possibility of such a thing; which unless the Maine Legislature is far superior to that of other States in the Union is hardly to be expected at present.

NEW YORK.

School-House Janitors and Contagious Diseases. — A controversy has arisen between the Health Board and the Board of Education over a case of measles occurring in the family of the janitor of a public grammar school in East 35th Street. In consequence of this the school-house was closed by order of the Board of Health, and nearly two thousand children have been forced to abandon their studies until the Board decides that it is safe to allow them to return to the building. It is a rule of the Board of Education that janitors shall reside in the schools and provisions are always made for apartments for their families in the buildings. In this way a considerable saving in wages is effected, as a deduction is made for rent, heat, fuel and light. On this account the Board has strenuously opposed the efforts which the Board of Health has made from time to time to have the janitors accommodated in quarters outside the school buildings. Quite a number of times during the past few years it has been found necessary to close school-houses for weeks at a time on account of the presence of contagious disease in janitors' families, and the occurrence of the present case has encouraged President Wilson of the Health Board to press the matter to an issue. He has communicated with Mayor Strong in regard to it, and the latter has written a letter in which he fully agrees with the stand taken by the Board of Health that janitors should be required to live outside the schools.

A New Medical Society. — A large number of physicians in the lower part of the city have organized a new society to be known as the Eastern Medical Society. In its platform the society denounces organizations giving free aid to the poor but which treat all applicants, dispensary physicians for allowing prescriptions of pay patients to be compounded at dispensaries, and physicians who give advice at drug stores.

"Health and Happiness." — The Charity Organization Society has issued a placard for distribution among the poorer classes which contains a considerable amount of useful information. It is headed "Health and Happiness," and is made attractive by pictures. Injunctions are given as to personal cleanliness and the importance of clean clothes, clean houses, and fresh air is dwelt upon. A diagram shows the relative value of staple foods and the time required to digest the different articles, and recipes are furnished for preparing a large number of cheap and nutritious dishes. Information is also given as to what should be done at once in cases of wounds, bruises, burns and scalds; and finally a number of maxims hinting how to be healthy and happy are printed.

Another Brooklyn Bridge Jumper. — On April 13th a man by the name of James Duffy leaped from the Brooklyn Bridge into the East River, and was killed. It is believed that he made the leap with suicidal intent, rather than to acquire fame as a bridge-jumper. Since the bridge was built seventeen persons in all have jumped from it, and of these ten were unhurt or escaped with comparatively slight injuries, while seven lost their lives.

## Miscellany.

### IN ACTIVE PRACTICE AT THE AGE OF ONE HUNDRED AND TWO.

The London *Daily Telegraph* for March 28, 1895, publishes the following interesting account of a most remarkable character:

"'I was born in 1793, and since then I have not been ill a single minute.' Such is the very satisfactory account of himself just given by Dr. de Bossy, the *doyen* of the French physicians, who is still in practice at Havre, hale and hearty as ever. He says that he has never followed any special *régime*, and that, in fact he is opposed to anything of the kind. Summer and winter he gets up at seven o'clock, and as soon as he is dressed he starts off on his rounds, generally on foot, but now and then in a tram-car, when there is a good deal of mud. He does not restrict himself to any particular dishes, but enjoys all. Coffee he has drunk all his life, and he has no objection to a glass of bitters, while as for tobacco, to borrow his own expression, 'that is another poison which I regularly absorb without being any the worse.' Then what is the secret of longevity, according to this veteran, who is still in excellent health? Moderation in all things, and he adds: 'I got the recipe from my father, who was one hundred and eight when he died. You perceive I have no infirmity.' All this he relates as if it were the simplest matter in the world, and within the reach of all, to become a centenarian. Dr. de Bossy's case is all the more remarkable inasmuch as he lived for some time in a tropical climate. He took his degree in 1818, went to England, and thence to India where he practised medicine, and then returned to Havre, where he has been busily at work for the past sixty-four years. He toiled for years in the East while epidemics, cholera included, were raging around him, but emerged scatheless from the ordeal. Nor, during the unwelcome visitation of cholera at Havre, in 1892, did Dr. de Bossy remain idle. On the contrary, he tended the sick in poor and crowded districts with such devotion that he was presented with a medal by the Government. He has two sons, the one settled at Havre

and the other at Rouen, the elder being sixty-eight years of age, and both, as he hopes, in a fair way to emulate the example, set them by their father and grandfather."

## Correspondence.

### A REPLY TO DR. ALBERT LEFFINGWELL.

1925 Chestnut St., Philadelphia.
April 16, 1895.

Mr. Editor: It does not seem to me necessary to make reply to the one-column letter of Dr. Arthur H. Nichols in the Journal of April 11th. I do not believe, nor have I in any way intimated, that the New England physicians are in any way different from physicians in other parts of the earth. Dr. Nichols is right in believing that my position is that the general laws prohibiting cruelty to animals, are all that are needed for the proper restriction of vivisection; and in this belief I am confirmed by the letter of Dr. Albert Leffingwell, which follows that of Dr. Nichols. If a gentleman of his culture and general intelligence cannot perceive that his words are an absolute misstatement, when the misstatement has been clearly pointed out, what is to be expected from those who are actually sunk in fanatical opposition?

It is hardly necessary for me to point out that unless I had quoted the whole of the circular he could have made charges of my quotation being garbled; and that I did not think it was necessary or essential to quote more than what seemed to me to have direct or necessary bearing upon the question. Pardon, however, if I re-quote, not in full, but what is necessary, referring to his letter for the rest of the paragraph. He says: "While State laws generally prohibit cruelty, yet in the great majority of cases there is *no law*, no college rule or regulation even, prohibiting the infliction upon animals," etc. This statement is certainly not true. The reason why I omitted and evaded the evidence on which it rests, to use the words of Dr. Leffingwell, is because the evidence is entirely out of court — foreign to the subject; in other words, no evidence at all. Quoting Dr. Leffingwell, he says: "The proof of this statement rests upon replies made by different college presidents to letters of inquiry." Does not Dr. Leffingwell know that *college presidents* do not make *laws?* Laws, when the word is used in the English language, without qualification, means laws made by legislators. If Dr. Leffingwell had said, "college laws" he might or might not have been correct in his statement; but when he says "laws," and especially when in antithesis he further says, not even a *college* rule or regulation, he says what is not true. Is it not odd that he cannot perceive this? Surely this is an instance of the effect of a Dominant Idea worthy of going into a physiological text-book. The only defence of his statement would be not the one which he makes, but the quibble that the law does not prevent inflictions.

The answer to this is that no law prevents any crime, and that in ordinary language when we speak of a law passed to prevent crime we mean one passed for the purpose of prevention.

The matter between myself and Dr. Leffingwell is of no importance to anybody; certainly, at least, not to me, and I suppose not to him, but the class of people with whom he is associated, at least in our thoughts and in the practical results of his efforts, are the class of people with whom we in Pennsylvania have been for years contending for our very lives. Ten years ago I myself was inclined to favor some special laws in regard to vivisection; but experience has shown that these laws are wanted simply for the purpose of enabling the anti-vivisectionists to put spies into every laboratory, to question every experiment, and to perpetually drag the experimenter before magistrates and juries composed of the peculiar material which abounds in our larger cities.

The mental condition of Dr. Leffingwell shows how an honest man may be incapable of perceiving the truth; and when to this fact is added the certain fact that the spies put into the laboratories would be paid for the purpose of achieving a certain end, would be under the influence of the most intense fanaticism, and would in a large proportion of the cases at least be completely ignorant of the matter under judgment, it will be seen that the life of the physiologist under such circumstances would be not worth the living. At present the physiologist everywhere receives little or no reward for his labors for the good of mankind; is usually underpaid almost to the point of starvation; has in America no social reward or consideration, which to many men is worth more than money; lives in fact *a perpetual sacrifice* for the good of his fellow beings. Isn't it a pity, when the world is full of infinite misery, that men of intelligence should give their thoughts and time not to lessening the sufferings of the human race but to impeding the progress of those who would do this thing?

Thanking you for the courtesy of your columns,

I remain, yours truly,

H. C. Wood, M.D.

### THE INJECTION OF STIMULANTS INTO THE HEART-WALLS.

Middletown, Conn., April 15, 1895.

Mr. Editor: — I noticed in the Journal's last issue an account of cardiocentesis in an attempt to perform only paracentesis. The remarks that followed by Dr. Sloan, quoted from the *Edinburgh Medical Journal*, were particularly interesting, as they seemed to throw more light upon the therapeutic value of cardiac puncture and injections.

Some cases of interest along this line of cardiac stimulation, after all common means had failed, presented themselves to me while an interne in one of the New York City hospitals.

Within a few weeks of each other three cases of delirium tremens presented me an opportunity to try cardiac injections; all three being cases in which all stimulants, such as digitalis, strophanthus, nitro-glycerin, etc., had failed to ward off a fast-approaching cardiac paralysis.

On being called to the first case, as was then supposed for the last time, I found that hypodermic injections of stimulants would no longer revive the heart's feeble motion. It was thought probable that if stimulants could be injected directly into the heart-muscle the much needed stimulation could be obtained. Accordingly one-fifteenth of a grain of sulphate of strychnia was given by means of a long needle-syringe. The immediate result of its administration was to slow down the heart's action without changing its irregular rhythm. In fifteen or twenty minutes this too improved. After one more injection of one-twentieth of a grain in one hour, the heart was beating about one hundred per minute, and quite regularly. This case eventually recovered from the attack, and was discharged in five days. The case, although the history is somewhat meagre in details, showed a beneficial result from cardiac injections of stimulants. The immediate effect, the heart's improved action, seems to have been due first to the puncture and secondly to the fact that the drug sustained the heart until the alcoholic narcosis had lessened its hold upon the patient.

The second case was similar to the foregoing, but was not quite so severe and required only one injection.

In the third case the injections were withheld in deference to the wish of the visiting physician, who insisted upon the use of other cardiac stimulation until the patient's condition became very critical. The pulse was imperceptible at the wrist, and respiration was only noticeable at intervals of ten or fifteen seconds. At last the injection of ammonia was made into the heart-muscle, but no change followed this first administration and the second was given in eight or ten minutes. The patient died in a few minutes after the last injection. Probably this last case had become so moribund at the time of the injection that no remedy could have kept the patient alive.

Very truly yours,

L. Pierce Clark, M.D.

## METEOROLOGICAL RECORD,

For the week ending April 6th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Amesbury | 10,926 | 2 | 0 | — | — | — | — | — |

Deaths reported 2,870: under five years of age 920; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 304, acute lung diseases 594, consumption 313, diphtheria and croup 128, scarlet fever and diarrheal diseases each 37, measles 22, cerebro-spinal meningitis and whooping-cough each 19, typhoid fever 18, erysipelas 13, small-pox (Cincinnati) 6.

From measles New York 16, Brooklyn 2, Philadelphia, Washington Cincinnati and Providence 1 each. From cerebro-spinal meningitis Washington 5, New York, Worcester and Lynn 2 each. Philadelphia, Boston, Cleveland, Fall River, Lowell, Somerville, Malden and Chelsea 1 each. From whooping-cough New York and Brooklyn 7 each, Worcester 2, Philadelphia, Cambridge and Springfield 1 each. From typhoid fever Philadelphia 7, Cleveland 3, Brooklyn 2, New York, Boston, Cincinnati, Lowell, Lynn and Springfield 1 each. From erysipelas New York and Philadelphia 4 each, Boston 3, Brooklyn and Somerville 1 each. From malarial fever New York 4, Nashville 1.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 6, 1895, TO APRIL 12, 1895.

CAPTAIN REUBEN L. ROBERTSON, assistant surgeon, is granted leave of absence to, and including July 3, 1895, to which date his resignation has been accepted by the President to take effect.

Leave of absence for two months on surgeon's certificate of disability, is granted CAPTAIN JAMES E. PILCHER, assistant surgeon.

The following named officers will report in person to MAJOR CALVIN DEWITT, surgeon, President of the examining board appointed to meet at Fort Leavenworth, Kansas, on Wednesday, May 1, 1895, at such time as they may be required by the board, for examination as to their fitness for promotion, and upon conclusion of their examination will return to their proper stations: FIRST-LIEUT. THOMAS U. RAYMOND, assistant surgeon; FIRST-LIEUT. HENRY D. SNYDER, assistant surgeon; FIRST-LIEUT. ALLEN M. SMITH, assistant surgeon; FIRST-LIEUT. JOSEPH T. CLARKE, assistant surgeon.

CAPTAIN WILLIAM B. BANISTER, assistant surgeon, is relieved from duty at Fort McIntosh, Texas, and ordered to duty at Fort Omaha, Nebraska.

FIRST-LIEUT. FREDERICK P. REYNOLDS, assistant surgeon, is granted leave of absence for one month, to take effect upon his relief from duty at the U. S. Military Academy, West Point, New York.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 13, 1895.

G. MCC. PICKRELL, past-assistant surgeon, detailed from U. S. S. "Newark" and granted three months' leave.

A. W. DUNBAR, assistant surgeon, detached from U. S. R. S. "Vermont" and ordered to the U. S. S. "Newark."

HENRY LA MOTTE, assistant surgeon, detached from U. S. S. "Newark," ordered home and two months' leave.

C. P. BAGG, assistant surgeon, detached from U. S. N. Hospital, Mare Island, Cal., and to the U. S. S. "Monterey."

## SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY.— The Annual Meeting will be held at 19 Boylston Place on Saturday, April 27th, at 8 P. M.

"Medical Advertisements in Newspapers," Dr. Walter Channing.

"Notes on Cases of Inflammation of and about the Vermiform Appendix," Dr. J. B. Blake.

Report of the Treasurer and Librarian. Election of Officers. Supper after the meeting.

H. L. SMITH, *Secretary*.

NEW HAMPSHIRE MEDICAL SOCIETY.— Members of the Society will take notice that the Executive Committee have changed the date of the Annual Meeting to Monday and Tuesday, June 3 and 4, 1895, and the programme will be issued accordingly.

The change is a necessity, as the time to which the Society adjourned will be Decoration day.

Per order of Executive Committee.

G. P. CONN, M.D., *Secretary*, Concord.

## APPOINTMENTS.

DRS. JOHN S. PHELPS and JOHN W. DEWES have been appointed district physicians to the Boston Dispensary.

## RECENT DEATHS.

JOSEPH HAGAR, M.D., M.M.S.S., died in East Marshfield, April 9, 1895, aged seventy-five years.

JOHN BLACKMER, M.D., died at Springfield, Mass., April 14th, aged sixty-six. He had seen active service during the war as a surgeon in both the Union army and navy. He was connected at times with various insane asylums, and at one time was in charge of the New Hampshire Asylum for the Insane. He was a prominent prohibitionist in New Hampshire, previous to his removal to Massachusetts in 1874. He had been Prohibitionist candidate for governor both of New Hampshire and Massachusetts.

## ROSE'S OPERATION FOR TRIGEMINAL NEURALGIA.[1]

BY N. P. DANDRIDGE, M.D.,
*Professor of Surgery and Clinical Surgery, Miami Medical College, Cincinnati, O.*

I MAY very properly introduce the following discussion on the results obtained by the removal of the Gasserian ganglion in cases of inveterate neuralgia of the branches of the fifth nerve, by the recital of a case in which Rose's method was employed, during March, 1894.

The patient, a German, was first sent to me some nine or ten years ago, on account of a severe and persistent neuralgia which involved the region supplied by the second branch. The man was engaged in a bristle factory, and the locality in which he lived rendered a malarial origin for his trouble not unlikely. His disease, however, was not in any way controlled by the long-continued use of quinine. He was a free drinker of both spirits and beer, and his indulgence had been unusually free at the time he was first seen. His age was forty-five.

He was sent to a dentist, but derived no benefit from his treatment. The infraorbital nerve was then removed. The infraorbital foramen was exposed, and the canal traced back on the floor of the orbit as far as possible, and opened, the nerve cut through, and the section pulled out of the foramen, and the terminal filaments removed. The antrum was not opened. After the operation the man became unruly, continued the use of stimulants, and developed an attack of delirium tremens, during which the bandages were displaced, and facial erysipelas ensued, which resulted in the destruction of a considerable part of the lower lid. This was subsequently repaired by a plastic operation by Dr. Sattler, not sufficiently, however, to fully protect the eye. The result of the removal of the nerve was extremely satisfactory, and there was complete immunity from pain for two years. It then returned in the region of the frontal. The supraorbital foramen was exposed, and as much of this nerve as possible removed. Complete relief followed for three months, and then returned, the pain, however, not being continuous, so that the man was able to keep on at his work. In the early part of March, 1894, he again presented himself, suffering most intense paroxysms of pain. These paroxysms were brought on when he attempted to speak or swallow, and on account of their severity a satisfactory examination of the mouth was impossible. This condition had now lasted some weeks, and involved all three branches, but was most intense at a point about three inches above the right eye, and an inch from the middle line. No matter in what region of the face the pain would start, it would concentrate its greatest energy on this spot.

For several weeks attempts were made with increasing doses of aconitine and galvanism to control the pain, but without results. It was then determined to attack the Gasserian ganglion, and Rose's method was selected. The H-shaped incision advocated by Andrews was made, and the zygoma cut through with a saw after being drilled so as to be wired at the completion of the operation. Subsequently it was found that further room could be secured by cutting away the anterior part of the zygomatic arch with forceps. As wiring was thus made impossible, the portion of the bone turned down with the masseter was completely removed. The coronoid process with the attachment of the temporal muscle was then exposed, and after being drilled for subsequent wiring was cut through, and the separated portion turned up with the temporal. The lower jaw was now depressed with a mouth-gag, and some fat abundantly supplied with veins which bled freely, removed, and the external pterygoid brought into view. This was separated from the greater wing of the sphenoid partly by the knife and partly by a blunt instrument. During this part of the operation the internal maxillary came into view and was ligated; in spite of this, however, the hemorrhage continued very embarrassing, and was only controlled by pressure. After a tedious dissection, which was prolonged by want of proper illumination, the foramen ovale was finally reached; the blood welling up from the depths of the wound rendered the recognition of the opening most difficult. It was finally definitely located by passing a grooved director into it, and with this in place a trephine was applied so as just to reach the edge of the foramen, and a button of bone removed. The opening was enlarged with a chisel and the nerve lifted up on a hook and cut through with scissors within the foramen. The view of the ganglion was obscured by the constant oozing; it was broken up by a blunt hook in a somewhat haphazard manner. The second branch was not seen within the skull. It was, however, readily brought into view with Meckel's ganglion, as it crossed the spheno-maxillary fossa. The nerve was torn away as it enters the infraorbital canal, and was then traced back to the foramen rotundum and twisted off. The supraorbital notch was now exposed, and some fine nerve filaments traced up for an inch or more and removed. The coronoid process was wired, and the wound packed with gauze, the end of which was brought out to supply drainage, and the external wound closed.

The operation lasted two hours and the patient was much exhausted, but soon rallied. On the third day he had a paroxysm of pain exactly similar to those suffered before the operation, and of extreme severity. The greatest intensity was on the top of the head. The pain was controlled after a hypodermic of morphia, and did not return. During the second week a superficial ulcer developed on the cornea, but soon yielded to treatment. There was some suppuration during the healing process, and there still persists now, ten months after the operation, a small sinus which leads down to bare bone. His general improvement was rapid, and in a few weeks he gained twenty-five pounds. His condition, ten months after the operation, is as follows: There is marked atrophy of the muscles of mastication on the side operated on, and the depression in the region of the zygoma produces considerable deformity. There, of course, still exists the defect in the lower lid left from the sloughing after the first operation. Sensation is nowhere completely lost, but is most deficient below the infraorbital foramen and over the submental. Pressure with the finger in front of the ear produces sensation, though not a painful one, over the submental foramen, beneath the infraorbital foramen, and over the spot on the forehead which was the seat of greatest pain. The sense of hearing is almost

[1] Read before the Surgical Section of the Suffolk District Medical Society, February 6, 1895.

lost in the right ear. The sense of taste on the right side of the tongue is impaired. A solution of salt can be distinguished when placed near the tip, but a solution of sugar cannot be distinguished from pure water. The movement of the jaw is impaired. He is able to masticate his food, but does so almost entirely on the left side, all of the upper teeth and most of the lower ones on the right being lost. The man expresses himself as entirely satisfied with the result, and is now at work daily. His son informs me that he has again commenced the free use of stimulants.

In the performance of this operation the incision suggested by Rose, commencing "over the malar bone about half an inch below the external angular process of the frontal and carrying it along the zygoma and down in front of the ear, over the parotid region to the angle of the jaw, and then forward along the lower border of the horizontal ramus as far as the facial artery," is probably better than the H-shaped incision employed by Andrews. It is desirable to secure bony union in the process of repair for the separated portion of the zygoma, as the depression otherwise resulting leaves an unsightly deformity. Most operators have drilled the bone in such a way that both ends can be wired on completion of the operation. Stitching the edges of the fascia together is said, however, to have given equally good results. Rose at first wired the detached portion of the coronoid process, but has latterly removed this entirely from the temporal attachment. Atrophy of this muscle must occur from destruction of its nerve supply. The location, and exposure of the foramen ovale is the difficult part of the operation — indeed, Rose himself reports in his third case that "the pterygo maxillary fissure was mistaken for the foramen, and the mistake only discovered by the protrusion of the orbital fat through the trephine opening"; and he further states that "the part of the bone which one first reaches in the deepest part of the operation is well in front of the foramen."

There is a great difference in the prominence made by the pterygoid ridge in different skulls, and in the angle made by the portion of the greater wing of the sphenoid below the ridge, which enters into the zygomatic fossa and the temporal portion, above. The more prominent the ridge, and the more nearly the surface of bone below approaches a right angle to the part above, the more difficult will be the exposure of the foramen, and the more difficult the application of the trephine. During this stage of the operation, there is decided advantage in adopting Rose's suggestion to have a skull at hand for reference. According to Doyen, the best way to reach the foramen ovale is "to trace the sphenoidal ridge backward to the transverse root of the zygomatic arch. This latter leads directly to the eminentia articularis, in front of which the opening will be found." The inferior dental or gustatory nerve may be used as a guide to the foramen if exposed, as they pass downward under the lower border of the external pterygoid muscle. In my case they were not seen until the foramen was reached. The external pterygoid plate is a useful guide as pointed out by both Rose and Mixter: "The foramen lies usually a little behind and external to the base of the outer plate," but sometimes directly behind it.

Mixter has pointed out some variations in structure which are found in this region, and may have an important bearing on the operation. He has called attention to the fact[2] that the ligamentum pterygo spinosum may be ossified, and may divide the branches of the nerve, and in order to expose the foramen it may be necessary to chisel this bridge away. The insertion of a grooved director into the foramen before the trephine was applied rendered the exact application of this instrument much easier, so that its edge just touched the foramen. Any enlargement of the trephine opening that is needed may readily be made by a chisel, or cutting forceps.

This operation leaves much to be desired in the view obtained of the ganglion itself; at least, such was my experience, and the removal of the latter is a somewhat haphazard affair. The especial dangers, which theoretically should be great, of wounding the sinus or internal carotid, do not seem to have really occurred; indeed, greater and more alarming bleeding has taken place when the skull has been opened from the side and the ganglion brought plainly into view by lifting the tempero-sphenoidal lobe, than in Rose's operation. That the removal of the entire ganglion can, however, be accomplished, is shown by Rose's later cases and by the case reported by Doyen to the Seventh Congress of French Surgeons (Septième Congrès de Chirurgie, Paris, 1893). In evidence of the thoroughness of his operation, he presented the specimen removed, consisting of almost the entire ganglion, with fifteen millimetres of the superior maxillary, and thirty-five to forty millimetres of the lingual and inferior dental.

In attempting to compare Rose's operation with that of Hartley, it seems to be generally admitted that the latter gives a freer view of the ganglion and more certainty in its removal. Rose, in a personal communication, in speaking of a case in which he had performed Hartley's operation, said he was "pleased with it and intended where feasible to try it again." It limits, however, the removal of the branches to the portion within the skull — in Rose's operation the nerves can be removed up to the bony canals they enter; indeed, we are hardly in a position to say that the removal of the ganglion will afford greater immunity from recurrence than removal of the branches at their respective foramen at the base of the skull. In both operations hemorrhage is a prominent feature. It occurs, however, under quite different conditions. In the Hartley method it occurs after the skull is open, and the brain exposed, conditions which may lead to most serious results. Keen and Richardson have both had experiences showing the gravity of hemorrhage at this time, though in both cases the danger was happily averted — in the former's case only, however, by stuffing the wound with gauze and delaying the completion of the operation for several days. The wound of the posterior branch of the middle menigeal, in Keen's, before the completion of the section of bone, when it could be efficiently dealt with, would certainly seem to threaten serious consequences. In Rose's method the hemorrhage is simply embarrassing, and prolongs the operation. It can at any time be controlled by pressure, and must to a large extent have ceased before the skull is opened. In the former, the hemorrhage is at the end and dangerous part of the operation; in the second, at the beginning. Park has ligated the common carotid as a preliminary step so as to avoid serious hemorrhage. It would seem, in case this step was deemed necessary

[2] Boston Medical and Surgical Journal, August 13, 1891.

simply for the control of hemorrhage, that the ligature had better be placed around the external carotid. Such a ligature would be equally or more efficient to control the bleeding, and certainly involve much less danger. Ligature of the common carotid alone has, however, been practised, some eighteen successful cases being reported by Fowler; so that it may play a certain rôle beside the simple control of bleeding during the operation. It must certainly add to the chances of a fatal result, and Park's example does not seem to have been followed.

In regard to the results obtained by Rose's operation, Mr. Rose writes of his seven cases: "The results have been most gratifying. In only one instance, and that a highly neurotic woman, has there been any return of the pain, and then not at all severe. I have noticed a little stiffness in the lower jaw, easily tolerated in comparison with the terrible pain from which relief has been obtained."

Rose's cases are reported as being operated on in April, 1890; January, October and November, 1891; and January, 1892, so that three, four and five years must have now elapsed.

Parks reports his cases, operated on in July and October, 1892, as still in satisfactory condition. Andrews has had "two relapses after being cured for a good while"; and "one in which there is still complete relief after three years."

Parkhill reports recurrence after full relief for two years. The Hartley operation was then performed, the patient dying from exhaustion. This is the only case in which Hartley's operation has been performed after Rose's method, so far as I can learn. Eskridge reports one case without recurrence at the present time, nearly two years after the operation.

It may be well in this connection to recall the figures given by Fowler,[2] and the results of removal of the infraorbital nerve.

In twenty-six cases, in which the infraorbital nerve was removed together with Meckel's ganglion, there was complete relief for over three years in three cases, for over two years in six cases, and over one year in nine cases.

The average relief in all was one year and five and one-half months. In twenty-six cases of neurectomy of the infraorbital without removal of Meckel's ganglion, there was immunity for three years in five cases, over two years in three cases, and over one year in seven cases. The average was one year, three and one-half months.

In my own case ten months have now elapsed, relief being still complete. It is to be remembered in this case that immunity for two years was secured by removal of the infraorbital in the same subject.

No comparison can yet be made between the immunity secured by the different methods. The condition of the patient after successful operation is certainly more desirable when Hartley's method has been practised than after Rose's operation. In the latter the scar is more visible and there certainly is less chance of primary healing and some chance of necrosis. In addition there may result limited movement of the jaw. This is present in a large proportion of cases.

In my own case there has been almost complete loss of hearing on the side operated on. Rose has pointed out the danger of wounding the Eustachian tube when the trephine is employed in the manner first described by him. The centre pin was projected as far as possible and inserted into the foramen ovale, as a half-inch trephine might readily wound the tube, "as it passes in immediate contiguity to the ridge of bone, which forms the inner boundary both of the foramen ovale and spinosum." In my case the grooved director was inserted into the foramen and the trephine was applied external to it. Without injury to the tube, however, it is difficult to explain the subsequent deafness.

To the nineteen cases of Rose's operation reported by Keen, there are four additional ones to be added: (Eskridge two, Andrews one, Dandridge one), with one death, or twenty-three cases with three deaths. Andrews reports a case of death from brain disease one month after the operation; if this be charged to the operation we have twenty-three cases and four deaths.

To the Hartley operation there are seven additional cases: Richardson one, Keen two, Parkhill one, Rose one, and Tiffany two, with three deaths (Keen, Parkhill, Rose). This gives, with Keen's nineteen reported cases, twenty-six cases and five deaths.

The results thus far obtained in the intercranial operations do not justify the abandonment of the more superficial neurectomies in persistent neuralgia, but certainly justify the expectation that they will afford great and possibly permanent relief where recurrence takes place — a relief so great as to fully justify the danger they involve.

## TWO CASES OF DERMOID CYST OF THE OVARY INVOLVING THE LARGE INTESTINE; REMOVAL OF CYSTS; RESECTION OF INTESTINE AND END-TO-END SUTURE; RECOVERY.[1]

BY MAURICE H. RICHARDSON, M.D.,
*Visiting Surgeon, Massachusetts General Hospital; Assistant Professor of Anatomy, Harvard Medical School.*

The two following cases of dermoid cyst of the ovary illustrate one of the most serious complications to be met with in the course of abdominal operations. In each the condition was entirely unexpected, and had to be remedied immediately. In one, the resources of a large hospital were at hand; in the other, those of my regular abdominal outfit.

In the first case, after the successful removal of a purulent Fallopian tube, a tumor as large as an orange was found wedged between the uterus and the rectum. This proved to be a dermoid cyst of the left ovary, which grew into the rectal wall and projected into and through its mucous surface. The portion thus attached was about two inches in diameter. The hair from the cyst grew into the lumen of the bowel. The tumor was removed by a clean dissection with scissors. The resulting opening in the bowel was situated deep in the pelvis, and involved the greater portion of the rectal wall.

With the patient in the Trendelenberg position, the opening was closed very satisfactorily by means of interrupted Lembert stitches. The distal and proximal ends were brought together and sutured with great difficulty by means of a long needle-holder.

In the second case the cyst filled the pelvis and involved in its growth the sigmoid flexure. The cyst was gangrenous, and in the necrotic process at least

[1] Read before the Obstetrical Society of Boston, February 9, 1893.

three inches of intestinal wall had been entirely destroyed. The portion of bowel attached to the mesentery was not affected. The tumor contained nothing but hair and fecal matter. Its separation from the bowel was easy, though complete resection was necessary. The whole portion affected by gangrene was removed, until a clean and healthy surface remained. The resulting edges were brought into careful approximation and held there by a single row of interrupted Lembert sutures of silk. Thorough search failed to show any further injury to the bowel.

In both cases provision was made against a possible fecal escape by sterile gauze drainage. In both, this provision proved the saving of the patient, for on the second or third day there was in each case an abundant fecal escape. The drainage, which of necessity followed, was brief. Recovery was rapid, and no interference with nutrition or with peristalsis resulted.

CASE I. Stella C., aged twenty-four, married, dressmaker, entered the Massachusetts General Hospital in July, 1894, with negative family history. She had had one child seven years ago. She has always had leucorrhea, which has been much worse during the last month. Three years ago the patient was attacked with excruciating pain in the right ovarian region, accompanied by excessive vomiting. This attack kept her in bed for nine months. Her catamenia were regular and normal during this time. July 8, 1894, ten days before her catamenia were due, she began to flow profusely. The flowing was accompanied by excruciating pain in the right iliac region, shooting down into the right leg. For the last two days the hemorrhage and pain have much diminished, while yesterday there was abundant discharge of pus from the vagina. Digestion was good, bowels regular. She was referred from the out-patient department by Dr. Townsend.

Examination showed a fairly developed but poorly nourished woman. The chest was normal. A mass, the size of an orange, could be felt on the right and partly behind the uterus, very sensitive to pressure through the vagina. Palpation of the abdomen showed no tumor or sensitiveness on either side. The uterus was in good position. The urine was normal.

Operation was performed by Dr. Richardson on July 21st, Dr. Cobb assisting. With the patient in the Trendelenberg position, an incision three inches long was made in the median line, below the umbilicus. On introducing the hand into the abdominal cavity, a sausage-shaped tumor could be felt in the right pelvis. This broke, on slight manipulation, and discharged a large amount of pus. The adhesions were carefully separated. The dilated and thickened tube was tied off with silk and removed. Another mass was then found behind the uterus and to the left of it, closely involving the sigmoid flexure and beginning of the rectum. Attempted enucleation showed that the tumor grew from the bowel wall, and was so intimately connected with it that separation without intestinal resection would be impossible. On trying to dissect the tumor from the intestine the cavity of the bowel was extensively opened. The abdomen was thereupon carefully protected with gauze, and the tumor removed by free resection of the intestine. Nearly the entire circumference of the gut was thus excised, the growth having invaded its entire structure and having projected into and through the mucous layer. The opening in the intestine was closed by interrupted silk sutures applied longitudinally. Drainage of gauze applied about a glass tube was used. The abdominal wound was partially closed by silkworm-gut sutures.

Recovery from the ether and from the shock was satisfactory. Four days after operation there was a foul and fecal discharge from the tube. This was fully controlled by drainage, and caused no harm. Five days later the tube was removed. She was discharged to the convalescent ward four weeks after the day of operation, with a granulating sinus remaining. She has been perfectly well ever since.

CASE II. Miss A. T., aged thirty-seven. Her father died of pneumonia at sixty-eight; mother at sixty-one from injuries. She had scarlet fever followed by ear trouble when three years old. She has been as well and strong as the average girl. Catamenia began at sixteen, and have been normal. She has always been troubled with constipation.

In January, 1894, about ten months before operation, she was seized with nausea and vomiting accompanied by fever. Her catamenia at this time were about three days late, but she began to flow before the pain started. The physician in attendance called it inflammation of the ovary. The pain lasted two days, and she was in bed five days. At the end of three weeks was as well as ever, with the exception of a slight discomfort in the right side.

On the 1st of April, four months from the first attack, after a movement of the bowels, severe pain came on in the right side of the abdomen, associated with nausea and vomiting. The pain was so severe that she was doubled up, with the legs flexed upon the abdomen. This attack lasted only twelve hours, when she was perfectly well again.

Four months later, on August 4th, she had a similar attack, with rise of temperature. The pain and tenderness extended over the abdomen and chest. This occurred at the time the catamenia were due. She began to flow three days later, when all the symptoms abated. She was up and about again in two weeks, but she was not as strong as before the attack. The bowels were very irregular, varying from severe constipation to excessive diarrhea. There was continual tenderness on the left side of the abdomen.

About September 9th, a week past her regular menstrual period, she had general abdominal pain, which kept her in bed until the 26th. Her bowels were very irregular, and she suffered much from general distention. Food caused almost constant nausea and distress. There was a slight rise of temperature all the time.

On September 26th she was brought to St. Margaret's from Hyannis.

Examination showed this patient to be rather slight, pale and delicate and much emaciated. Pulse 120, weak and easily compressible. The chest was negative. To the left of the median line, just below the umbilicus, a somewhat indefinite mass could be felt through the abdominal wall. Nothing was perceptible on the right side, although she complained of some soreness in the right ovarian region.

By vaginal examination the pelvic region varied from day to day. At one time nothing positively abnormal could be felt; at others a sense of indefinite boggy resistance. One day a tympanitic prominence above the pubes; at another time what suggested a distended bladder. Bimanually, under ether, an in-

definite mass could be felt between the fundus uteri and the abdominal wall.

For the next three weeks the patient was kept under close observation. Her chief symptom was pain in the thorax which seemed like dry pleurisy; there was also difficulty in digestion. After a week or ten days of careful dieting she was able to take abundant nourishment and stimulation. The bowels, which had previously been irregular, acted well by moderate use of laxative pills. The temperature did not rise more than a degree or a degree and a half, and on many days was normal. On the whole, she seemed to gain in her general condition, so that she could get up for part of the day. The pain in her right side entirely disappeared, but there was still to be felt at times a slight resistance to the left of the median line. After careful consideration an exploratory incision was deemed advisable.

October 16, 1894. A median incision was made below the umbilicus, the patient being in the Trendelenberg position. On opening the peritoneal cavity and introducing the hand, a mass was found everywhere adherent, situated partly behind and partly to the left of the uterus. The abdominal cavity was then carefully protected by gauze barriers, and a large, gangrenous, dermoid cyst, containing pus, hair and feces, was easily separated from its adhesions and removed. Several inches of the sigmoid flexure were found completely destroyed, nothing remaining but the attachment of the mesentery. The whole pelvic cavity was flushed with boiled water, and packed with gauze. The ragged ends of the sigmoid flexure were then drawn into the incision, carefully surrounded with gauze, trimmed with scissors and united by interrupted Lembert sutures. The coil was then replaced in the abdomen and the line of suture protected by gauze. The pelvis was drained by means of a glass tube. The abdominal incision was closed by silkworm-gut sutures.

After the operation she was given stimulative enemata every four hours. There was no nausea, and after twelve hours the patient was able to take small amounts of milk, lime-water and champagne. This was deemed necessary on account of her poor condition, though usually we do not give nourishment for the first twenty-four hours in abdominal cases.

For several days after the operation her condition was serious. The pulse remained at 120. The temperature gradually came down to normal. The glass tube was sucked out every six hours; the discharge, though serous at first, became fecal after twenty-four hours. The amount of discharge increased until the bowel emptied itself entirely through the wound.

On the third day the patient was taking a fair amount of nourishment and stimulant by mouth; enemata were therefore stopped, as they escaped through the abdominal opening. The temperature was still satisfactory, although her pulse varied around 120, and was very weak.

On the fifth day there was a slight improvement in her general condition, although the discharge of liquid fecal matter and gas from the abdominal opening was enormous. Up to this time absolutely nothing passed by rectum. This condition lasted for eleven days, her general condition improving a little, on the whole. She was able to take nourishment at frequent intervals, but after every feeding there seemed to be an increased amount of discharge from the abdominal opening. As far as the nurse could tell, there had been no discharge of gas by rectum, although the patient thought that two or three times a little had escaped that way.

Fecal movements by the rectum began a few days later, with great relief to the patient. From this time the amount of discharge from the abdominal opening steadily diminished; gas and feces passed freely by rectum. The patient's condition immediately improved, and she was able to sit up at the end of four weeks, with the abdominal wound entirely granulated.

On the second day after the operation it was observed that the patient was unable to extend her right hand. Examination showed complete musculo-spiral paralysis. During the operation, which lasted something over an hour, the patient's arms had been kept extended above her head.

For four weeks she had massage and electricity every day, with almost no improvement in her condition. At the end of three months the functions of the nerve were entirely restored.

Experiments on the cadaver, made by Dr. Walton and myself since this experience, shows that the nerves of the brachial plexus are brought up against the clavicle when the arms are fully extended over the head. Pressure upon these nerve trunks in this position, continued for an hour or more, seems to be sufficient to produce a temporary paralysis. It is best, therefore, to avoid extending the arms in the use of the Trendelenberg table.

December 27th. Up to ten days ago the patient had improved so that she was up all day, and had decided to take a journey to Chicago — her home. Without any premonitory symptoms she was taken one night with a chill and pain in the right side, with a temperature of 102°. The pain extended the next day over the entire abdomen, which was somewhat distended. In twenty-four hours she began to flow, and after four or five days the symptoms all abated. This attack of pain, her sister says, was similar to attacks that she had previous to the operation.

In the first case the question arose after operation whether, on the whole, it would not have been better to leave the tumor. Up to the time of my operation upon the second case, I was doubtful on this point. The close relation of the tumor to the bowel, with the increase in size sure to take place, rendered it certain that an operation would some day be necessary, and probable that sooner or later the cyst would get infected. In either event an operation would be imperative; in the former, under difficulties increased by the enlargement and probable adhesions, and in the latter complicated by septic conditions of the most alarming nature. On the other hand, no one could say positively that the dermoid would cause any trouble whatever. So serious an operation as that of opening the rectum would therefore be of doubtful justification, to say the least. In this particular instance the problem was solved by the unexpected and unintentional opening of the rectum. Nothing could be done except immediate enucleation, with such repair of the gut as we might be able to make. The second case throws much light on this important question. The bowel and the tumor, both intimately grown together, after a time became involved in total necrosis. Operation under these unfavorable conditions was clearly imperative. The successful issue is a matter of congratulation hardly to be expected in a second case. In fact, could we have foreseen that a frail woman was to have gangrene of a large

dermoid, with sloughing of the intestine for three inches, in which the rotten cyst was to act as the only barrier against a general fecal extravasation; that in the midst of so hopeless a condition her only chance lay in the removal of the tumor, resection and suture of the bowel, and relief of the existing peritonitis — could we have predicted in Case I a reasonable probability that such complication would arise, excision even of the portion of the bowel under the favorable conditions then present would have been deemed imperative.

The most important question in connection with the operation is that of drainage. The whole question of the method of applying sutures is of no importance if there is under all a possibility, even, of fecal extravasation. Such extravasation is admittedly possible, no matter how you sew; it is the great and the only risk to be feared after that of shock. Fecal extravasation must, therefore, be provided against. This can safely be done by means of gauze barriers, as I have described before, but the use of gauze must not lead to carelessness in making the joint. In the second case I was convinced that the sudden and excessive fecal discharge came, not through the line of sutures, but from an undiscovered spot of necrosis lower down. This disaster was effectually met by the method of drainage used.

With such a provision against accident we are not obliged to use any of the time-taking sutures; nor is a double row essential. On its own merits the interrupted Lembert stitch surpasses all other sutures. It is much more easily and rapidly applied, and it is quite as efficient. All other elements in the question aside, the saving of time is enough to place this method where it belongs — at the head of intestinal sutures. My opinion is based upon many abdominal operations, including twelve intestinal sutures after resection of the entire lumen. Eight have recovered. The fatal cases were (1) shock (woman of sixty-eight, with five days' gangrenous hernia, joint perfect); (2) shock after removal of large, solid abdominal tumor through which the transverse colon ran (joint tight); and (3) exhaustion after complete obstruction for several weeks (joint intact, no extravasation, no peritonitis); (4) shock after excision of four feet of gangrenous intestine. In all other cases, including a resection of ten inches for gangrenous hernia, a resection of the entire ileo-cecal coil, recovery followed.

## THE MURDER OF JAMES FARRAR.

### A Medico-Legal Report.[1]

by julian a. mead, m.d., of watertown, mass.

At half-past two in the morning of May 17, 1894, James Farrar, a farmer in the town of Lincoln, was awakened by a burglar who left the room as soon as he saw that Mr. Farrar was awake. Mr. Farrar arose immediately, dressed, and aroused a man who lived in his house, and then called up four other men who lived in the neighborhood.

In the meantime, a window in the kitchen of James Farrar's house was found open, and under this window was a peculiar foot-print pointing toward the house. Similar foot-prints, leading to and from the house, were found in the dusty road. For some time the peace of the town of Lincoln had been greatly disturbed by several burglaries, and James Farrar, who was a constable, considered it his duty to arrest the man who had broken into his house. Together with four companions, he followed these peculiar foot-prints now plain, now obscure, now leading up a side-road or into the yard of some house, but always onward toward the town of Weston. When they reached the Tower Hill station of the Massachusetts Central Railroad, which is about four miles from Mr. Farrar's house, they lost track of the peculiar foot-print that they had followed so persistently. At this point the party separated; James and his brother Edward went down the track, and the other three drove in the carriage around to the Cherry Brook railroad-crossing, which is some distance nearer Boston.

James and Edward, encouraged by finding a single foot-print on a sleeper, pressed steadily on down the track, and soon descried in the distance a moving object which, in the dim, uncertain light of dawn, seemed to be a man. This object at once disappeared around a curve in the track, and, when the Farrars reached the spot, was nowhere to be seen. They heard, however, at this time a noise like the breaking of branches in the woods at the side of the track. They went into the woods, and found a man standing at a freshly kindled fire. After some talk of the danger of building a fire in the woods, they put the fire out, and asked the man to come with them; but this he refused to do. James then said, "We intend you no harm, but you must come with us." The man, who subsequently gave his name as Barrett, pulled out a revolver, covered the Farrars, and said that he would not go with them. He then went toward the railroad track, pointing the revolver at them as they slowly followed him. On reaching the track, he started down towards the Cherry Brook crossing, keeping his pursuers all the time covered with his revolver. Barrett had not gone far when he saw the rest of the party, who had gone around the highway, coming up the tracks towards him. His retreat being cut off in this direction, he ran up the bank on the opposite side of the railroad. James Farrar rapidly followed him, and reached the bank soon after Barrett, whose retreat was cut off by a barbed-wire fence. Barrett, cornered and at bay, began to fire at James who reached him just as he fired the third shot. James sprang upon Barrett, and with the help of his brother Edward, soon had him on the ground. In a few minutes James said, "I am shot." He then fell over and died.

I found the body dressed in a leather jacket, woollen vest, two thin shirts, trousers and shoes. In about the centre of the breast of the leather jacket there was a black spot and a ragged hole. There was also a corresponding hole in the vest and shirts. At the back there was a hole in the shirts and vest, but none in the leather jacket. A bullet was found beneath the back of the vest and the leather jacket.

On the following day I made an autopsy, assisted by Drs. Wood and Jackson. There was a black spot in the middle of the front of the chest, two inches long and three inches wide; in the centre of this spot was a circular hole that measured one-quarter of an inch in diameter. This hole was an inch above a line drawn between the two nipples. The upper part of the left side of the face, and the left ear were sprinkled with black spots (powder-marks).

[1] Read before the Massachusetts Medico-Legal Society, February 6, 1895.

On dissection, a small hole, corresponding to the hole already described in the skin, was found in the sternum, just opposite to and near the upper border of the third rib on the left side. The under side of the sternum presented a ragged hole about an inch long pointing toward the left.

The left pleural cavity contained two litres of blood. The left lung was collapsed.

The path of the bullet could be traced by a dark blue line along the upper border of the upper lobe of the left lung, which was slightly wounded at one point. This line led to the left common carotid artery, which was found to be nicked.

There was a small irregular hole, from which blood was slowly oozing, on the left side of the back at a point three inches from the spinal column, and two and one-quarter inches above the spine of the left scapula.

All other organs were found normal.

The cause of death was hemorrhage from the left common carotid artery.

Barrett was indicted for murder by the grand jury, and was tried at Cambridge on the 19th of November, 1894. The trial was ably conducted by Attorney-General Knowlton and District-Attorney Wier for the Commonwealth, and Messrs. Goodrich and Selfridge for the defendant.

The defence tried to prove that Barrett did not know that he was being arrested for burglary, or that James Farrar was a constable, and that, therefore, he acted in self-defence. In order to strengthen this theory of self-defence, Barrett's lawyers tried to prove that he, instead of deliberately firing three shots, as testified to by eye-witnesses, fired but one shot, which was discharged more or less accidentally, after Farrar had seized Barrett. The defence maintained, therefore, that the ball entered the breast at an angle of forty-five degrees, and that the powder-marks on the left ear, and upper part of the left cheek were made by the powder that discharged the fatal bullet that entered the chest.

The medical experts for the Commonwealth, Dr. Draper and myself, testified that the bullet entered the breast at right angles, and was deflected in its course by the sternum. We were led to this conclusion by the fact that the hole in the skin and sternum was perfectly round. We also testified that the wound in the chest, and the powder-marks on the ear and cheek could not have been made by one and the same shot.

In support of our opinion, we undertook, by experiments, to reproduce as far as possible the position of the revolver when the shots were fired. Using Barrett's revolver and the same kind of cartridges, we fired, at different distances, into an old leather jacket which closely resembled that worn by Farrar on the morning of the murder, until we obtained a hole that corresponded to that in Farrar's jacket. To obtain this similarity in appearance it was necessary to hold the revolver about an inch from the jacket. It was conceded by the defence that this distance was correct.

We determined the distance at which the revolver was held, when the shot was fired that made the powder-marks on the ear and upper part of the cheek, by firing at pieces of blotting-paper, and noting the result. The first shot was fired at a distance of eight feet and left no powder-marks on the paper; at seven feet there were a few marks; at five and six feet the marks were somewhat increased but still quite scattering; at four feet the spots were quite thick; at three feet and a half they corresponded in appearance to those seen on the ear and cheek at the autopsy; at two feet they were very thick, and nearly covered the centre of the paper.

These experiments show conclusively, I think, that the revolver was between three and four feet from the face when the powder-marks were made. Is it possible to reproduce the picture more completely by showing how near the head the bullet passed? You will notice on the blotting-paper targets that the powder-marks are not visible to any extent at a distance of more than four inches from the hole made by the bullet. The bullet could not, therefore, have gone further from the head than four inches, and the number of powder-marks in Farrar's face show that it must have gone as near as three inches, and perhaps a little nearer.

These experiments demonstrate beyond a doubt that the revolver was not farther than an inch from the chest when the fatal shot was fired, and that it must have been three or four feet from the face when the powder-marks were made.

If it is not already clear that separate shots are necessary to produce these two appearances, we have further experiments to show the impossibility of one shot causing both the wound in the chest and the powder-marks.

Experiments were made to see how far from the wound, made by a revolver bullet, powder-marks are visible. At about an inch, the distance at which the wound in the chest was made, there was no spattering of powder, but simply a smutting around the hole; at three inches the result was much the same; at six inches the smutting was present, and some grains of powder were visible; at twelve inches the smutting began to disappear, and the powder-marks were abundant; at twenty-four inches the smutting entirely disappeared. In none of these experiments did the powder-marks appear to any extent beyond a distance of four inches from the bullet-hole. This held true in angular as well as in direct shots.

To substantiate their theory the defence must prove that powder-marks can be deposited one foot from the bullet-hole when the revolver is held about an inch from the wound.

These experiments prove that such spreading of powder is impossible with modern powder and revolvers.

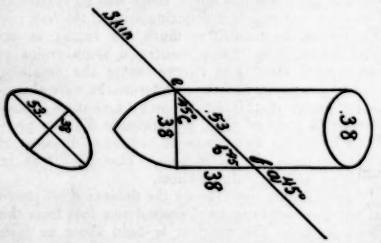
There were, in this particular case, certain additional facts that make the ground of the defence untenable. You will have noticed that no mention has been made of powder-marks on the chin or neck or lower part of the cheek. There were none. Moreover, Professor Wood, after a careful microscopical examination of the jacket above the bullet-hole, was unable to find any grains of powder.

Drs. F. A. Harris and Charles Hibbert testified for the defence that the circular hole in the skin was no criterion whatever as to the angle at which the bullet entered the body. Dr. Hibbert admitted on cross-examination that if the hole in the sternum was circular, the bullet must have gone in straight. Dr. Harris was not asked his opinion on this point.

Both Drs. Harris and Hibbert were asked if a pistol-shot could make a circular wound at the junction of the third rib with the sternum, and at the same

time scatter powder-marks on the left ear. To this question they both answered, "Yes."

We now come to the consideration of the statement made by the defendant's medical experts, Drs. Harris and Hibbert, "that the condition of a bullet-wound in the skin, as to its being round or oval, is no criterion as to the angle at which the bullet was discharged."



The additional circular hole in Farrar's sternum makes this point of little importance in this case, but the general question is well worth some special attention. Since the trial, Captain Gibson, of the Ordnance Department, U. S. A., and I have made some investigations on this subject.

The question is, Does a bullet entering the surface of the human body obliquely make an absolutely circular wound? It is not doubted that bullets fired point-blank and at a little distance may turn to such a degree as to make an oval or irregular wound.

In answer to the above question both the experts for the defence testified that a bullet fired obliquely often makes an absolutely circular opening. Dr. Hibbert said that this was true because the skin, being an elastic and contractile tissue, contracts after an injury, and assumes more or less the shape of the object which caused the wound.

We may admit the truth of his reason without subscribing to his conclusion; and, if it can be shown that the form of a bullet entering the skin at an angle is elliptical and not circular, he must necessarily change his conclusion.

Let us now see what is the shape of a bullet's cross-section as it enters the skin at an angle.

The figure represents a thirty-eight calibre bullet entering the skin at an angle of forty-five degrees.

The problem is to find the length of the line *e f*. We know that the angle *a* is forty-five degrees, and that the base of the right-angle triangle is thirty-eight, the diameter of the bullet. It follows then that the angles *a* and *b* are both forty-five degrees, and that the perpendicular is also thirty-eight. By extracting the square root of the sums of the squares of the other two sides, we find that the line *e f* is fifty-three. This shows that the form of the wound is an ellipse whose major axis is fifty-three, and minor axis is thirty-eight.

Now, if the skin contracts after the bullet enters, as it undoubtedly does, it is absurd to say that it contracts in only one diameter. It is more reasonable to suppose that there is a general contraction, and that the size, and not the form of the opening, is changed.

To see if this theory holds true in practice, we fired at an angle into various objects, such as chamois skin, cloth and paper, and found that the opening was always elliptical. As none of these things have the elastic principle of the skin, we chloroformed, and fired shots into, a dog. We found that while the elasticity of the skin made the ellipse somewhat less marked, the elliptical form, in different degrees, was present in all the angular shots, and absent in the direct shots. There was always a bevelling of the skin at that part of the wound nearest the point from which the shot was fired.

I have been unable to find much on this subject in the authorities. Taylor says that "the aperture is round only when the bullet strikes point-blank, or nearly so. If it should strike obliquely, the orifice will have more or less of an oval or valvular form."

Roswell Park, in Witthaus and Becker's new work, states the matter much the same as Taylor does.

Capt. Louis La Garde, of the Medical Department, U. S. A., conducted a series of experiments on the cadaver to determine the difference in destructive effects between the projectiles of large and small calibre from hand rifles. He writes me that bevelling in the track of the projectile would indicate that the piece had been held at an acute angle with the plane of the part hit; and an absolutely circular opening without bevelling would indicate that the projectile had entered when its line of flight was at right angles to the point hit.

It seems clear that the experts for the defence were not justified in asserting that the form of the entrance wound of the bullet is "absolutely no criterion" of the angle at which the shot was fired; or that an oblique shot often makes a perfectly circular opening.

Barrett was convicted of murder in the second degree, and was sentenced to the State Prison for life.

## Clinical Department.

### DIPHTHERIA, INTUBATION, NASAL-FEEDING, RECOVERY.

BY CHAS. B. STEVENS, A.M., M.D., WORCESTER, MASS.

It has been frequently said of late that, by the use of antitoxin in diphtheria, not only will the number of operative cases be diminished and the percentage of recoveries in operative cases increased; but also, the operation of intubation will more often than formerly prove to be adequate and preferable to tracheotomy, because the period of wearing the tube will be shortened.

The three principal causes of death in operative cases are broncho-pneumonia, sepsis, and extension of membrane. Antitoxin opposes especially the last two causes. To avoid broncho-pneumonia, which is caused largely by the inhalation of food through the tube, Dr. W. A. Morrison has practised feeding through a rubber tube passed through the nose into the stomach.

The following clinical case bears upon these questions:

Healthy child, two years old, began to be croupy March 3, 1895. No history of exposure.

March 6th, 1 P. M., it was found to have marked retraction of lower ribs, with some cyanosis. Pulse very weak and rapid, mouth and pharynx normal, no nasal discharge. Emetics, poultices, steam, calomel fumigation, and subcutaneous stimulation gave no relief. Therefore, at 3 P. M., I performed intubation, Dr. R. S. Wilder assisting. Relief was immediate and perfect. Antitoxin was not used because I sus-

pected the case to be pseudo-diphtheria, but a culture from the pharynx was taken immediately after the intubation.

Finding that attempts to swallow food caused severe coughing, I began the next morning to feed the child by a tube passed through the nares into the stomach. A No. 7 soft-rubber catheter was used, and four to six ounces of milk or egg-nog were given, four times a day, as long as the O'Dwyer tube was worn. There was no local treatment and but very little stimulation by brandy and nux vomica.

March 7th. Culture taken March 6th, examined by Dr. F. H. Baker, showed no Klebs-Löffler bacilli. Another culture was taken.

March 8th, Dr. Baker reported Klebs-Löffler bacilli in last culture; and twelve cubic centimetres of antitoxin (Gibier, 1–50,000) were injected in the lumbar region.

March 9th. O'Dwyer tube removed. Antitoxin, thirteen cubic centimetres, injected. Immediately after removal of tube the respiration became somewhat labored, but after one hour began to improve.

Convalescence was uninterrupted. The temperature, which had been between 99.5° and 101°, reached normal March 15th, when the throat was free from the Klebs-Löffler bacilli.

The temperature rose one or two degrees after each injection of antitoxin, and a peculiar restlessness came on, lasting one hour. No cutaneous eruptions appeared at any time. No albuminuria.

## A QUICK METHOD FOR THE FILTRATION OF A SMALL QUANTITY OF URINE.

BY LOUIS FAUGERES BISHOP, A.M., M.D., NEW YORK.

For a very long time it has been a problem to know how, with the apparatus usually at hand, to obtain quickly and easily a small quantity of clear urine from a cloudy specimen in order to make the usual test for albumin.

The following plan which has proved extremely easy and satisfactory in my own case will, I think, be found equally so in the hands of others: A small quantity of the cloudy urine is placed in a test-tube, the mouth of the test-tube plugged with cotton with a moderate degree of firmness. A second test-tube is placed with its mouth to the first. The position of the tubes is now reversed so that the one with the urine is bottom upward. The upper tube is now carefully and gently heated over the flame of a Bunsen burner or alcohol flame, and the expansion of the air above the urine immediately forces it through the cotton plug, and the filtered urine collects in the lower tube. In this we imitate to a degree the rapid-filtering apparatus of laboratories, but use pressure above the fluid to be filtered instead of an air-exhaust below.

Instruction in Tropical Diseases. — Dr. Patrick Manson has been appointed Lecturer on Tropical Diseases in St. George's Hospital Medical School, London. He will give a course of twenty lectures on the principal diseases peculiar to the tropics and Eastern Asia, beginning early in June. The lectures will be especially adapted to the needs of medical men preparing for tropical or Eastern service, and the admission to them will not be limited to the students of St. George's.

# Medical Progress.

## RECENT PROGRESS IN THORACIC DISEASE.

BY GEORGE G. SEARS, M.D.

### SERUM THERAPY IN PNEUMONIA.

The great interest which has been recently excited in the treatment of diphtheria by antitoxin renders the following summary of the results obtained by similar treatment in pneumonia[1] of special interest.

F. and G. Klemperer have treated twelve cases of the latter disease with the serum of rabbits which had been rendered immune, a dose of five to ten cubic centimetres being injected under the skin of the gluteal region. In five of the cases crisis undoubtedly resulted from the natural evolution of the disease; but in each of the other seven a drop in the temperature and a diminution in the frequency of the pulse and respirations followed the injection. According to these observers there was no question but what the disease was rendered more benign. In eight other cases they injected virulent cultures, which had been exposed to a temperature of 60° C., with very satisfactory results, a gradual fall of temperature beginning twelve to twenty-four hours after the injection. If it rose again, as occasionally happened, a second injection was made. They have also made inoculations with serum taken from a patient immediately after the crisis, and found that the reduction of temperature thus produced was often the beginning of complete defervescence.

Foa and Carbon have seen pneumonia arrested on the fourth day by injections of serum from a vaccinated rabbit, while Foa and Scolia in ten cases used the serum of rabbits which had been rendered refractory to the disease, some of the patients receiving as many as three injections. In four of the cases the crisis seemed to have been hastened.

Janson has also seen this mode of treatment produce early defervescence.

Lava in ten cases where he used the blood-serum and visceral extracts of animals who had been ill with pneumonia was unable to observe any marked immediate influence on the fever, but the temperature curve as a whole was not so high and the frequency of the pulse and the respiration was diminished, while convalescence was rapid and no complications ensued. No local reaction, either immediately or later, followed the injections in any case.

### THE HEREDITARY TRANSMISSION OF TUBERCULOSIS.

The possibility of the direct transmission of tuberculosis from mother to fetus has lately been proved by the occurrence of several positive instances, not only in animals but also in man. Gärtner[2] collected seven undoubted cases of the latter from the literature, beside others which were very probable, and was able to demonstrate experimentally that in pregnant animals with pulmonary consumption the fetus is not so rarely infected with the bacilli. Lehmann[3] on careful examination of three placentas from tubercular patients found characteristic lesions in two, one being from a case of miliary tuberculosis, and the other from a case of chronic laryngeal and pulmonary consumption, both the fetal and maternal parts of the placenta being af-

[1] L'Union Médicale, December 8, 1894.
[2] Zeitschrift f. Hygiene, 1893, Bd. xiii.
[3] Berl. klin. Woch., June 25, 1894.

fected in the latter instance. No typical lesions were found on autopsy of either child but from the ease with which bacilli could be transmitted from one fetal structure like the chorion to another, the glands or bones, for example, the possibility of congenital tuberculosis being more common than is usually accepted, is suggested. He considers that more diligent search would have demonstrated their presence in many cases where they were not found, since only the most careful examination prevents their being overlooked.

Schmorl and Kockel[4] report three similar cases, in two of which the patients died during pregnancy from miliary tuberculosis and in the third from chronic laryngeal and pulmonary consumption. In all these bacilli were found in both the maternal and fetal portions of the placenta, but only in one, a case of miliary tuberculosis, could they be found in the body of the fetus, and then only by the microscope. In cases of miliary tubercle the bacilli must be equally distributed by the blood to all organs and the only explanation of their being found in less numbers in the placenta than elsewhere, as occurred in these cases, is to suppose that the placenta is more resistant than other organs to their invasion. They think that the reason why so few bacilli reached the fetal circulation is found in the changes occurring in the vessels of the tuberculous villi, which effect their closure by the production of an overgrowth of endothelium and the formation of hyaline thrombi, and thus form a partial barrier to the spread of the bacilli.

### A CASE OF EXTREME CARDIAC DISPLACEMENT.[5]

Heyse describes in great detail the case of a woman, forty-six years old, in whom the heart was displaced so far backwards and to the left that the apex beat was plainly seen in the ninth intercostal space under the angle of the scapula. The area of cardiac dulness was found on the left side behind, immediately above that caused by the liver and spleen, while in its usual place the percussion note was vesicular. Since all other causes could be excluded he reached the conclusion that such extreme displacement could only be due to a fetal arrest of development of the lower lobe of the left lung, and quotes cases from literature in support of this etiology.

### THE ETIOLOGY AND PATHOGENESIS OF CARDIAC HYPERTROPRY IN DISEASE OF THE KIDNEYS.[6]

Since the explanations given of the coexistence of some forms of kidney disease with cardiac hypertrophy have thus far been most inharmonious, De Dominicis has tried whether by experiment any light could be thrown on a difficult subject. He found that ligation of both renal arteries caused death in dogs just as quickly as did removal of both kidneys. Next, the renal artery on one side only was tied, and in twenty successive experiments it was found that for three or four months the animals, if well tended, remained in good health, but after that time they grew thin without presenting any morbid signs in any particular organ. The urine showed the following changes: in the first five days after the ligature there was slight albuminuria which entirely passed away, while the solids in the urine were diminished in amount, especially the uric acid, but no casts were found. For a day or two the amount of urine was diminished but after that there was polyuria. With respect to the heart no increase of rate or force could be detected, either by palpation or by the cardiograph. Microscopic examination of the kidneys of some of the animals killed twenty-five to twenty-seven days after showed changes in the kidney, whose artery had been ligatured, due to degeneration of epithelium and interstitial nephritis, the latter changes being present also in the untouched kidney. Reviewing the experimental and the clinical evidence the author concludes, first, that idiopathic hypertrophy of the heart occurs often enough without any kidney lesion; and, secondly, that serious and extensive changes may be induced experimentally in the kidneys without any functional disturbance of the heart, and without even giving rise to the general condition of Bright's disease. When cardiac hypertrophy and renal disease exist together they must be regarded as common effects of a chemical poisoning of the blood.

### DIAGNOSIS OF TRICUSPID INSUFFICIENCY.[7]

Hamburger describes a case of tricuspid insufficiency, completed by autopsy, which was under observation a number of weeks, yet auscultation revealed no deviation from the normal sounds. Hypertrophy of the right ventricle and other cardiac signs usual in this condition were present in but slight degree, nevertheless the diagnosis was correctly made from the presence of a strong venous pulse, according to Bamberger the only sure sign of this lesion. Hamburger emphasizes the point because most text-books fail to make it sufficiently plain that serious functional disturbances of the valve are not always accompanied by murmurs. He agrees with Dieulafoi in ascribing their absence to so high a grade of dilatation of the orifice that fluid veins are not formed.

### RELATIVE INSUFFICIENCY OF THE PULMONARY VALVES IN MITRAL STENOSIS.[8]

Pawinski says that he has been unable to find in literature any notice of a relative insufficiency of the pulmonary valves, which was dependent on mitral stenosis and not on sclerotic changes in the intima, and yet in his experience this condition is not so very unusual. He has been able on several occasions to demonstrate the presence in cases of mitral stenosis of a diastolic murmur at the left edge of the sternum at the level of the third or fourth costal cartilage, which can also be heard, though less distinctly, in the parasternal line and in the second intercostal space. As a rule it is propagated over the upper left half of the thorax but cannot be heard beyond the right side of the sternum, nor in the so-called aortic area. It was most often found in young, well-nourished individuals, especially women, but was by no means a constant phenomenon when found, often being present for several days or weeks at a time and then disappearing for a longer or shorter time. Favoring circumstances for its production or intensification are a rise of pressure in the pulmonary circulation in consequence of some affection of the lungs or pleura. Clinically it was found that under the influence of digitalis this murmur became at first more audible, but later, as the pulse became slower, it became less distinct and finally disappeared, a markedly accentuated second sound alone

[4] Beitrage z. path. Anat., Bd. xvi, H. ii.

[8] Deut. Arch. f. klin. Med., 1894, Bd. liii, p. 519.

remaining. The diagnosis between a diastolic murmur arising in this way and that due to uncomplicated mitral stenosis, aortic insufficiency, tricuspid stenosis or a sound produced in the vena cava superior or inferior would depend upon its character, seat of maximum intensity, line of propagation, the absence of vascular signs and the presence of an accentuated pulmonic second sound. Pawinski was unable to determine any modification of the sound from inspiration or expiration. The sign is of value in prognosis since it shows a hypertrophied and powerful right ventricle on which the mitral lesion is dependent for compensation, and in treatment since it shows excessive pressure in the lesser circuit and indicates measures of relief for that condition.

### CYCLING AS A CAUSE OF HEART DISEASE.[9]

Herschell says that the reason why cycling may become more injurious than some other forms of exercise is the fact that the rider takes much more exercise than he is aware of and is very frequently tempted to overtax his powers. This stricture is applicable not only to those who ride for prizes, especially in that suicidal form of racing known as hill-climbing contests, but to the thousands of every-day cyclists who strain themselves in trying to make a given distance within a specified time, or to keep up with the rest of the party, or in using a gear much too high for their strength.

The effects upon the heart of the strain of excessive cycling may be divided into four groups: First, simple hypertrophy, which may be looked upon as a compensating effort of nature to enable the work to be performed, and which may either terminate in recovery or lead to valvular disease and disease of the aorta or to degeneration of the cardiac muscle. Second, acute dilatation of the heart, especially in those who have passed their early youth, ending either in recovery, if the cause be removed, or in more or less sudden death, or in the production of valvular disease. Third, chronic valvular disease, due to one or the other of the first two groups, the result being due either to stretching of the aortic ring by pouching of the aorta and the production of regurgitation, or to the actual giving way of a valve or to sclerotic changes in the valves. In any of these cases the disease will follow the usual course of valvular mischief produced by other causes. Fourth, functional derangements of the heart, many of which are slight and promptly recover, others are similar to those chronic cases of tachycardia, which Da Costa observed among the men engaged in our Civil War and to which he applied the term of "irritable heart." The chief symptoms of this condition which he has observed are palpitation and intermittency of the heart's action, shortness of breath, a sensation of sinking at the epigastrium and the occasional occurrence of angina-like symptoms.

As an offset to these possible evils of excessive cycling we have the undoubted fact that in moderation and under proper conditions it is one of our most potent remedial measures in establishing that compensatory hypertrophy, which alone can enable the victims of valvular cardiac disease to live in comfort and happiness.

In considering the precautions to be taken to obviate the dangers of the sport, he lays stress upon the following points: the use of a low gear, the upright position in riding, adequate food when riding and the avoidance of muscle poisons, such as beef-tea, as well as preparations of kola and coca. Perhaps the most important point of all is that the cyclist should on no account continue riding after he has begun to feel short of breath or when there is the slightest sensation of uneasiness in the chest.

The subject has also been considered by Sir B. W. Richardson,[10] who arrives at essentially the same conclusions, but in addition says that it is often more important to consider the peripheral condition of the circulation than the central in advising patients on the subject of cycling, since enfeebled or worn-out arteries may be more dangerous than the feeble heart. The same remark would also apply to cases where there is a local arterial injury, such as aneurism. Venous enlargement, on the other hand, seems rather to be benefited than injured by cycling, conditions marked by sluggish circulation through the veins being often greatly relieved by the exercise.

In commenting on the paper, Dr. Ernest Sansom said that he could recall but one instance of rapid heart in a cyclist and had never met with a case of irregular heart among them, and thought that the influence of cycling was decidedly more in the direction of good than of harm. As a therapeutic agent in the treatment of actually existing heart disease it was quite in accord with the teaching of Professor Hirst of Munich, but in his opinion it had many advantages over climbing, which the latter extolled.

### INDURATIVE MEDIASTINO-PERICARDITIS.[11]

Harris has collected from literature nineteen cases of this condition, completed by autopsies, and has added three others hitherto unpublished. From these cases it would appear that it is not more common in children than in adults, since only nine occurred in persons under eighteen years of age, while thirteen, only two of whom had reached thirty, were over it. It also seems that males are more frequently affected than females since the former predominated in the proportion of seventeen to five. In some of the cases there is a history of an acute illness, usually an acute chest affection, ante-dating the time at which the symptoms of mediastino-pericarditis manifested themselves, which in some instances was clearly an attack of acute pericarditis, but in others the only acute illness in the previous history of the patient was one of the acute fevers, most commonly scarlatina or measles, while in still others the onset was perfectly insidious. Trauma does not appear to have commonly played a part nor does tubercle seem a frequent associate.

The symptoms are chiefly those of failing cardiac compensation, to which are added a pulsus paradoxus and inspiratory swelling of the veins of the neck, but all symptoms are not necessarily present in every case. Dropsy may either be general or confined to the abdominal cavity with little or no anasarca of the lower limbs. At first the patients are able to lie down fairly comfortably in bed but later orthopnea may develop. The position, however, described by Jaccoud as important in diagnosis, in which the patient sits up in bed with the trunk markedly bent forward in consequence of the increased dyspnea and intra-thoracic pain when the erect or still more the recumbent posture is assumed, must be very exceptional.

The physical signs show an increase in the area of

[9] Lancet, March 2, 1895.

[10] Quoted in New York Medical Record, February 16, 1895.

[11] Medical Chronicle, October, 1894, to January, 1895, inc.

cardiac dulness, which may extend as high as the first rib, especially when the heart is pushed up by fluid in the abdominal cavity; but this extensive increase is much more likely to be due to the coincident cardiac enlargement than to the mediastinitis, though in some cases enlarged caseous glands together with the fibrous tissue in the mediastinum may contribute to its production.

The occurrence of ascites in some cases without noteworthy anasarca may possibly result from a chronic inflammation of the liver resulting from chronic passive congestion, or it may be due to a chronic peritonitis, arising either as an independent affection or as a result of passive congestion. Regarding the pulsus paradoxus, on which so much stress has been laid in diagnosis, it has been observed not only in mediastinopericarditis, but in different forms of pericarditis without mediastinitis, in cases of large pleuritic effusion, in great cardiac weakness, and in convalescence from long standing febrile affections as well as in a case of mitral incompetence with dilatation of the heart, in cases of great dyspnea from narrowing of the air passages and in cases of mediastinal tumor, so that it can no longer be considered as pathognomonic, yet its detection in any case should direct the attention to the possible presence of the affection. Engorgement of the veins of the neck is common, as in cases of marked dilatation of the right ventricle and the engorged veins may show marked pulsations, but an inspiratory distention of the right external jugular vein may or may not be present, so that its absence does not necessarily invalidate the diagnosis. It has also been observed in an uncomplicated case of pericarditis exudativa.

The duration of the affection appears to vary from a few months to several years, death resulting in a majority of cases from cardiac dilatation and heart failure. Bronchitis and catarrhal pneumonia frequently assist in bringing about the fatal termination, and attacks of pleurisy, which seem to be very common, may aid in reducing the power of resistance of the patient, while in other cases the development of acute tuberculosis or the extension of a pre-existing phthisis may be the principal cause in producing death. The article is enriched by a full bibliography.

## Reports of Societies.

### THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

Regular Meeting, February 9, 1895, the President Dr. James Chadwick, in the chair.

Dr. M. H. Richardson read a paper on

TWO CASES OF DERMOID CYST OF THE OVARY INVOLVING THE SIGMOID FLEXURE, NECESSITATING RESECTION AND SUTURE OF THE INTESTINE.[1]

Dr. F. H. Davenport said he would feel more doubtful about the issue in leaving the dermoid than if he continued the operation. Aside from the growth of the cyst there is great danger of infection and suppuration, especially when the rectum becomes involved. He had operated on several suppurating dermoid cysts.

Dr. W. L. Burrage: Last summer I had a case of tear of the rectum due to intimate adhesions between an old salpingitis with degenerated ovaries and the bowel, and also a case of intestinal anastomosis for cancerous stricture of the sigmoid flexure.

The first case was a hysterectomy in a neurasthenic patient. In tearing the tubes and ovaries away from their attachments, I opened the rectum for a distance of three-quarters of an inch in its lower half. The rent was closed with a continuous Lembert stitch of fine silk; no abdominal drainage. The patient made a perfect recovery. In the second case I was called to do an emergency operation on a patient who had had symptoms of obstruction of the bowels for five weeks, and had been plied with castor oil, jalap elaterium, and croton oil for four days before I saw her. She was in a very bad shape, and operation was offered as a forlorn hope. The strictured portion of the gut was not firmly attached to the pelvic wall, and I did an end-to-end anastomosis. In a similar case now I should either use the Murphy button or be content with forming an artificial anus. The patient died of shock.

Injuries of the rectum and sigmoid flexure are much more easily repaired now than they were before the days of the Trendelenberg posture. I have a feeling that gauze drainage about a joint in the intestine is safer than without it.

Dr. F. B. Harrington said that the point made by Dr. Richardson of the use of gauze as a protective was of great value and saved much time. The use of the Murphy button also enables one to save a great deal of time. As regards the wounding of the ureters, he was interested in the remarks by Dr. Kelly in a recent number of the *Johns Hopkins Hospital Bulletin*, where in three cases he feared he might have sutured the ureter by mistake. In all of them he made a longitudinal cut in the ureter and passed a probe up and down. In one of the cases he found that a stitch had been put in.

Dr. W. H. Baker said he would like to emphasize the point brought out by the reader, that the man who opens the abdomen must be ready to face any emergency that may arise. The more clearly we can make our diagnosis in advance the better prepared we shall be. The dermoid cyst is more like a fibroid tumor in its slow growth. It is also more sensitive than any other tumor, for example, a pus-tube, fibroid or ovarian cyst.

Then there are more dense adhesions with a dermoid cyst than any other, hence we have to face greater difficulties in their removal. The sigmoid flexure and rectum are the places for nature's openings to occur. Dr. Hare has reported one that opened into the bladder, which is unusual.

Dr. J. R. Chadwick said that he had recently opened the ureter in doing a vaginal hysterectomy, so that the urine on the eighth day began to flow from the vagina. Ten days later the patient had a chill and the urine from the vagina showed a septic kidney. From this the patient recovered in two or three weeks, and a week later the opening into the vagina from the ureter spontaneously closed. Since then the patient has been perfectly well, and the urine now contains no casts.

Dr. E. W. Cushing, being requested to relate his experience in regard to these operations, said: This paper relates to very important matters, and I am glad that a surgeon of the authority of Dr. Richard-

[1] See page 399 of the Journal.

son has emphasized the necessity of being prepared in every abdominal operation to find what is unexpected and to do whatever is necessary, even if it is requisite to resect the intestine or to suture the ureter.

Every surgeon is liable to be met by conditions demanding the highest degree of technical skill, conditions where it is imperative to proceed to finish the operation *secundum artem*, and where retreat is disgraceful to the operator and fatal to the patient. Unfortunately there is a great deal of imperfect work, from lack of preparation, if not from lack of skill and courage.

My own experience in suturing the intestine has been mostly in cases where there was a pre-existent opening from a pus-tube into the bowel, where in the course of enucleation of the tube the fistulous communication had been discovered. In my early operations I lost two cases from not finding these openings; and later I learned to be on the watch for them, particularly when there was a history of repeated discharges of pus by the bowel, or where during the operation after a difficult enucleation of a pus-tube I found in it a rounded opening emitting pus, not a tear but the opening of the fistula. Some time ago I reported to this Society three cases in which I had found such an opening and had repaired it with successful results. I have had several others since.

Now that we have the immense advantage of the Trendelenberg position, so that we can have the benefit of sight in separating adhesions, it would be inexcusable to overlook such a condition, and thus sacrifice the patient.

To a lesser extent it is often necessary to repair the serous coat of the bowel when it is inevitably torn in separating dense adhesions, in removing pus-tubes or adherent tumors. This is one of the principal reasons why in the treatment of pyosalpinx abdominal section is to be preferred to the method by vaginal hysterectomy, which has lately become so popular. Yesterday I removed suppurating tubes and ovaries in the presence of a gentleman who is here to-night and who is the principal advocate of the French system of vaginal hysterectomy for such affections, and I called his attention to the fact that with every advantage of Trendelenberg's position, with the tube and adherent intestine in plain sight, it was impossible, even with the utmost delicacy, to separate them without damaging the serous coat of the bowel so that several sutures were necessary. My experience of the difficulty of operating on such cases through the vagina makes me firmly believe that when the present enthusiasm for the latter procedure has spread about in this country, it will lead to a large amount of bad surgery, such as leaving of masses of suppurating tube and ovary in the abdominal cavity, tearing and clamping of the intestine, rents of the bladder, clamping of the ureter, etc.

My own experience in resection of the intestine for injuries received during operation, or in order to complete an operation, is limited to two cases. The first was for an entero-vaginal fistula, which opened the tenth day after a very difficult vaginal hysterectomy for cancer of the uterus. I twice attempted to close the fistula from below, but did not succeed. The abdomen was opened, and the injured part of the small intestine (some three inches) was resected, the ends of the bowel being sewed together with silk in the ordinary way. The patient recovered from the operation very well. The other case was an elderly woman who had had a tumor, supposed to be a fibroid of the uterus, for more than twenty years. Her sufferings finally became intolerable, with symptoms of obstruction of the bowel, and at the same time the tumor commenced to grow rapidly. On opening the abdomen I found a dermoid cyst, which had become cancerous at the lower part, involving the sigmoid flexure of the colon, which passed through the cancerous mass. By the aid of the Murphy button I resected about six inches of the bowel, and found that by the use of this little device the resection was extraordinarily rapid and easy, forming a marked contrast to a case where I once resected the colon for malignant stenosis before the days of the button, and where the different size of the intestine above and below the stricture rendered the operation difficult and tedious. It is a particularly valuable feature of the button that it makes it easy to unite two ends of intestine of different sizes. I always have one at hand in operating in the abdomen. This case also recovered, the button coming away on the twentieth day. In both cases I used gauze drainage.

In regard to injuries of the ureter, my first experience was in removing a large fibroid tumor from a patient of Dr. T. Garceau. When the rubber ligature was removed from the stump eight days after operation, there was an escape of clear fluid which was evidently urine. Nevertheless, the case went on to recovery, and for a long time there was a urinary fistula at the site of the lowest part of the abdominal incision. Much against our expectation this finally closed, and the patient now enjoys perfect health, more than six years after the operation. In December, 1892, I removed an enormous myoma of the uterus, which had grown principally from its lower part and thus, as afterwards appeared, had lifted the whole peritoneal covering of the pelvis and with it the ureters. Suspecting something of the kind, I made the incision of the peritoneum of the tumor some four inches above the brim of the pelvis, and yet on the right side I cut the ureter. It had already been tied, as I supposed it to be a blood-vessel; but as some drops of clear fluid issued from the end above the ligature, which was on the tumor, the ligature was loosened, the lower end found and united to the upper end by two silk and one catgut sutures. The ureter on the other side was avoided. When the tumor was removed the pelvis was bare of peritoneum and the iliac vessels could be seen, but the large flaps of peritoneum from the tumor, carrying the ureters, covered in the pelvic surfaces. The tumor was fixed in the angle of the wound, and glass and gauze drainage was brought out at an opening separated from the stump by some sutures. On the third day some urine appeared in the gauze; but by care the stump was kept dry, and the patient recovered with a urinary fistula, which discharged perhaps half the urine from one kidney, or one-fourth of the total amount. Gradually the opening closed, and after about a year the discharge ceased entirely. I received a letter from this patient a few days ago, and she is now, two years after the operation, perfectly well and strong. The fistula has long been healed completely. I have referred to this case thus particularly because I believe it was the first time in this country, if not anywhere, that the ureter severed during operation was repaired, the patient surviving.

I certainly had then never heard of such an opera-

tion; and when I reported the case at the meeting of the Philadelphia Obstetrical Society in February, 1893, no one there had any knowledge of such a case. I published the case with a photograph of the specimen.[2]

Besides these two cases I have had two others in which the ureter was clamped in vaginal hysterectomy, in the days when I used clamps in this operation. In both the leak was noticed soon after the clamps were removed. In the first there was also a vesico-vaginal fistula. I passed a probe into the bladder through the urethra and out through the fistula into the vagina, then I passed it into the opening into the ureter, and having it held in place I proceeded to dissect the mucous membrane in such a way that I covered the probe entirely, thus turning the urine into the bladder. The patient recovered completely, and has had no trouble since. In the second case there was no vesico-vaginal opening; and so, encouraged by the result in the first case, I passed the sound into the bladder as before, through the urethra, and selecting a spot near the opening of the ureter into the vagina I made bold to thrust the sound through the bladder, from within outwards into the vagina, when I covered it in as before in the other case. This patient also recovered perfectly, and both have now been well for several years.

DR. RICHARDSON, in closing, said that the discussion confirmed the position he had taken, that one who opens the abdomen may have to deal with most grave and unexpected complications.

In the first case reported suture would have been impossible without the Trendelenberg position. He prefers end-to-end suture to the use of any mechanical contrivances, even if the time occupied is a little longer.

He does not think that any method of intestinal suture is safe against leakage; hence he always uses gauze drainage, as the patient, without drainage, would probably die if a stitch should give way. The Murphy button should be in every operating bag, but should be used only when time is very important, otherwise the suture is far better.

A single row of stitches is usually all that is essential in intestinal suture. He would agree with Dr. Baker as to the importance of exhausting every means of making an accurate physical diagnosis before opening the abdomen.

Finally, he would express his surprise at what nature will accomplish in these cases in the closure of fistulæ whether from the parotid, the bladder, the intestine, the gall-bladder, or even the ureter. It is not worth while to borrow trouble about these fistulæ, for in the majority of cases spontaneous closure will take place. Intestinal fistulæ especially have a way of taking care of themselves, not five per cent. probably requiring operative measures. In fact, unless a very considerable portion of the intestinal lumen is gone, spontaneous closure cannot be prevented.

A paper by DR. J. G. BLAKE was read in his absence by the Secretary, entitled

### THE PERMANENT RESULTS FROM THE ALEXANDER OPERATION.[3]

of which the following is an abstract:

[2] Annals of Gynæcology for February, 1893.

[3] To be published in the sixth series of the Boston City Hospital Medical and Surgical Reports.

Dr. Blake had received reports from operators throughout the United States and England, and had tabulated the results, aggregating with Dr. Chadwick's figures reported this evening, thirteen hundred cases. The failures did not exceed ten per cent. of the whole number operated upon, and applied chiefly to the early cases. He reported also fifty-three childbirths in which the position of the uterus was found to be unaffected by pregnancy or delivery.

The result of the investigation satisfied Dr. Blake that the operation was a useful and reliable one within its limits — backward displacement without adhesions — and was almost absolutely free from danger in competent hands. Hernia and abortion were also found to be of very rare occurrence.

DR. R. A. KINGMAN thought that the unfavorable results reported by some operators were due to the fact that the cases were badly selected. He had operated a large number of times by the Alexander method, failing in two cases only: one where the ligament was partly degenerated and broken, and one where the ligament could not be found. He considers the operation to be one absolutely free from danger and uniformly successful in properly selected cases.

DR. G. H. WASHBURN had seen the discomfort of frequent micturition follow the Alexander operation, from pulling the uterus up too close against the bladder. In properly selected cases he considers the operation a good one.

DR. E. W. CUSHING: It is with considerable reluctance, that I rise in response to the invitation to speak on this question, for I much dislike to mar the unanimity of an Alexander symposium, or to appear as the *advocatus Diaboli*, raising objections to the conclusions which would naturally be drawn from this able and carefully prepared paper. Nevertheless, I regret to have to say that after fair trial, and somewhat extended use, the Alexander operation has failed to answer my expectations, or to fulfil the claims that were originally made for it. There are radical objections to it in theory, and serious disadvantages connected with it in practice.

When the operation was first introduced into public attention in this country by the articles read at the Ninth International Medical Congress in 1887, I gave the procedure full acceptance, and collected for publication articles and abstracts, showing the status of the operation at that time.[4] I soon began to perform it, first by the method then somewhat in vogue, finding the ligaments at the external ring and tying the ends together, over iodoform gauze, across the abdomen. The ligaments dried into hard cords and it was very certain that they would not slip during the healing of the incisions. Then came the method practised by Etheridge, Kellogg and others, by which the roof of the inguinal canal was opened and the ligaments fished up through a very small aperture in the fascia. Dr. Blake will bear me witness that this makes a very neat operation, and that when I disparage the results of my own operations, as well as of those of others, it is not to be attributed to any particular want of skill on my part.

I performed the operation some thirty times or more and then I found fewer and fewer cases which seemed to me suitable for this procedure; because, with increasing knowledge of abdominal pathology, the field of the operation grew more and more circumscribed,

[4] Annals of Gynæcology, December, 1887.

and with increasing confidence in abdominal operations the procedure of the Alexander-Adams was more and more replaced by others of greater certainty and less liable to the remote bad results, which I began to find not only in my own cases but also in those who had undergone the operation at other hands.

What then are the real objections to the operation? First, as a matter of surgery, it is often unsatisfactory, because the ligaments may be rudimentary and hard to find. The bight of the ligament at best must be buried in the wound where it is likely to give rise to late trouble by having its nutrition cut off. In other words, there is an undue disturbance of the anatomical relation of the parts, which too often gives rise to suppuration soon or to hernia later.

Now this question of hernia is very serious, and I do not think that it has received sufficient consideration in the paper which we have just heard. We have there a long series of operations, but very little said of the resultant herniæ. Nevertheless, they do occur: Of my thirty cases no less than four were followed by hernia, and I know that the same result attended the operations of some of the gentlemen whose statistics are quoted in the paper, although at this moment I am not at liberty to state my authority beyond some observations of my own.[5]

Besides the facts cited in regard to difficulty, suppuration and hernia, it is not to be gainsaid that there is some danger to life in the operation. Not many fatal cases are reported, but they do occur; and on the whole there is nearly or quite as much danger connected with this operation as there is in expert hands with some of the more radical operations which may be used instead of it with greater certainty of good results, and without leaving two wounds instead of one — wounds in the weakest part of the human system, the inguinal canal, a part which although strong enough when our progenitors went on all fours, has not yet become able to endure the strain to which it is subjected in a considerable percentage of the present human race.

Apart from these special objections to the operation, there are others which are more important and which are fundamental. The operation is done in ignorance of the real condition inside the pelvis, and can therefore offer no certain promise of relieving the sufferings of the patient. As a matter of fact, it does not relieve them in a very considerable proportion of cases, and the wretched woman must again undergo the more radical operation which she should have had in the beginning.

To be sure, a very large part of the claims which were made for the Alexander operation in the beginning, or only a few years ago, are now abandoned. We do not read now of severe cases of procidentia uteri cured by this operation alone, such as were once reported and figured.[6] The claim has also been abandoned that the operation is suitable for cases where there are even moderate adhesions of the uterus, binding it down. If then the operation is limited strictly to cases where the uterus is entirely free and the uterine appendages are entirely healthy, it need not be condemned except for two facts. In the first place, I make bold to say that under such conditions the women do not suffer enough to justify the operation; and if they do suffer, we can never be sure just what the trouble is which causes the suffering. After we have excluded the commoner causes of retroversion — such as chronic metritis, subinvolution, ruptured perineum, overstretched pelvic floor, small fibroid tumor, etc. — even if we can be sure that the uterus is freely movable, and that the ovaries and tubes are not greatly enlarged or plainly adherent, we still have to remember that the commonest adhesions both of the uterus and of the tubes are to the intestines, and that it is perfectly possible to have an uterus apparently quite movable and yet bound to the bowel by a band of adhesions, either directly or by means of a tube, in such a way that after being replaced it will be pulled back again. The same thing occurs after Alexander's operation in a great many cases; and it is rarely possible to be sure of the absence of such bands, or of other diseases of the appendages, in women who really suffer enough to justify any important operation.

While, therefore, I would not be dogmatic and condemn the operation of Alexander and Adams in certain such rare cases, where there are no adhesions or diseases of uterus or appendages, yet practically I have not met in the last two years any case in which I did not prefer either to open the abdomen if the condition of the tubes was doubtful, or to perform vaginal hysterectomy where either the tubes and ovaries were certainly diseased, or the need and desire for restoration to full health so overshadowed the hope or expectation of further pregnancies, that it seemed better to remove the heavy and diseased uterus and the appendages and thus relieve the patient with certainty once for all.

On the whole, then, I consider the Alexander operation as belonging to a transition stage in the advance of gynesic surgery; both as a general step in the progress of our art, and, in my own case at least, as a stage of my development in knowledge, skill and experience.

Dr. J. R. Chadwick said he thought favorably of the operation, having performed it some one hundred times in private practice. The results were not all favorable, about fifteen in all proving unsuccessful. In only one case he failed to find the round ligaments. He never operated where there were adhesions of any account. He had never seen hernia following the operation. He always uses a pessary for a month or two following the operation.

Dr. F. B. Harrington considered the danger of hernia after the Alexander operation much less than after a laparotomy. There is no need of cutting the canal. As to the comparative danger of the two operations, it is infinitesimal in the Alexander, which we cannot say of laparotomy.

Dr. J. G. Blake, in closing, said that where hernia occurred his correspondents said they had used catgut. This was never the case where silk was used. In his own experience he had never seen hernia follow the operation. Rather than wear a pessary for life, the Alexander operation was far preferable.

[5] Since the day of the meeting where these remarks were made I have been permitted to publish the following letter:

Hospital for Ruptured and Crippled, New York.

My dear Doctor: — In reply to your letter about Alexander's operation, I will say, we have under observation here fourteen cases of hernia following the operation. The names of the surgeons I shall not give, but I will say that they are well-known gynecologists who advocate the operation. The patients, with hardly an exception, stated that there had been no improvement in the condition of the uterus. In several of the cases the hernia was very large and difficult to control with any form of apparatus. I do not mean to say the operation does no good in ideal cases, but I believe the possibility of hernia following the operation has been too little considered. I have no objection to your quoting the source of the statistics as I intend publishing them in detail soon. Very sincerely yours,

William B. Coley.

## SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

C. L. SCUDDER, M.D., SECRETARY.

REGULAR Meeting, Wednesday, February 6, 1895, DR. M. H. RICHARDSON in the chair.

DR. EDMUND D. SPEAR: I wish to present to the Section a patient whose case illustrates

### THE NASAL ORIGIN OF MANY TRIGEMINAL NEURALGIAS.

For the relief of pain in the face, the patient has suffered most of the operations upon the fifth nerve except that of resection of the Gasserian ganglion. He has had, in the first place, the lower branch of the fifth resected in the jaw; the second branch of the fifth, under the eye, removed; has had quite a number of teeth extracted; and finally had evulsion of the second and third branches of the fifth at their exit, by Dr. Richardson. The man suffered intense pain in his face for a period of ten years. He first applied to Dr. Blake, the aurist, for relief of pain in his ear, and Dr. Blake found suppurative inflammation of the ear with a polypus, which latter he removed without relief to the pain. Patient next consulted his family physician, who prescribed for him for a number of years. He also saw Dr. Beach, who prescribed for him. He then had Dr. Putnam see him, and some operation on the nerve was advised. In 1889 he had the final operation for the removal of the roots of the fifth. He was entirely relieved from pain for a year and a half. The pain usually came on about the time we get our hay-fever cases, and extended through the winter into the spring, so that about two-thirds of the time he was suffering from this neuralgic affection, which finally became very excessive and incapacitated him from work at times. After the last, the deep operation, he went to Dr. Wyman, who was accustomed to apply the galvanic current with a fair amount of relief so that he was able to work at his business, but he had to go for treatment every morning and night. I saw him the next year. He had been suffering seven weeks with excruciating pain in the upper jaw. The day he came to me he was unable to eat anything which required motion of the muscles. Could not touch his face in any part around the affected region, so that he could not even wash his face. There was also a remarkable difficulty in speech, apparently due to defective innervation of the facial and labial muscles. Almost complete sensation had returned in the face with the hyperesthesia of this nerve. On examination of the nose an enlarged hyperesthetic second turbinate was discovered. I began treating him locally in the nose. I cocainized the turbinate, treating it pretty carefully because the slightest stretching of the nostrils with the nasal speculum brought on pain. In a week he was able to eat solids. At the end of the next week I went into the country, and transferred the case to Dr. Wyman, whom I instructed in the use of local applications. At the end of six weeks the man was practically cured. He had a relapse the next season, a "cold" having probably induced congestion; and he had an attack of pain of the lancinating character, but not attended with spasm. I treated him locally again, relieved him, and later he had another attack which I relieved. He has now, for nearly a year, been free from pain.

DR. LOUIS M. TIFFANY of Baltimore, Md., read a paper on

### THE TREATMENT OF TRIGEMINAL NEURALGIA BY INTRACRANIAL NEURECTOMY.[1]

DR. N. P. DANDRIDGE, of Cincinnati, O., described

### ROSE'S OPERATION FOR THE REMOVAL OF THE GASSERIAN GANGLION.[2]

DR. MIXTER: Almost the last point mentioned in Dr. Dandridge's paper is interesting in this connection, and that is the question of other neurectomies in the treatment of this disease; and that I feel I am more competent to speak of, perhaps, than the operation on the Gasserian ganglion.

I have performed the operation of dividing the terminal branches in fifteen cases of division of the second and third divisions at the base of the skull; three I think were only divisions of the third division. It is interesting to know that in a certain number of those cases the pain has returned. In the first couple of years in which I had been performing this operation of taking out the nerve at the foramen ovale and rotundum, I began to think the patients were permanently cured; and although Rose and others published their operations on the Gasserian ganglion, I questioned the advisability of attacking the ganglion when the operation could be done so much easier at the foramen. Within the last six months, however, I have had three patients come back with severe neuralgia, in spite of this comparatively radical operation. That brings up, I think, the whole question as to whether in cases of beginning neuralgia which promises to be of epileptiform variety, where it may come on for a time and then disappear under treatment, whether it is best to go as far as we possibly can and take out the ganglion or do the more superficial neurectomies; whether time will show that removal of the Gasserian ganglion is a permanent cure. In a certain number of cases several years have elapsed since the nerves were divided at the foramina, and in certain cases the pain has returned. In the cases where pain has returned, operations had been performed before, and more superficial neurectomies had been performed. In one case the operation which I did was the sixth or seventh operation, and in that case the pain is back, but it is not as severe; and in none of these cases is the pain severe enough to force the patient to the further operation of removal of the Gasserian ganglion except one. That is the case operated on by Dr. Porter some three or four years ago, and the inferior dental nerve was removed. I operated on him about two years ago, and removed the second and third divisions at the foramina, and they were thoroughly removed; and then he got just about as long immunity as from the first operation — about eighteen months. Last summer I removed his Gasserian ganglion. You see eighteen months' or two years' immunity after dividing the superficial branch sometimes. I have seen the same immunity after dividing a deep branch; and some cases show return after division of the Gasserian ganglion. I think it rests with the neurologists and pathologists to show how fast these changes extend up the nerve, and whether we can by coming back to the Gasserian ganglion get behind them as you can in case of gan-

[1] Reserved for publication.
[2] See page 397 of the Journal.

grene get beyond it. The operation of removal of the Gasserian ganglion was in one of these cases of recurrence, and I did Hartwell's operation, not strictly perhaps Hartwell's, because I was not able to do it exactly as he has described it. The skull was very thick, and I could not break it down, and simply took it out with rongeur forceps as far down as necessary, and none of the bone taken out was replaced. I went through the dura twice, dividing and tying the middle meningeal. The brain was lifted up, having no dura to protect it, it having been torn slightly; but apparently that did no harm. The ganglion was reached with considerable difficulty. It is a very difficult operation. I have only performed one more difficult, and the ganglion was pretty thoroughly removed piecemeal with forceps and fine curved scissors. There was a very sharp attack of hemorrhage. Whether I wounded the sinus or not I do not know; but packing controlled it, and the patient recovered well from the ether with little shock. The packing was left in the skull. Rather a remarkable thing about the case was that two or three days after the operation the patient had an attack of erysipelas of the wound, the only case I had in my service last summer at the hospital. I expected he would die of meningitis, because it was a genuine attack of erysipelas over the face and head and about the wound; but he had not a single symptom pointing to the brain, and he recovered perfectly. There was a little sinus a short time and a stitch came out; and he has been well since. The man is now at work as surgical-instrument maker.

There are one or two points in regard to dividing the nerves at the base of the skull and not sawing through the zygoma, that might be mentioned. One is the question of wiring the zygoma. At first I always drilled and wired it, but later I seldom took the pains even to stitch up the fascia over the bone and simply let it drop into place. The temporal muscle atrophies, and by far the greatest deformity is depression caused by atrophy of the temporal; and the zygoma, if allowed to take whatever position it likes in the wound, will cause very little deformity.

Another point is the question of deafness after these operations. I think I have spoken of that in a paper. It has occurred several times. I have been so fortunate as to have Dr. Blake examine the ears of these patients. In one case there was a large ecchymosis about the eye where I went in over the second division through that incision; and also there was a large ecchymosis in the membrana tympani, and between the layers of that there was a very considerable quantity of blood in two or three cases, and deafness and noises in the ears persisted a long time.

Dr. Putnam: The pathology of the subject still seems to be in a great deal of obscurity. A few interesting anatomical observations have been published. One of the first of these was by Dr. Schweinitz of Philadelphia, who found a marked degeneration of the nerve fibres, while Dr. Dana of New York published the notes of several cases in which he had found a marked arterio-sclerosis of the blood-vessels and not much degeneration of the nerve-fibres. Since then there have been a limited number of others. I examined some years ago, the nerves from five patients operated on by Drs. Richardson, Cabot, Warren and Mixter. In some of them there was very marked degeneration; in others well-marked arterial change, such that some arteries were entirely plugged. But in others again there was no great change to be seen, so that even in cases where neuritis is present we cannot say positively that it was the real cause of the neuralgia. My own impression is that there are two elements present: one, peripheral irritation of one or another sort, and the other a — so to speak — physiological disturbance of the nervous centre which gives the neuralgia its peculiar character; for example, the neuralgia of the lower branches of the fifth is usually quite different from that of the supraorbital branch, in my experience. Then the question arises, supposing neuritis to be present and to be the main cause of the trouble so that the nerve deserves to be treated as a foreign body and removed, whether we can form any idea how far the neuritis has progressed in a given case. I think the history of parallel cases of neuralgia of the limbs after amputation are important in this connection. Dr. Abbe, of New York, has in several cases made section of the posterior nerve roots of the spinal canal above the ganglion in which they primarily arise, and although there was relief for a time, the pain returned, I think, in all, indicating that some change had taken place still further up. In cases of these facial neuralgias of the fifth pair where the nerve is so short it would seem that we might expect the neuritis to reach the Gasserian ganglion very early, the question would be whether it would go beyond it? I do not know that we have any reason to think it might not do so. It would certainly seem as if removal of the trophic ganglion of the nerve would afford an additional security although it may prove that the security is not so great as would seem.

I think there are one or two other interesting matters to consider in connection with the general subject. In the first place, the pain sometimes disappears for a long period, sometimes indeed ceases quite suddenly either spontaneously or as a result of some treatment such as Dr. Spear has spoken of, or from the careful relief of constipation or by aconitia, although the anatomical conditions remain the same.

Dr. Tiffany spoke of affection of taste as being absent in some cases and not in others. I think that is explained by the fact that taste conduction probably occurs through the fibres of the glosso-pharyngeal, which usually run in the course of the fifth nerve but have their origin in a different place.

As among the curious disturbances observed after these operations, I should like to mention a case operated on by Dr. Richardson where a peculiar lisp was brought on which never entirely disappeared, and indeed remained very marked for several years.

I think the fact referred to by one of the gentlemen, namely, the roughness of the skin of the forehead before the operation, which disappeared afterwards, is of great interest, as bearing out the view that trophic changes in the skin are due much less to absence of the influence of the nerve than to some morbid influence exerted by a diseased nerve, a fact long ago commented on by Dr. Weir Mitchell, Brown-Séquard and others.

Dr. Folsom: Personally I have had no experience of the operations described in these papers, but I have seen quite a number of cases, and there is one point to which my experience has led me which has not been referred to. I think, as Dr. Putnam says, that the causes of this condition are twofold. In the first place, they depend partly on distinct pathological conditions which can be recognized, and partly on

molecular or physiological conditions analogous to those which produce epilepsy. It seems to me that from both points of view it is very important, as soon as the diagnosis is distinctly made, not to delay the operation. Just as in epilepsy, the longer you delay the operation after you are tolerably sure of the conditions, the longer the habit has been established and the more difficult to eradicate; and so far as it depends on pathological changes, the longer you delay the greater the probability is of an extension of the pathological process. My course now is, when I see one of these cases in which the features are perfectly clear and distinct, to say: "This is not a medical case; it is a surgical case." And I decline to treat it. I saw a case in Lowell a little while ago in which I was urged by the family and patient to try various palliative measures, but I refused even to see the patient a second time. Dr. Richardson performed the external operation with success. It now and then happens that patients do not accept the advice; but the result in my experience has been that they have been disappointed with palliative measures, have spent time and money and at last regretted that they had not had the operation done before. Of course, a certain amount of treatment is often necessary in order to establish the diagnosis.

DR. WALTON: It is a boon to have this operation to fall back on as a last resort, especially if its results prove permanent. It is too early to decide that point. I was very glad to hear Dr. Dandridge speak as he did of the difficulties of the Rose operation. Perhaps my observations have been too limited to allow me to express an opinion on this point, but the Hartley operation has seemed to me a better operation as affording a much better view of the parts. It has seemed to me that the danger of injuring the Eustachian tube might add to the disadvantageous features of the Rose operation. One who has seen the Hartley operation, and is told that the difficulties of the Rose operation are greater, will, I think, be satisfied to rest with the former operation. The dangers of ocular paralysis by injury to the ocular nerves or of injuring the carotid artery or the cavernous sinus appear to have been exaggerated in apprehension as both the gentlemen have said. The latter injuries have not occurred although we have had about fifty cases now. And even if ocular paralyses do occur they are quite sure to prove temporary. The same is true of aphasia. The necessary manipulation of the temporo-sphenoidal lobe necessarily pressing on the centre for speech is apt to produce this symptom — certainly in Dr. Richardson's case the aphasia was very marked, but it was only a matter of a few days before it entirely disappeared, so that the patient may be assured that this symptom will be temporary.

If removal of the Gasserian ganglion gives permanent relief in all those cases of intractable neuralgia in which drugs have proved useless it may be wise to at once advise it; but if time shows that removal of the Gasserian ganglion is, like the others, temporary, it will be wiser to advise the peripheral operations first as they do seem to offer a certain immunity, and perhaps this order will always be followed in any event, owing to the formidable nature and the difficulties of the intracranial operation.

DR. ELLIOT: I have seen one case that may interest the Society. That is a case that came to me in the summer with every indication that the neuralgia which had existed for five years or more had returned centrally after the peripheral operations had been done; first, in 1888, the inferior dental was cut, with relief. In 1890, the nerves were cut at the base of the skull at the foramen ovale and foramen rotundum. In 1894, he came to me with return of all his symptoms, that is, he had had three years of immunity. This seemed to indicate the removal of the Gasserian ganglion; but, rather as an experiment, I thought I would expose the foramen ovale again and see what could be done. On cutting down I found something that looked like regenerated nerve fibres, although I could not get enough of them to have them examined; but on cutting away those fibres and putting a tenaculum into the foramen ovale and rooting it round to stir up the ganglion as much as possible and packing the foramen ovale with iodoform gauze, I got an immediate relief and so far a perfect cure. This, I thought, would be interesting as showing that, if the neuralgia returned after section of the nerves at the base of the skull, it is not impossible that still more relief can be obtained by secondary operation before removing the Gasserian ganglion.

DR. TAYLOR: Through the kindness of Dr. Harrington, I have had an opportunity to examine the lower division of a fifth nerve removed for neuralgia. In connection with the pathological anatomy the nerve showed interesting changes, although it is not easy to say whether they are to be regarded as pathological or due simply to the violent method of extraction of the nerve. This nerve was removed by twisting, and, as a result, showed when stained by the hemotoxylin method of Weigert a curious breaking up of the myeline. There was also a cell infiltration about the smaller blood-vessels, apparently the beginning of an inflammatory process. Neither Dr. Councilman nor the others who saw it, however, were willing to say, without further control experiments, that that also might not have been produced by the violent method of extraction of the nerve.

DR. WARREN: I have listened with much interest to the discussion. My experience with the more radical operations has been but limited. I have performed one operation according to Mixter's method. Of course, I have done quite a number of the more peripheral operations. I wish that I could give the Section some statistics about the results. Dr. Putnam has followed those operations more than I have. In some cases the neuralgia has returned. I recall one operation performed, at the request of Dr. Putnam, on a very old lady, for division of the infraorbital nerve by tracing it to the end of the infraorbital canal. There has been no return.

The removal of the Gasserian ganglion appeals to me as an attractive operation. In the first place, judging from my experience in trephining operations in that locality, that one can see better what he is doing than when trying to reach the nerve roots as they emerge from the skull. Recently, in an operation for a cyst, I was in the neighborhood of the Gasserian ganglion, and it seemed that it would have been an easy matter to have exposed that nerve structure.

The removal of the Gasserian ganglion also appeals to me from the point of view of regeneration of the nerve tissue. We know that nerve tissue is actively regenerated. I have seen the whole infraorbital canal refilled with nerve tissue after an operation. The nearer we get to brain-structure the less we have of

repair, and it is stated by pathologists that there is practically no repair of brain tissue itself. In ganglion tissue we have tissue closely allied to that; and if we destroy the ganglion, we must cut off the approach of the nerve trunks to their point of origin in the brain substance. I agree with what has been said, that the minor operations are operations to be advised in the first instance, and that we ought to reserve these major operations for selected cases.

DR. RICHARDSON: I have been very much interested always in the subject of the peripheral nerves, especially in the matter of neuralgia, and have approached gradually the Gasserian ganglion, beginning first with the infraorbital, supraorbital and finally getting at the ganglion itself. It seems to me we ought to exhaust every method of treatment before taking out the ganglion; for in many cases by so simple an operation as evulsion of the mental, infra- or supra-orbital portions, devoid of danger, we may secure a permanent immunity. Of course, the number of cases cured by so simple an operation is not many, but then we can repeat the deeper operation in the sphenomaxillary fossa. That operation, although one of the most difficult operations in surgery, does give a long immunity. In the case Dr. Spear has shown, on which I operated first on the infraorbital, dental, finally by evulsing entirely the third division, as I understand, since that last operation there has been immunity in the course of the third nerve, and while there is regeneration probably of the second division, the third remains still without pain. If so severe a neuralgia as this patient had can be cured by the trivial operations of Dr. Spear, we are not justified in resorting to such measures as opening the skull. I have had very little experience on the ganglion except on the cadaver. It is very hard to get at it. Rose's operation seems to me much more difficult than the Hartley method. It is because you cannot see what you are doing; and while Dr. Dandridge's reasons for preferring that operation appeal to me in that the hemorrhage is in the beginning rather than at the end, still I should prefer very much to do an operation where I can see exactly what is going on. In my single case I was able through the unfortunate tear in the dura mater to see perfectly everything I was about, and could and did cut the nerve between the pons and edge of the petrous portion where it became invested in the dura mater. That patient has been well since, although only a few months have elapsed. The neuralgias are very discouraging; and if we find that the Gasserian ganglion operation gives no greater immunity than the peripheral ones, we ought to go by gradual steps to the most radical operation, each one giving the patient from one to two years of immunity.

Upon motion of Dr. Porter, the thanks of the Section were extended to Dr. Tiffany and Dr. Dandridge for the papers presented.

### ANATOMICAL SPECIMENS.

DR. WALTON: Through the kindness of Dr. Warren and Dr. Harrington, I have here two specimens of crushed spinal cord, both from cases of fracture in the cervical region. We often read of this condition, but do not often have an opportunity to see it post-mortem. In one case, crushed at the fourth cervical root, there was complete paralysis of the arms and legs with numbness, whereas in the other the biceps and deltoid were spared so that the patient had the arms elevated in the characteristic position which always denotes crushing injuries at about the height of the fifth to the sixth roots. In Dr. Warren's case the crush was not directly under the point of fracture. The fracture was of the second cervical vertebra, whereas the crush was lower, showing either that the crush was produced by a sudden bending of the cord or else by the bones falling back into place as they sometimes do. These cases illustrate another important point, which is that palpation is very apt to be at fault, most serious crushes being found where examination of the spinous processes shows nothing. I have not found in literature any records of successful cases of luminectomy for fracture in this particular region. I should be inclined to agree with Thorburn that in the dorsal region the operations are, as a rule, unsatisfactory except where the fracture falls below the first lumbar vertebra so as to press on the cauda equina rather than on the spinal cord itself. Even if the vertebra falls back into place, the chances are that the cord has been crushed, and there is very little to hope for in the dorsal region and less yet in the cervical.

## THE NEW YORK NEUROLOGICAL SOCIETY.

STATED Meeting, Tuesday evening, March 5, 1895, DR. E. D. FISHER, President, in the chair.

### BRAIN SPECIMEN.

DR. ALFRED WIENER exhibited the brain removed from a boy aged fourteen years, who eight weeks ago had an attack of acute articular rheumatism. From this he recovered entirely and was able to return to school. Eight days ago he began to complain of pain in the right occipital region and some pain in the right ear. The pain gradually grew more severe, and afterwards became more pronounced on the left side. There were no eye symptoms and no discharge from the ears. A diagnosis of meningitis was made. The patient was seen in consultation by Drs. Sachs and Gruening, the latter suspected a thrombus in the lateral sinus. The temperature became more and more elevated, and pyemic in character towards the last, and the boy died in a stuporous condition on the seventh day. At the autopsy, made twenty-four hours after death, a necrosis of the posterior surface of the petrous portion of the right temporal bone was found, with an acute meningitis on the opposite side of the brain. There was also a small thrombus of the lateral sinus, and the tentorium cerebelli was infiltrated with pus. Four months ago the boy had a suppurating otitis, which seemed to heal entirely.

DR. L. F. BISHOP presented a case of

### EDEMA OF THE RIGHT UPPER EXTREMITY.

The patient was a female, age thirty-nine. Family history negative. She had never had any serious illness. There was no organic trouble, no hysteria. Seven months ago she first noticed a swelling of the thumb on the right hand, which gradually extended upward as far as the elbow. The capillary circulation is more sluggish than in the opposite forearm. There is no change in the pulse-rate; no loss of power. All local causes for the edema have been carefully excluded. Recently, during an attack of influenza, the swelling temporarily disappeared. Dr. Bishop termed the case one of angio-neurotic edema.

DR. JOSEPH COLLINS said that Dr. Bishop's case, in most of its characteristics, did not agree with those that have been usually observed in these cases. Angio-neurotic edema is evanescent, the swelling rarely lasting more than a few days. In this case there is slight pitting on pressure and an absence of the tense, hard skin usually seen.

DR. C. L. DANA said that while this case did not correspond with the ordinary picture of this affection, yet there are cases of neurotic edema which affect the limb in this way. All other possible causes of the edema must be carefully excluded.

### AN OPENING IN THE SKULL.

DR. WILLIAM M. LESZYNSKY presented a woman who had an opening in the skull, in the left parietal region. The opening did not extend through the inner table. It was irregular in outline, with fissures running in different directions. There was no history of trauma, and the condition had existed from early childhood. Six years ago the patient began to suffer from epilepsy, the attacks being general in character. Dr. Leszynsky thought the loss of bone might be the result of a trauma in early life, followed by periostitis.

DR. DANA said the deficiency in the cranium in this case was probably the result of a defect in osseous development, and regarded it as one of the stigmata of degeneration which sometimes accompany epilepsy.

### PATHOLOGICAL SPECIMEN OF INFANTILE PARALYSIS.

DR. L. STIEGLITZ exhibited a pathological specimen in connection with the report of the following case: The patient was a female; age twenty months. She was first seen in February, 1894, when she presented the clinical picture of complete left hemiplegia, and paralysis of the right third nerve. The child was poorly developed. The left knee-jerk was exaggerated. Both pain and temperature sense were unaffected on the paralyzed side. The mother stated that six months before she had noticed that the child did not use its left arm as freely as the right. The paralysis from that time on gradually increased, until the child gave up all attempts at walking. Three months before coming under observation the ptosis of the right eye came on, with divergent squint. A diagnosis of tumor, probably tubercular, in the right crus was made, although the possibility of glioma was considered. In the following December paralysis of the left third nerve developed, and the child grew drowsy and apathetic. On February 17, 1895, there were twitchings, epileptic in character, on the paralyzed side of the body. Death occurred two days later. At the autopsy, which was made two hours after death, the brain was found to be large, the lateral ventricles dilated. In the right crus a tumor was found, with a cheesy centre; this spread upward and forward across the median line into the left crus, involving the region of the third nerve.

DR. FISHER, the President, said that the epileptic seizures in this case were of interest, as the tumor was so far from the cortex. They could only be explained on the ground that the impulses were interrupted as they passed downwards.

### PALMUS.

DR. LANDON CARTER GRAY read a paper with this title. He stated that within the last few years he had seen a number of patients with certain muscular movements to which the French authors have given the name *tic convulsif*. They were first described in 1885 by Gilles de La Tourette, under the name "A Nervous Affection characterized by Motor Incoördination, accompanied by Echolalia and Coprolalia." The details of this description are as follows: Motor incoördination is the first symptom, beginning gradually and without apparently influencing the general health. The face or the upper extremities are first affected. It is first noticed that the fingers are alternately extended and flexed, or that the shoulders are raised. At about the same time the muscles of the face become implicated; there is often incessant winking, or the buccal commissures are actively drawn upward and outward, or there is contraction of the masseters, causing a grating of the teeth, or there may be projection of the tongue. The muscles of the neck may take part in the movements, the head being alternately flexed and extended. The lower extremities may share in the general disturbance, but the incoördination in them is somewhat different, in that the movements are not limited to isolated muscular groups, as is the case in the parts above described, but extend over the entirety of the muscles of one or the other member, and sometimes over both. The patient stamps his foot, stoops or erects himself, or the movement may consist of a veritable jump. All these movements are very sudden and rapid, and may be accompanied by an inarticulate cry. At times this cry may be articulate, consisting of a word which varies in different patients, and which was supposed to possess certain characteristics of an echo; hence the name "echolalia." The coprolalia was regarded by La Tourette as pathognomonic, and consists of profane oaths or obscene epithets. The French authors had their attention directed to this subject by the descriptions of two American writers, those of Beard upon the jumpers of Maine, published in 1880, and that of Hammond upon *Miryachit*, a similar disease of the Orient.

Dr. Gray said that the main symptoms of this affection are much more frequent than has been hitherto supposed, and he has ventured to coin for it a new name, "Palmus," from the Greek word πάλμος, meaning palpitation or twitching of the heart. The affection is divisible into the following types:

(1) Facial Palmus. This constitutes the most frequent type. It consists of sudden, shock-like movements of lightning-like rapidity, causing a sudden wink or twitch of one cheek, occasionally of both, or of the brow. This series of movements is generally followed by a second series, weaker than the first, and sometimes by a third. In the majority of cases the winking is bilateral.

(2) General Palmus. This consists of intermittent, shock-like movements of different muscles of the body.

(3) Acute Palmus. In one case of this coming under his observation the patient was a boy aged six years. He had then had the trouble about six months. His palmodic movements were very curious. For instance, when standing near a table looking at something, his chin would suddenly come down with a thump that would leave a black and blue mark; or, while standing quietly, his legs would give a sudden twitch and he would be thrown violently to the ground.

(4) General Palmus with Pseudo-Melancholia. Of this type two cases have come under his observation.

The diagnosis of palmus can be readily made. The

only disease with which it is likely to be confounded is chorea, from which it differs radically. In chorea the movements usually involve the fibrillæ of muscles and not muscular groups, either acting singly or in coördination with other muscular groups.

The prognosis varies according to the type. The author stated he has never yet seen a case of the facial or general variety cured; however, in none of those cases was he able to carry out prolonged and rigid treatment. The case of acute palmus was readily cured under large doses of arsenic and rest in bed. One case of palmus with pseudo-melancholia was cured; the other was lost sight of.

Thus far no light has been thrown upon the pathology of this disease. As regards treatment: arsenic has a beneficial effect, but this is not of as long duration as the same drug has in chorea. In the facial and general varieties the arsenic alone will not answer, and in one case of generalized palmus with pseudo-melancholia it had no effect whatever. Hyoscyamine and hyoscine have a good effect in some cases. Iron has been utterly useless; also the bromides. Galvanic electricity is of distinct benefit. In facial palmus he has seen good results from the removal of errors of refraction or irritative lesions of the naso-pharynx. Absolute rest is also indicated, particularly at the outset, and the general health of the patient should receive attention.

Dr. David L. Webster said that palmus appears to be an affection which is known under various names. About twenty-five years ago he first became acquainted with it under the name of "blepharospasm;" later on it was called "blepharo-facial spasm," and still later "hemi- or bi-facial spasm," the latter when both sides of the face were affected. Then again it was heard of under the name of *tic convulsif*, and finally "palmus." There are several varieties of the disease. The easiest kind of all to cure is that which only simulates the real disease and is produced by a local irritation, such as foreign bodies in the eye, etc. Another variety is most common in school children, who are perhaps poorly nourished and use their eyes too much; sometimes a number of cases occur in the same school, which is probably due to imitation. These cases are generally curable. One such case under his observation was cured by the local use of atropine and proper glasses. In another case the symptoms disappeared after a congenital phimosis had been removed. A very severe and intractable variety of the disease is sometimes met with in the aged. Internally, he usually employs arsenic in the treatment of these cases. Conium has also been recommended.

Dr. G. M. Hammond said that about eight years ago he read a paper on this subject in which he reported a number of cases. In his experience, arsenic, even in toxic doses, rarely proves of much benefit. On the other hand, he has used conium with much success. He usually begins with five-drop doses, gradually increasing to twenty-five or thirty drops.

Dr. T. R. Pooley said that two varieties of blepharospasm are usually recognized: the symptomatic, which depends on some eye lesion, the presence of a foreign body, etc., and the essential blepharospasm, which is entirely independent of such cause. In the first variety, if we cure the eye trouble we cure the blepharospasm. In both varieties the symptoms may manifest themselves in either the clonic or tonic form; in the former the movements of the lids are momentary, while in the latter form the lids may remain closed for a considerable period of time. In nearly all of these cases pressure points may be found, generally in relation with the trigeminal nerve or some of its branches. The supra- and infra-orbital branches are often favorite locations. Such pressure-points may also be found in the nose, throat and mouth, especially when carious teeth exist. In exceptional cases they are found in other and more remote parts of the body. When such a pressure-point is pressed upon, the movements cease like magic. The way to cure the disease is to attack the point from which the reflex irritation starts. Stretching of the nerve is recommended in severe cases.

Dr. Joseph Collins presented

### A CASE OF TABES, ASSOCIATED WITH UNILATERAL REFLEX IRIDOPLEGIA AND POST-HEMIPLEGIC ATHETOSIS.

The patient, a man thirty-seven years old, was presented by Dr. Collins at the last meeting of the Society (February, 1895). The symptoms in the case were not those of a single clinical entity, but presented themselves in the form of an athetosis, indicating a lesion in the internal capsule or crus, and locomotor ataxia, pointing to involvement of the posterior root zones of the cord. Although no history of syphilis could be elicited, and in the face of the fact that specific treatment had produced no improvement, the speaker said he had assumed that the man's symptoms were a manifestation of cerebro-spinal syphilis; and he presented the patient as one of cerebro-spinal syphilis of the tabic type, associated with athetoid movements. At that meeting, three members of the Society stated that in their opinion there was nothing in the case to warrant either the assumption or the diagnosis, and they expressed the view that the case was one of multiple sclerosis. Since then these members have had an opportunity to examine the patient at their convenience and substantiate either their or his own diagnosis.

Careful investigation has also led to the discovery of new evidence which clears up some of the obscure points in the case, and likewise tends to uphold the original diagnosis. The most important of these new facts, which was obtained from one of the patient's previous physicians (he himself having failed to make any mention of it), was that about fifteen years ago he had an attack of hemiplegia, the right side of the body being completely paralyzed. There was some disturbance of speech. There was no loss of consciousness. The patient did not think that his eyes were affected at that time. This attack, Dr. Collins said, was probably one of cerebral thrombosis, of specific origin. The patient, however, continued to deny any knowledge of infection. One of his sisters, on being interviewed, stated that six or seven years before the appearance of the hemiplegia he had a sore on the inside of his lip which lasted for several weeks; it was elevated, and the physician who treated it dusted it with powder and gave him medicine internally for quite a time. Although much stress cannot be laid on this labial affection, it is within the bounds of possibility that it may have been a chancre.

Dr. Collins said that some of the gentlemen who examined the patient and reached a diagnosis of multiple sclerosis attached great importance to the

twitching movements of the eye-ball. This he has been accustomed to think is not a very rare symptom in tabes dorsalis. Berger has found it absent but six times in 109 cases. The speaker has found it present in five cases out of 26 which he now has under observation. Therefore, instead of militating against the diagnosis of tabes, it would rather tend to favor it.

In an examination of the patient's eyes made on March 3d by Dr. Ward A. Holden, he states in his report that this twitching of the eyes is not a true nystagmus, in the sense in which the term is used by ophthalmologists, but the twitching that may occur with paralysis of the extrinsic muscles of the eye and with various cerebral and spinal affections. He also found left unilateral reflex iridoplegia, which is of very rare occurrence, and in the few cases that have been reported was associated with mydriasis and not with myosis, as in this case. Dr. Collins said that, so far as he could learn, only five cases of unilateral reflex iridoplegia have been reported, and four of these were in tabes.

DR. SACHS said he was inclined to regard the case as one of cerebro-spinal syphilis of the tabic type. He would insist on that diagnosis even if no history of syphilis was obtainable. One very important symptom which points in that direction is the dissimilarity of the ocular conditions on the two sides. The movements of the right hand Dr. Sachs said he hardly regarded as an athetosis; to call them ataxic or choreic he thought would be more correct. They were probably due to an irritating lesion of the capsule or the ganglia surrounding it. As regards the movements of the eyes, the speaker said that these lateral jerky movements which are frequently styled nystagmus are not to be compared with the rapid oscillatory movements we get in true nystagmus. He has noticed slight movements of this character in persons without tabes and without cerebro-spinal syphilis.

DR. HERTER said he still held to his original view that the case was one of multiple sclerosis. He did this chiefly because he believed that a certain proportion of cases of multiple sclerosis were of syphilitic origin. Notwithstanding the fact that it has been pretty clearly shown that this man has had syphilis, his symptoms correspond more closely to multiple sclerosis than to tabes. The man has probably had cerebro-spinal syphilis, and at the present time he has that sclerotic process going on which belongs to the later periods of the disease. The changes that have occurred in his brain and cord are probably of a sclerotic rather than of an inflammatory nature. Recent researches show that in multiple sclerosis we have patches of degeneration scattered in an irregular way throughout the nervous system, and there seems to be no doubt that these patches are related to the blood-vessels.

Dr. Herter said that in reaching a diagnosis in this case, he laid considerable stress on the nystagmus, which he believes is more commonly met with in multiple sclerosis than in tabes. This patient also has marked slowness of speech. There is an entire absence of ataxia in the legs, and he has never had any lightning-like pains. The pupils are not the typical Argyll-Robertson pupils, and are more in line with those found in multiple cerebro-spinal syphilis than in tabes. It was stated at the last meeting that the man was impotent for a time; on questioning him about this, he stated that there was a loss of sexual desire, but he was always able to have erections. The slight optic atrophy which exists is quite as characteristic of multiple sclerosis as of tabes.

DR. J. ARTHUR BOOTH said that during his examination of the man made a few days ago, forced flexion and extension of the head produced a distinct oscillatory tremor, which is regarded as a symptom of sclerosis. The man's penis bears a scar, which he claims was produced by bringing it in contact with a hot stove.

DR. FREDERICK PETERSON said that in view of the additions made to the previous history of the case he was not prepared to uphold his diagnosis of multiple sclerosis, but he still failed to see any justification for the diagnosis of tabes. It appears that the only symptom of tabes the man has is the absence of knee-jerks, which may be congenital or occur in multiple sclerosis or under other circumstances. He has never had any pains; he has not the typical Argyll pupils; there is no history of impotence; the cilio-spinal reflex is present on both sides.

DR. COLLINS, in closing the discussion, said he did not see how this could be regarded as a case of multiple sclerosis, unless our present conception of that disease be entirely changed. It is very difficult to get a true history of the case, as the man's statements are very unreliable.

## MASSACHUSETTS MEDICO-LEGAL SOCIETY.

F. W. DRAPER, M.D., SECRETARY.

THE Society met February 6, 1895, eighteen members present, and the President, DR. Z. B. ADAMS, in the chair.

DR. J. A. MEAD, of Watertown, read a paper on

### THE MURDER OF JAMES FARRAR.[1]

DR. S. W. ABBOTT said that the paper seemed to him to present an extremely interesting, as well as clear and correct, statement of the subject discussed. He thought the effects of pistol-shots fired at an angle with the skin could be still farther illustrated well by exaggerating the angle and bringing it nearer the plane of the skin, making a very acute angle; if the pistol were held within five or ten degrees of the plane of the skin, instead of forty-five degrees, the bullet would make a longitudinal mark or wound; and if this is true of a five or ten degrees' angle, it ought to be of a forty-five or even seventy degrees.

DR. MEAD explained that he selected forty-five degrees for his experiments, because that was the angle at which, according to the defence in the trial reported, the bullet entered the murdered man's body. The purpose of the experiments was to show that the shape of a bullet-hole made by firing at an angle of forty-five degrees was elliptical and not circular.

DR. QUIMBY, of Gloucester, said that he had noticed in some cases of suicide, in which the weapon was naturally supposed to be in close contact with the skin, that powder-marks were absent; the pistol must, he thought, be held at some little distance before leaving visible powder-marks.

DR. HARTWELL, of Ayer, commented unfavorably upon the appearance, at the trial, of a medical examiner acting as a medical expert for the defence. Dr. Hartwell recalled the able essay of Dr. Fish, of Amherst, on the external appearances of pistol-shot

[1] See page 402 of the Journal.

wounds and especially the original observation relative to the brand above the entrance-wound of the bullet and its contrast with the other appearances in the vicinity of the lesion.

DR. ADAMS, of Framingham, spoke of the interesting fact brought out in the paper and alluded to by Dr. Quimby, that in order to get the spattering effects of powder-grains, the pistol must be held at some distance; if held very near, the effect is to burn; it must, he thought, be held at least twelve inches away to make powder-marks. Most of these marks would be found on the upper side of the wound.

DR. MEAD said that Dr. Fish's observation was that the exaggerated brand on the skin was always to be found, with relation to the wound, on that part which corresponded with the position of the pistol's hammer in the act of firing.

DR. GILBERT, of Quincy, said he had made some experiments with a pistol with a view to ascertain at what distance the powder-marks would show and whether they would show above or all around. They invariably showed above; that is, in the direction from the pistol where the cock of the weapon was. He attributed it to the rebound in firing.

DR. HARTWELL asked why, if the weapon "kicked" in the firing, the bullet did not go upward as well as the powder.

DR. JOHNSON, of Salem, said the explanation seemed to him to be in the shape of the revolver and the consequent leverage in holding it in firing; the interval of time must be extremely small between the discharge of the ball and the escape of the powder, yet there might be opportunity to get a throw to the powder that the ball did not have.

DR. PAINE, of Brockton, reported the case of a man, an epileptic, who had attempted suicide by shooting himself in the forehead. There was no blackening of the skin or staining with powder-marks.

DR. ADAMS spoke of the ease with which bullets are deflected from a direct line in passing through the tissues. A bullet will be altered in shape by striking soft parts, without contact with any solid tissue, like bone. Even thin plates of bone are quite enough to change the missile's course abruptly. He related a case illustrating deflection within the skull.

DR. ABBOTT contributed some examples of extraordinary deflection of bullets.

DR. MEAD, recurring to the Barrett trial, said that the defence took the ground that the sternum was too soft a bone to deflect the bullet, that it was a spongy bone and so unequal to the task of turning a bullet. The attorney-general asked if flesh alone would not cause a bullet to deviate from a straight course; and Dr. Hibbert did not know what "flesh" meant, and avoided answering. The experts for the State, on the other hand, were clearly of the opinion that the sternum was made of tissues quite capable of deflecting a bullet in the way demonstrated at the autopsy.

DR. HOWE, of Cohasset, inquired whether in those cases in which the ball pursued a circuitous course, the velocity had anything to do with the result — whether the bullet was a spent missile or was fired at close range.

DR. ADAMS was of the opinion that it made not the slightest difference; that the speed of the ball would not alter the main fact, which is that the bullet would be deflected by striking soft substances as well as hard, within ordinary limits.

THE BOSTON

# Medical and Surgical Journal.

THURSDAY, APRIL 25, 1895.

## SCIENTIFIC RESEARCH IN MEDICINE.

AT the recent Thirteenth Congress for Clinical Medicine held at Munich, Professor von Ziemssen delivered the opening address. His remarks were directed toward the advantages to be derived from such meetings for the development of medicine in general; this led him to a consideration of recent progress and the part which scientific investigation has played in that progress. We venture to quote at length a passage, which admirably defines the attitude which physicians everywhere should hold toward what they are too apt to regard as unpractical and therefore beyond the sphere of their interest and support. Von Ziemssen sums up the function of a Medical Congress, as representative of the medical body at large, as follows:

"Our Congress strives continually toward the common end of widening our knowledge and increasing our ability, working in conjunction with all the special branches, and with related sciences. While we hold clearly before us the ideal functions of medicine to help the sick, and to protect the healthy from disease, yet, at the same time, we regard no fact which pure science affords as unimportant, even if its value for the practical end of medicine be obscure. *Only through knowledge comes the power of intelligent action.* Only when it is possible to get at the causes of (physical) appearances, and to have knowledge of the laws, according to which the acts of life take place, will it be possible rightly to judge the diseased processes of the human organism, and to find the means of directing them again into normal channels. The Bavarian Academy of Science states its aim in the words: 'Rerum cognoscere causas.' Gentleman, our efforts to-day should lay claim to this sentiment. It is not only for its practical end that we pursue our science, but also for its own sake and with the exalted consciousness that every scientific fact at some future day may so develop as to have a far-reaching influence upon the health and life of the individual as well as of the community at large.

"Herein lies the greatness and the exaltation of science, that every new fact, every new method conceals within itself the germ of future advance in the line of civilization. Especially is it new methods of investigation which open fresh paths for science and for life. This fact the history of medicine during the present century most certainly teaches."

To a certain small class in the medical community these statements may seem trite enough. There have always been a few earnest investigators whose only adequate reward has lain in the satisfied consciousness

of the performance of careful work, with no thought as to its definitely practical outcome. To such men, and they are unfortunately few, von Ziemssen's remarks will appear altogether commonplace and unnecessary. The idea of research, however, as an end in itself has no hold whatever upon the mind of the general public. Utility has been the watchword; and where utility has failed to assert itself with sufficient force, people — physicians as well as others — have drawn back in anxiety lest they were compromising themselves by devotion to that which was unpractical. Such is the sentiment that we meet at every turn. That it is not dead in Germany Professor von Zeimssen's earnest appeal would seem to indicate; that it is extremely prevalent in America the smallest experience clearly shows. And yet the slightest consideration, if we are fair-minded, must convince us of the weak foundation upon which such a view rests, and how detrimental it is to the further development of medicine.

In the first place, we should distinctly recognize the fact of the value of knowledge for its own sake, and in such recognition see the highest utilitarianism. The definite establishment of facts of whatever character must, in the nature of things, make future deductions more easy in fields apparently remote. It is often quite impossible to say what such a deduction will be, and how such isolated facts may work in bringing about a practical result, but that such is inevitably the case no one of education may for a moment doubt. The whole process of the development of a practical science, like medicine, rests upon a foundation of more or less isolated facts of a purely impractical nature. The modern surgeon is not always aware that the practice of his art is rendered possible by the theoretical investigations of Pasteur on the organisms in atmospheric air, a scientific fact which it was Lister's function merely to render practical. The comparative failure of Koch's specific treatment of tuberculosis has blinded the eyes of many to the incalculable value of the principle which he has done so much to inaugurate, and which in modified form is now bearing its fruit in the doctrine of serum-therapy. Almost a parallel case is the ever-contested question of vivisection. Here, again, if the positive utility to man of every experiment is to be maintained as a justification for its continuance, the practice must evidently stop. If its justification rests upon anything, it rests upon the broader conception, upon which we have been insisting, that investigation for its own sake is a worthy end, and that the ultimate results will unquestionably justify the broader view by leading to a final benefit, whose scope we are at present quite unable to see, but of whose existence we feel morally certain, since we believe knowledge *per se* to be ultimately useful. Such is the broader utilitarianism for which Zeimssen contends, and for which every one must contend who has the true interests of medicine at heart.

It is altogether to be regretted that even the rising generations of physicians are not imbued with this idea, in spite of the hopeful scientific tendencies of the last half century. There still exists a depressing atmosphere of practicality. Young men of marked ability are forever weighing their scientific tastes in the balance with the practical demands of their profession, and entirely apart from the pressure of circumstances, are finding the greater weight of inducement in the practical fields. The very commonest answer to the appeal for scientific workers is: "How will that help me to cure my patients? What definite utilitarian benefit am I to get from my laboratory work?" In other words, such a man says, "I will be a good follower, I will gladly benefit by the results of the work of other men; but personally I will not use my mind to increase the stock of general knowledge." This is the gloomy side of the picture. There is another as well. The number of men who are doing original scientific work in our community, as in others, is constantly growing. The spirit of research for its own sake is gaining ground. There are at least a few men who are imbued with the enthusiasm of progress, and who see no possible path for such progress except along the lines of painstaking and self-sacrificing research. When such a spirit becomes general, and each and every man comes to regard himself as a possible leader, and not only a faithful follower, will medicine in any community leave behind its superstitions and come to stand for a true utilitarianism, based on a right conception of the real meaning of progress.

## MEDICAL NOTES.

ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES. — The fifth annual meeting will be held at Buffalo, N. Y., May 21, 22 and 23, 1895.

ANOTHER "FAITH-CURE" FATALITY. — The coroner at Dayton, O., has held Col. F. B. Mead and his wife to be responsible for the death of their twelve-year-old daughter, who was by them permitted to be treated by "faith-cure" methods, while she was suffering from tubercular meningitis.

THE PAY WARDS OF THE GREAT NORTHERN CENTRAL HOSPITAL. — At the annual meeting of the Great Northern Central Hospital of London, notice was given of the following resolution: "That this meeting of Governors of the Great Northern Central Hospital regrets the recent changes in the administration of the hospital by which pay patients have been admitted to its wards to be attended gratuitously by the honorary staff, and is of opinion that such a system is not likely to conduce to the welfare of the hospital or the advantages of the poor, for whom such institutions exist, and should, without further delay, be abandoned."

THE REPUTED EPIDEMIC AT LITTLE ROCK. — A physician of Little Rock, Ark., writes to the *Journal of the American Medical Association* to correct a statement recently published in that journal that 82 cases of small-pox and 14 deaths had occurred at Little Rock.

The writer states that Hot Springs is the place to which the figures refer, and says, "there is no smallpox at Little Rock, *but we have the legislature.*"

THE SAMARITAN HOSPITAL FOR WOMEN, MONTREAL.— A new hospital for women, with the above name, was opened by Her Excellency, the Countess of Aberdeen, wife of the Governor-General of Canada, on the 17th of January, 1895. It is non-sectarian, and supported entirely by voluntary contributions, of which latter, enough were handed in during the first month to carry on the work during a whole year. It is the only special hospital for diseases of women in Montreal, and will be moulded on the pattern of the New York State Women's Hospital in New York City.

MEDICAL LEGISLATION IN KANSAS.— The Kansas Medical Practice Bill was defeated chiefly through the influence of the Populists. In the House, according to the Kansas *Medical Journal*, Mr. Winters, a Populist member, said: "We Western people can't support your plug-hat doctors. We've got a lot of old women who are better than any of them." Kansas is certainly a most fortunate State, if its laws are to be made for it by legislators who are swayed by such arguments as that. The logic of Populism as applied to medicine is certainly consistent with that by which it settles financial and other questions.

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, April 24, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 41, scarlet fever 32, measles 197, typhoid fever 3.

THE STATE BOARD OF HEALTH ANTITOXIN. — The Massachusetts State Board of Health has now distributed 150 packages of antitoxin to the authorities of several public hospitals and to boards of health and physicians for use in cases of diphtheria. The distribution began the 25th of March, and has been in all cases gratuitous. There has been a steady demand since the distribution was begun; but just at present, as commonly takes place in warm weather, the disease seems to be somewhat abating. The results so far reported from the use of this antitoxin have been uniformly favorable.

### NEW YORK.

THE COMMISSIONERS OF CHARITIES AND CORRECTION.— Considerable disappointment was felt in the medical profession that Mayor Strong did not appoint a physician as a member of the Board of Commissioners of Charities and Correction, in the place of Dr. Charles E. Simmons, as it was expected that he would do. The appointment that he made, however, was a very good one, namely, Mr. John P. Faure, whose name has long been associated with various charitable and philanthropic movements. For a number of years he has been Secretary of St. John's Guild, and he is at present Chairman of the Floating Hospital Committee of that organization. He is also Secretary of the Committee of Seventy (for political reform), and Chairman of the Board of School Trustees of the Ninth Ward.

THE PROGRESS OF SCHOOL REFORM.— School reform really seems to be making some progress. A notable instance is seen in the plans for a new public school building at the corner of Henry and Catherine Streets, in the crowded tenement district of the Seventh Ward, which were adopted at a recent meeting of the Board of Education. The school-house is to be provided with twenty shower baths in the basement for the free use of the children, and on the roof there is to be a play-ground with an area of ten thousand square feet. At a meeting of the Board of Estimate and Apportionment held April 16th, it authorized an issue of bonds to pay for a new school building in Harlem. When the comptroller announced that the plans included living rooms for the janitor and his family the mayor strongly objected, on the ground that the occurrence of contagious diseases in the families of janitors living in school buildings necessitated the closing of the schools, as in the recent case in East 35th Street. The comptroller agreed with him, and the Board ordered the plans changed accordingly.

EASTER AT BELLEVUE HOSPITAL.— On the day before Easter a number of ladies distributed two large truck-loads of potted flowering plants among the various wards of Bellevue Hospital.

AMALGAMATED TWINS.— On April 15th a German woman by the name of Koehler, under the care of Dr. Sigmund Tynberg, gave birth to female twins who were joined together by a pliable muscular band extending from the upper part of the spinal column to the coccyx. Together the children weighed fourteen pounds, one being about a pound and a half heavier than the other. This monstrosity is believed to be similar in character to the well-known "Millie-Christina" twins. The Koehler twins differ from the latter, however, in being able to face each other. Prof. Egbert H. Grandin, after an examination of them, expressed the opinion that they would live, but that it would not be safe to attempt an operation for separating the children.

DEATH OF DR. PRIMUS C. SMITH.—Dr. Primus C. Smith, a well-known dentist of Brooklyn, met a singular death on the night of April 19th. As his wife was going to bed he went into the kitchen to make himself a cup of tea. Mrs. Smith fell asleep, but awoke at 1 A. M., and not finding her husband with her, arose and went down stairs. In the kitchen she discovered his dead body, the head lying in a pool of blood. He had been subject to attacks of vertigo, and it is thought that he was seized with one while making his tea, and fell upon the stove. In doing so his head struck upon the sharp corner of the stove in such a position that the left temporal artery was severed, and as a result he bled to death.

## Miscellany.

### NUCLEIN IN DIPHTHERIA.

At a meeting of the Society for Medical Progress of the New York West Side German Dispensary, held April 14th, Dr. William Jacobson read a paper on the use of nuclein in the treatment of diphtheria and other contagious diseases. For the introduction of this agent (which is a normal constituent of blood-serum chemically represented by 49 parts of hydrogen, 32 parts of oxygen, 29 parts of carbon, and six parts of phosphorus), he said we were indebted to the researches of Prof. Victor Vaughan and Dr. Charles McClintoch, of the University of Michigan. Out of 200 cases of diphtheria, scarlet fever and measles, which were observed during several months, he claimed that there had been only nine deaths, and that in these cases the fatal result was due either to the fact that the nuclein injections were not made until the disease was too far advanced for any remedy to be of any service, to necessarily fatal complications, or to lack of proper care or other unfavorable conditions affecting the patient. The theory upon which nuclein was employed was that, as nuclein was found to a greater extent in the blood of healthy than in that of diseased persons, it was the real food upon which the blood tissues fed, and as such was nature's own antitoxin.

Nuclein was first tried on a girl four years of age, who was suffering from diphtheria. The agent was introduced into the system hypodermically and in a very small quantity. It was found that the temperature at first slowly rose, and then had a sudden drop. The pulse soon became normal, and in three days the child showed no sign of disease. The result was so successful that the treatment was resorted to in other cases, and with similar good results. "To treat fever," said Dr. Jacobson, "we must remove the cause, the toxines, and especially, as in contagions, the microbe and its poison. Nuclein is the substance to which the cell owes its resistiug power, and if present in sufficient quantity the microbe and its toxine are prevented from attacking the cell, and are ultimately destroyed."

### MORTALITY OF CHICAGO DURING THE PAST WINTER.

Dr. A. R. Reynolds, Health Commissioner of Chicago, compares the mortality of the winter quarter of 1895, ended March 31st, with the mortality of the corresponding period in previous years.[1] The comparison shows an increase of 27 per cent. in the total mortality of 1894. The total deaths from all causes during the quarter were 6,648 — an annual rate of 16.62 per thousand of 1,600,000 population; the average death-rate of the corresponding quarter for the previous ten years, 1885–1894 inclusive, was 19.10 per thousand; the lowest in 1894, 13.08 per thousand; the highest, in 1891, 23.40 per thousand. Acute lung diseases, complicated with influenza, are responsible for the increased death-rate. This group — pneumonia, bronchitis and influenza — shows an increase of 14.3 per cent., as compared with the winter quarter of 1894, and pulmonary consumption shows an increase of 12.5 per cent. The commissioner says that the prevalence of influenza has been more general than is indicated by the number of deaths (143) returned as from that cause. To its complications are to be attributed the great severity and fatality of pneumonia and bronchitis, as well as a large number of non-fatal cases of illness of masked or obscure symptoms which have affected the tone of the general health of the community and especially of the aged and enfeebled. It is, however, the unusual seasonal influences which have caused the increased death-rate, rather than the prevalence of influenza. The mean temperature for the month of January was 6.8° lower than the average January temperature of the previous twenty-five years, and the extremes ranged between 9° below zero to 51° above. During February the deficiency in temperature and the range of extremes was still more marked; the mean temperature was 10.7° below the normal, the accumulated deficiency of daily mean temperature at the close of the month was 50.4°, and the extremes ranged from 15° below zero on the 8th of the month to 61° on the 28th — a range of 76°. More than half the month was cloudy, or partly cloudy with an excess of humidity. During this month the deaths from pneumonia rose in number from 163 in January to 444, or nearly one-half of the total number for the quarter.

Concerning the small-pox, Dr. Reynolds says: "With the close of the first quarter of 1895, it seems to be entirely safe to say that the fourth serious — and at one time most threatening — visitation of small-pox upon Chicago is at an end. The disease has steadily declined since June, 1894, that is to say, from a period within thirty days after the great vaccination campaign was fairly inaugurated. That work is now conceded, both in this country and abroad, to be one of the most signal triumphs of preventive medicine on record, and a feat of sanitary administration without a parallel in respect of magnitude and diversity of population dealt with, of successful avoidance of overt opposition to the enforcement of health ordinances and regulations, and of direct results in the prompt check and ultimate suppression of the ravages of a pestilence."

[1] Journal of the American Medical Association.

### A SIX-DAY RECORD OF OPHTHALMIC SURGERY.

As an evidence of the very large amount of ophthalmic work occasionally done in a village district of India, we may place the following on record. A few weeks ago Surgeon-Lieutenant-Colonel G. C. Hall, F.R.C.S., Eng., surgeon to the Allahabad Eye Hospital, was called upon to operate on a patient in a village in the province of Oudh. The village was some twelve miles from the railway and twenty-six miles from any English station. No means were taken to let the people in the surrounding villages know of the intended visit of an ophthalmic surgeon to their neighborhood, but the news nevertheless spread. Surgeon-Lieutenant-Colonel Hall lived in camp. The natives arrived in various ways — some in bullock carts, having been four or five days on the road, from distant villages; some came on foot, led by others not quite so blind as themselves; others were carried on the backs of their relatives. A large number had no eyes left to be dealt with, but all had a large amount of faith. It was altogether an extraordinary and weird spectacle to see these poor, helpless people coming into camp in the early morning and quietly sitting down in groups patiently waiting until their turn came. During six days

the total number of patients seen was 394, the total number of cataracts extracted 69, and the total number of operations performed was 147. The operations were all done in the open air under the shade of a large mango tree, the patient lying on a native bed, the operator sitting at the head of it. As far as possible all the cases were treated antiseptically, and notes were taken of them with the prognosis formed at the time of operation. When Surgeon-Lieutenant-Colonel Hall left, which he did on the sixth day, a native assistant remained to look after the patients, to whom sixty-five pairs of spectacles have already been forwarded for the successful cases. We think our readers will concur with us in considering that the foregoing account records an enormous amount of hard and successful work of a most humane and philanthropic kind, of the accomplishment of which any one may well feel proud.

## Correspondence.

### THE CHARCOT MONUMENT FUND.

NEW YORK, April 20, 1895.

MR. EDITOR:— The following is a statement of the contributions to the Charcot Monument Fund, to date:

ST. LOUIS. Dr. E. B. Fry, $5.
SAN FRANCISCO. Dr. J. D. Hirschfelder, $10.
ROCHESTER. Drs. E. H. Howard, E. B. Potter, E. B. Angell, each $10; Dr. John D. Roe, $5.
BOSTON. Dr. Morton Prince, $25; Dr. F. C. Shattuck, $20; Dr. F. B. Greenough, $12; Dr. Geo. B. Shattuck, $10; Drs. Geo. L. Walton, Walter Channing, J. B. Ayer, J. J. Putnam, H. P. Bowditch, $5 each; Drs. H. B. Howard, R. D. Edes, $3 each.
NEW YORK. Dr. Graem Hammond, $10; Drs. S. T. Armstrong, H. Knapp, $5.
CONNECTICUT. Dr. Frank Hallock, $3.
Previously acknowledged, $642. Total, $813.

Owing to an oversight, the names of the following contributors (through members of the Committee) were not given for publication:

Through Dr. T. Diller, of Pittsburg: Drs. S. Ayers, J. W. Dixon, J. A. Lippincott, W. H. Daly, A. Fleming, F. Lemoyne, R. M. Tindle and J. S. Lange, each $5; Drs. G. G. Rahauser, C. C. Hersman, J. D. Thomas, D. C. Boyce, D. N. Rankin, J. D. Crombie, D. P. Miller, W. T. Burleigh, J. Milton Duff, W. H. Mercur, W. T. English, S. O. Brumbaugh, J. M. Brockerhoff, C. H. Voight, X. D. Werder, M. N. Gerhard, each $1. Dr. T. Diller, $2.

Through Dr. J. W. Putnam, of Buffalo; Drs. Chas. S. Jones, and Wm. C. Krauss, each $5.

Through Dr. Jas. Stewart, of Montreal: Drs. Wm. H. Hingston, E. P. Lachapelle, and Dr. Jas. Stewart, each $5. Dr. J. P. Pottot, $4.

The fund will be forwarded to Paris without delay.

C. A. HERTER, M.D., *Secretary*, 819 Madison Ave.

### DR. LEFFINGWELL TO DR. WOOD.

CAMBRIDGE, MASS., April 22, 1895.

MR. EDITOR:— The communication from Professor Wood does not, I think, require any reply from me. If I were to ask the further use of your columns, it would be only to express my wonder at the blindness that could again repeat an argument so completely answered a week before by your correspondent, Dr. Nichols; to doubt, whether in Great Britain the government inspection of physiological laboratories for the last eighteen years has been done by "spies"; and to thank you sincerely for the courtesy you have extended me. I am, sir,

Yours faithfully,

ALBERT LEFFINGWELL, M.D.

### METEOROLOGICAL RECORD,

For the week ending April 13th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | We'th'r.* | | Rainfall in inches. |

Deaths reported 1,915: under five years of age 601; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 188, acute lung diseases 442, consumption 213, diphtheria and croup 72, scarlet fever 30, typhoid fever 28, diarrheal diseases 16, cerebro-spinal meningitis 14, whooping-cough 10, measles 6, malarial fever 5, erysipelas 4, small-pox 2.

From diarrheal diseases Brooklyn 6, Cleveland and Fall River 3 each, Lowell 2, Philadelphia and Nashville 1 each. From cerebro-spinal meningitis Worcester 3, Philadelphia, Boston, Washington, Fall River, Lynn, Somerville, Lawrence, New Bedford, Salem, Pittsfield and Clinton 1 each. From whooping-cough Brooklyn 4, Boston 2, Philadelphia and Cincinnati 1 each. From measles Brooklyn 3, Philadelphia, Boston, and Cambridge 1 each. From malarial fever Brooklyn 4, Nashville 1. From small-pox (Cincinnati) 1.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 13, 1895, TO APRIL 19, 1895.

Leave of absence for two months, to take effect on being relieved from duty at Fort Huachuca, Arizona, is granted CAPTAIN RUDOLPH G. EBERT, assistant surgeon.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING APRIL 15, 1895.

GEORGE PURVIANCE, surgeon, detailed as Chairman Retiring Board for physical examination Officers of Revenue Cutter Service, April 8, 1895.

H. W. AUSTIN, surgeon, detailed as Member Retiring Board for physical examination Officers of Revenue Cutter Service, April 8, 1895.

H. R. CARTER, detailed as Recorder Retiring Board for physical examination Officers of Revenue Cutter Service, April 8, 1895.

A. H. GLENNAN, past-assistant surgeon, granted leave of absence for three days, April 9, 1895.

J. B. STONER, past-assistant surgeon, when relieved to proceed to Philadelphia, Pa., for duty, April 5, 1895.

G. M. GUITERAS, past-assistant surgeon, granted leave of absence for six days, April 5th and 8th, 1895.

J. C. PERRY, past-assistant surgeon, to proceed to Portland, Or., and assume command of Service, April 5, 1895.

J. M. EAGER, past-assistant surgeon, to proceed to Gulf Quarantine Station for temporary duty, April 5, 1895.

W. J. S. STEWART, assistant surgeon, to proceed to Philadelphia, Pa., for temporary duty, April 9, 1895.

SEATON NORMAN, assistant surgeon, to proceed to Norfolk, Va., for temporary duty April 9, 1895.

H. S. CUMMING, assistant surgeon, to proceed to Boston, Mass, for temporary duty April 9, 1895.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 20, 1895.

G. McC. PICKRELL, past-assistant surgeon, detailed from U. S. S. "Newark," home and two months' leave.

L. N. STONE, assistant surgeon, ordered to the U. S. S. "Newark."

C. H. T. LOWNDES, past-assistant surgeon, detached from coast-survey steamer "Hassler" and to Mare Island Hospital.

C. M. DEVALIN, assistant surgeon, detached from U. S. S. "Vesuvius" and to the U. S. R. S. "Vermont."

HOWARD SMITH, surgeon, retired, leave extended six months to remain out of the United States.

THE THIRD INTERNATIONAL CONGRESS OF DERMATOLOGY

Will be held in London, August 4 to 8, inclusive, 1896. A partial list of officers is as follows:

President, Mr. Jonathan Hutchinson.

Vice-Presidents for the United States, Dr. Duhring, of Philadelphia; Dr. White, of Boston; Dr. Nevins Hyde, of Chicago; Dr. Bulkley, Dr. Keyes and Dr. Fox, of New York.

Treasurer, Mr. Malcolm Morris.

Chairman of the Reception Committee, Dr. Radcliffe Crocker.

Chairman of the Museum and Demonstration Committee, Dr. Stephen Mackenzie.

Chairman of the Bacteriological Committee, Dr. Sims Woodhead.

Secretary for the United States, Dr. George T. Jackson, of New York.

Secretary-General, Dr. J. J. Pringle, 23, Lower Seymour Street, London, W.

REGULATIONS.

1. All duly qualified medical men, British or foreign, or others interested in science invited by the Council, who shall have paid the fee of £1 sterling, and who shall have enrolled themselves, shall be members of the Congress and entitled to the volume of Transactions.

2. The official languages of the Congress shall be English, French and German, but with the permission of the President, members may express themselves in the language with which they are most familiar.

3. The proceedings of the Congress shall be embodied in a volume of Transactions, edited by the Executive Council.

4. Communications relative to membership, papers, or other matters connected with the Congress, should be addressed to the Secretary-General, Dr. J. J. Pringle, 23, Lower Seymour Street, London, W., or to one of the Foreign Secretaries.

5. The fee for membership shall be payable in London, at or before the opening of the Congress. It will greatly facilitate the work of the Executive if the fee is forwarded as soon as possible after the 1st of May, 1896.

6. Members who are unable to attend the Congress shall receive the volume of Transactions.

7. The Subjects treated of shall be of two orders: (1) Those selected beforehand by the Executive Council and introduced by gentlemen chosen for that purpose by the Council. (2) Those selected by individual members themselves.

8. Subjects selected for debate by the Council shall take precedence over those selected by the members.

9. The sittings of the Congress shall take place from eleven to one in the forenoon, and from three to five in the afternoon, of each day.

10. There shall be clinical demonstrations of patients every morning from nine to half-past ten, and every afternoon from two to three.

11. Members contributing papers must submit an abstract of them to the Secretary-General on or before the 1st of May, 1896, which will be printed either in full or in part, and embodied in the general programme of the Congress which will be distributed at its opening.

12. At every debate precedence will be given to gentlemen who have communicated beforehand their intention to take part in it.

13. No papers lasting more than twenty minutes will be permitted. Speeches will be strictly limited to ten minutes each. MSS. of the papers read must be left with the Secretary-General before the end of the sitting. The Executive Council shall decide as to the entire or partial publication of such papers in the Transactions of the Congress.

## SOCIETY NOTICES.

MEDICO-LEGAL CONGRESS. — The Medico-Legal Society makes the preliminary announcement that it will hold a Medico-Legal Congress at or near the City of New York during the last week of August or first week of September, 1895 (time and place to be hereafter announced), open to all students of Medical Jurisprudence.

An enrolling fee of $3.00 will be required of each member to aid in the expenses and the publication of the *Bulletin* of the Congress, to be sent each member free.

H. W. MITCHELL, M.D., *President.*
CLARK BELL, ESQ., *Secretary.*

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday evening, April 29th, at 8 P. M.

Dr. E. B. Lane will present a paper on the "Causes of Insanity." Drs. M. Prince, P. C. Knapp and G. T. Tuttle have been asked to take part in the discussion.

Dr. S. J. Mixter will report a case of "Meningocele; Operation; Recovery." Drs. G. L. Walton, A. T. Cabot and R. W. Lovett have been asked to take part in the discussion.

JAMES G. MUMFORD, M.D., *Secretary.*

THE SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION, will hold its regular monthly meeting, this meeting being the last one for this season, on May 1, 1895, at 19 Boylston Place at 8 o'clock.

The subject for discussion will be "Penetrating Wounds of the Abdomen." Dr. James G. Mumford will present the subject in a short paper.

Dr. M. H. Richardson will report "A Case of Gun-shot Wound of the Kidney."

Dr. C. L. Scudder and Dr. H. Lothrop will give a *résumé* of cases of penetrating wounds other than gun-shot wounds up to date.

Dr. S. V. Goldthwaite will report and exhibit "A Case of Pyelo-Nephritis; Operation; Recovery."

Dr. G. H. Monks will show and report "A Case of Stab-Wound of the Abdomen," — wound of intestine, prolapse of bowel through wound, operation, recovery.

MEETING OF ACTING ASSISTANT SURGEONS. — A special meeting of the Association of Acting Assistant Surgeons of the United States Army will be held in Baltimore, Md., May 8th, during the coming session of the American Medical Association.

It is earnestly desired that every member of the Association will make an effort to be present, to consider matters of importance. By direction of the President,

W. THORNTON PARKER, M.D., *Recorder, A.A.A.S.*
GROVELAND, MASS., April 17, 1895.

## RECENT DEATH.

WILLIAM MASON CORNILL, M.D., M.S.S.S., died in Boston, April 14, 1895, aged ninety-four years.

## ACUTE INFECTIOUS PROCESSES IN BONE.[1]

BY ROSWELL PARK, A.M., M.D., BUFFALO, N. Y.,
*Professor of Surgery, Medical Department, University of Buffalo.*

That which the surgeons of past times used to speak of as "ostitis interna" has been of late years much more carefully studied, and is now usually spoken of as "osteomyelitis acuta seu infectiosa." This has been brought about largely by the labors of Chassaignac, who in 1853 presented a communication to the Académie in Paris, and whose labors were during the ensuing years ably seconded by Demme, Klose, Roser, Lücke, Kocher, and many others. As the result of their combined labors, there has been described a fairly typical form of acute infectious disease occurring beneath the periosteum, usually of the long bones — no bone of the body, however, being exempt; most common in early childhood, that is the period of the growth of bones — which has become now among surgeons and pathologists so well recognized that already it is called by numerous different names, none of which perhaps are more appealing, though perhaps more accurate, than Chassaignac's expression "typhus of the limbs."

When Piorry introduced the expression "pyemia," he made us acquainted with what he called "a purulent diathesis," which was supposed to be the starting-point of many of these infections, although both Piorry and Astley Cooper had stated that in malignant fevers, in chicken-pox, and after measles, the bones often underwent acute necrosis. Piorry also called attention to the connection between cases of osteomyelitis and pyemic manifestations, considering the former as illustrating frequently a spontaneous form of the disease. Later, Klebs found in the marrow of the femur and of the clavicle of a patient dying with osteomyelitis, numerous zoögloea masses, along with which were free spores and bacteria-like rods. In the lungs he found fat-embolism; in the kidneys the metastatic foci contained vessels filled with spores. From this case Klebs deduced that we might have an internal multiple inflammation belonging to the mycotic diseases and strongly resembling the septic processes of injured patients. Recklinghausen repeated their experiences, and Eberth determined that there were cocci swarming in the blood of a patient with osteomyelitis of the femur, which were the cause of secondary abscesses. Pasteur also separated from a case of osteomyelitis, operated on by Lannelongue, a large number of cocci, and cultivated them, so that later he identified them as similar to those found in furuncles. He, consequently, formally stated that osteomyelitis is a furuncle of the bone marrow. Thellier and Schueler also saw in the periosteum of inflamed bones and in their surrounding infiltrate, that similar microbes were collected in large numbers. One of the most positive advances in the etiology of osteomyelitis was made by Rosenbach and Kocher when they applied the then new method of isolation and cultivation of these organisms to the study of those which had been found in osteomyelitic cases. The names of some other observers are equally worthy of mention in this connection, although time may fail in which to give each the credit due him. But when one studies this subject, he will always find that the path of research has been made easy by the labors of Krause, Rodet, Garré, Kraske, Passet, Ribbert, Kohts and Golzi.

This disease—to various expressions of which I shall invite your attention—is generally at present known under the name of "acute infectious osteomyelitis." Or, inasmuch as its most prominent expression is sometimes found between the bone and the periosteum, it may also be known as "acute infectious periostitis." Anatomically, the activity of the disease may vary a little in location; pathologically, the condition is essentially the same. It is essentially an expression of an infection, although the path of infection or its source cannot always be determined. A great deal, however, can be done in every case by individual study.

I wish, first of all, to divide the disease into two forms, in accordance with the division which I have elsewhere made of the bacteria which may act to produce pus. In some lectures on "Surgical Pathology," published three years ago in the *Annals of Surgery*, I made a division of the pyogenic bacteria into the obligate and the facultative — the former being those whose functions seemed to be simply pyogenic and nothing else, which could always be relied upon to produce pus if time and opportunity were afforded them; and, the latter, those which seemed to produce pus only under certain conditions. The staphylococcus forms, with certain other pyogenic germs, seem to be in man always almost strictly obligate in their pathogenic activity. It is so with several forms of the streptococci. It is not so, however, with certain other forms which I group as facultative. Here may be reckoned, for instance, the typhoid bacillus, the colon bacillus, the tubercule bacillus, the pneumococcus, etc. Inasmuch as now I shall have to insist upon it that acute osteomyelitis may be produced by any one of these organisms, I must at once divide the cases into two groups, depending upon whether they are caused by the obligate or by the facultative pyogenic bacteria. Preferring to approach this subject from the pathological side first, I will first give a brief *résumé* of the organisms which are known to produce these diseased conditions.

In the first group, we have the staphylococcus pyogenes aureus, which is the form most commonly met with, and that which Rosenbach and Ogsten first studied in these cases. Next to this comes the staphylococcus pyogenes albus, generally supposed to be somewhat less virulent in its activities and met with less often than the aureus, the cases characterized by it running usually a somewhat milder and more prolonged course clinically. (The staphylococcus pyogenes citrus can be disregarded here.) Next there are certain mixed forms, where both (or several) staphylococci are met with. Next to the staphylococci come the streptococci. These vary much in their virulence, and cases due to these organisms may be very acute or may run a quite mild course. Cases are also met with where we have mixed infections with both coccus groups. Next to these comes, perhaps, the bacillus pyocyaneus. This organism does not seem to be ordinarily particularly virulent, although nearly all cases of suppuration characterized by its presence are known to pursue a tardy or a disappointing course. It is the organism which gives the peculiar blue or green tint sometimes seen in pus. It is said that there are two organisms closely resembling each other. Their re-

[1] Read before the Surgical Section of the Suffolk District Medical Society, March 8, 1895.

semblance is so marked as not to concern us here. The micrococcus tetragenus is an organism often found in the lungs of tubercular patients, it apparently being a frequent inhabitant of the human mouth and passing down into the pulmonary cavities with the saliva or other secretions. Some years ago I reported one case of abscess outside of the jaw bone in which this organism was the one principally at fault, the surface symptoms being somewhat peculiar, suppuration being prolonged and the induration about the abscess being hard and pronounced. Since then I have seen that others have noted the same peculiarities. Subperiosteal abscesses about carious teeth sometimes contain this organism.

It has been long noted by various observers, that occasionally during convalescence from typhoid there would be acute suppurations in the bones as in other parts of the body. In time past they have been explained as a sort of metastasis. Now, however, we know that in the pus from such abscesses we occasionally find typhoid bacilli and no other organisms. There are now on record a large number of cases of post-typhoidal abscess, within bone and without, which amply justify the statement that the typhoid bacillus of Eberth may be a facultative pyogenic organism. It is in typhoid also that we get numerous cases of mixed infection — as, for example, where we find pyogenic cocci and typhoid bacillus together, these cases for the most part running a more acute course.

Sequelæ of infection in bone after pneumonia are certainly rare; nevertheless, such cases have been reported — one case in particular by Ullmann (p. 42); also Hansen in 1877, and Achard in 1889.

That the pneumococcus, or diplococcus of Fränkel may be an active factor in the production of osteomyelitis and periostitis has also been very recently shown by Fischer and Levy;[2] also previously by Lannelongue and Achard.[3]

Efforts have been made by numerous authors to carry diagnosis to the point of determination as to the specific microbe at fault. Thus, according to Lannelongue, streptococcus cases always have an acute beginning, which, however, usually subsides if there be no general infection, pain increasing rapidly from the incipient symptoms. The skin becomes more red, and takes on an erysipelatous appearance, while the surrounding tissue is quite edematous. In staphylococcus cases the superficial veins become more distended and the lymph nodes are not so quickly involved. When these cases run a severe course they also begin quite violently, and the bone destruction is usually greater and more serious than in the streptococcus cases, in which sequestra usually form. Lannelongue and Achard also believe that prognosis of a given case can be based in a measure on this exact diagnosis. They hold that the staphylococcus forms are the most dangerous; the streptococcus forms next most so; while the mildest are those due to the pneumococcus and other forms. Nevertheless, too much stress cannot be laid upon these features, since the well-known variability in virulence in the same organism at different times plays a most important rôle.

After diphtheria there is but one case, so far as I know, at present on record; that is one reported by Pauli.

The other acute infectious diseases in the course of which acute bone affections are most likely to be met with are the following:

*Variola* — By several different authors, acute inflammations of joints as well as acute osteomyelitis has been noted during the course of this disease. Witzel, for instance, has seen necrosis of the lower end of the humerus during the course of variola, with multiple sequestrum formation also in other bones of the same patient. Fischer has reported a most violent and acute inflammation of the tarsal bones with extremely high fever, typhoid condition, and acute course, in complication with variola. After opening the degenerating mass, a quantity of pus was evacuated. From Kaschmir, Neve has reported three cases of acute necrosis; in each case the bone disease followed very quickly after the small-pox. The upper extremities were involved in each instance, and all finally recovered. Kolaczec has reported a case of multiple osteomyelitis with numerous sequestra in various parts of the body. The active pathogenic agent in variola being yet unknown, we are unable to say whether these cases should be considered as due to it, or whether they are not mixed infections, since in almost every instance the ordinary pyogenic organisms have been met with.

*Measles.*— Three generations ago, Sir Astley Cooper noted the frequency with which necrosis followed chicken-pox and measles. Similar observations have been made also with regard to scarlatina. Concerning the active agent in all three of these diseases, we are still in ignorance, although Babes inclines to the view that the entire scarlatinal process is a modified streptococcus infection. It seems, however, rather likely that the acute suppurative processes here are due to either secondary or mixed infections in which the streptococci play the principal rôle. In every instance with which I am familiar where suppuration has occurred during the progress of scarlatina, the ordinary pyogenic bacteria have been found in its products. Inflammations of bone marrow during and after scarlatina are by no means rare. In fact, in the experience of many surgeons, most of the cases of non-traumatic necrosis give a history of this inflammation following more or less quickly after scarlatina. Suppurative periostitis leading to acute necrosis is also quite common as a sequel of scarlet fever; and Kennedy has reported several cases of epiphyseal separation which he observed in Dublin during the years 1834 to 1842. That particular surface variety of necrosis affecting the alveolar process and resulting in loss of teeth, which was described so well by Salter, occurs very frequently during scarlet fever and measles. The disease affects children from the third to the sixth year, and begins with pains in the jaw, coming on within a few weeks after the cessation of the fever.

During the past few years, we have learned that the influenza or *Grippe* which has spread so widely over both continents may also leave its relics in the way of numerous surgical complications among which perhaps none are more frequent than those seen in the bones. Most of the reported cases, however, have concerned the periosteum rather than the bone marrow; but at least one most distinct case of this kind has been reported by Walker. A sequestrotomy was required, which had for its result the removal of the entire shaft of one tibia.

A study of osteomyelitis, made partly in the hospi-

[2] Deutsche Zeitschrift. f. Chir., Band xxxvi, p. 94.
[3] Cinquième Congrès Français de Chir., 1890.

tal and partly in the experimental laboratory, will give about the following conclusions: Osteomyelitis is a disease which can be experimentally produced in animals, to which end, however, it is necessary to introduce the organisms either into the circulation or into the bone marrow, and at the same time to inflict some quite serious injury upon the bone, by which its circulation may be disturbed. Unless this be done, one very seldom produces the disease experimentally. The disease is one which can be caused by more than a single organism, it being probable that all bacteria which have pyogenic properties can, in one way or another, be made to produce it. The organisms which are experimentally redeemed from these animals are the same as those introduced for the purpose of experiment.

In the human species, the disease is most commonly a staphylococcus infection, there being no doubt but that it is produced more often by these forms than by all others put together. There is ample reason to believe, however, that a variety of other forms may produce the same condition. The so-called "secondary osteomyelitis" is distinguished from the so-called "primary" in that in the former case the port of entry or path of infection is known, and in the latter it is not. Thus, in a case of furunculosis, we know that the bacteria have entered at that point where the furuncle is first met with, and to this an osteomyelitis would be secondary.

In studying this disease, it is most important, if possible, to make out the path of infection, since it is questionable whether any case is ever really primary, although it may appear so at first glance. In the great majority of cases, some lesion of the surface may be found — possibly very insignificant — such as a trifling abrasion, a hangnail, a bruise, or perhaps something more in evidence. One should then, if possible, convince himself that during, at least, several weeks previous to the beginning of the disease there have been no abrasions of the skin, canker-sores nor other lesions within the mucous membrane of the mouth, no styes, no bruises, no hidden ulcerations anywhere, through which bacteria might have penetrated. Kocher, for instance, has related a case where the disease in the bone seemed to follow fourteen days after a small furuncle on the right knee. Kraske has described an analogous case, where there had been a small furuncle on the lower lip of a young lad. Incision had permitted the evacuation of considerable pus. As the result of surgical attention, the lesion in the lip had almost completely healed, when suddenly the patient began to complain of intense pain in the ankle as well as in the pericardial region. In his case there quickly developed an osteomyelitis in the tibia and a pericarditis. Other abscesses subsequently developed in other parts of the body, and the patient died in a few days from general septic infection. In seeking, then, for the path of infection, there should be a most thorough and careful inspection of the entire surface of the body.

The next most frequent path of entry is through the alimentary canal; in fact, Kocher holds this to be that most commonly followed. It is now generally known that even through the unbroken mucous membrane of the intestine, the colon bacillus, and perhaps other organisms can pass. How much more then through lesions such as are permitted by typhoid ulceration, or those produced from other causes! In fact, when we remember that osteomyelitis can occur this way at all, it will seem strange that it does not occur much oftener as a sequel of typhoid.

The experiments which have been instituted by various writers with a view to settle this point seem to leave it as unsettled as ever. Kocher is a firm believer in the possibility of producing osteomyelitis after injury to the bone by feeding animals with the products of putrefaction. Ullmann has obtained just the contrary results. Nevertheless, the fact that acute osteomyelitis may really occur as the result of infection from the intestine seems to be proved quite positively by the studies of Kraske and others. Equally possible is infection through the respiratory organs, although of its absolute occurrence we are perhaps less positive. Kraske, Lücke, and others have reported cases in which it would appear that the pneumococcus can be disseminated from the lungs, and can produce an acute inflammation of this kind in bone tissue.

That congestion and disturbances of nutrition may be produced in bone and bone marrow by violent irritation or by appropriate chemical or mechanical means without the influence of bacteria, is unquestioned; but under conditions thus brought about there is no formation of that which is really entitled to be considered pus, while such experimental conditions lack all the characteristics of infectiousness, and in fact almost everything that goes to give them any really genuine or serious character. They are, moreover, conditions which are rarely, if ever, reproduced in clinical experience. So too, a number of experimenters have tested what can be done with cultures of various pathogenic organisms. They have all found that it is possible to produce a certain amount of disturbance, but not one of them has reproduced the clinical features of the infectious disease. From all of which, therefore, it most positively appears that osteomyelitis is an expression of localized suppuration within bone marrow or bone tissue. It is no more a specific disease than is an abscess. It is, however, always produced by micro-organisms, and can be experimentally reproduced only by working with them.

Before considering the actual causes of the disease as it is met in the human species, we must consider for a moment what predisposes to this condition. The combined influence of cold and wet seems to be that which more than anything else predisposes to an acute outbreak of this kind. As the result of the combined action of these two factors, we seem to have such local disturbances of circulation as to predispose bone marrow above all things to liability of infection. If in combination with this, we have injury or exhaustion and fatigue the disease is certainly invited. Lannelongue has spoken of certain professional causes which seem to predispose. The osteomyelitis of workers in mother-of-pearl has been particularly described by Gussenbauer, while workers in certain metals, and especially those who are concerned in grinding them, seem particularly liable. Another predisposing factor is the period of growth in the human organism and the peculiar circulatory activity that goes on in the neighborhood of the epiphyses of the long bones. So far as the influence of recent infectious diseases like those mentioned — namely, variola, scarlatina, etc.— goes, it is certainly open to question whether their influence is direct, or whether it may not really be explained by the mere lowering in vitality, which

every such severe infectious disease produces. Certain it is that the majority of patients who suffer in this way have not attained the twentieth year of life. Freund has collected 36 cases of post-typhoidal osteomyelitis, of which only two had reached the age of thirty, and 25 were under the age of twenty-five, 12 of those being below twenty.

### PATHOLOGICAL ANATOMY.

Kocher has made out three distinct stages through which most of these cases pass: First, the period of purulent infiltration with formation of local foci in the bone marrow, and speedy secondary involvement of the periosteum and synovialis. Second, the period of sequestration, or formation of a sequestrum inside of an abscess cavity. Third, the stage of repair.

*First Stage.*— During the first period there occurs first a most violent inflammatory infiltration of the bone marrow, which involves localized areas that become at first hyperemic, and then infiltrated with blood extravasation. This latter is indicative both of this stage of the disease, as well as of the intensity of the infectious process, since often during this period one finds enlargement of the spleen and hemorrhagic exudations in serous cavities, even at a distance, such as the pleura and pericardium. The locally affected areas of the bone marrow quickly break-down into depots of pus, which pus rapidly spreads in the worst cases either toward the epiphyseal line or else through the Haversian canals toward the periosteum, which it both infiltrates and loosens. This loosening of the periosteum is particularly marked about the diaphyses, rather than at the joint-ends, it being apparently looser in the former location. As a general rule, that end of the bone toward which the nutrient artery is directed is the one whose epiphysis is first loosened, while with the spread of the disease the other end may be similarly attacked. Nevertheless, about the knee it would seem as if the lower end of the femur and the upper end of the tibia are the particularly predisposed localities. Some authors have laid particular stress upon the direct influence of thrombosis and obliteration of nutrient arteries. There does not seem to be any sufficiently definite programme followed out in this regard, nor in the exact delimitation of the resulting sequestrum ever to permit the laying down of any definite rule. The separation of the periosteum usually takes place only over the portion of bone primarily affected, and the limitation of this process is a fair index of the extent of the deeper destruction. From the periosteum the inflammation either extends toward the covering soft parts, in which case we may have a parosteal abscess; or it perforates toward the joint cavity, so that we soon have a condition of empyema of the joint, as well as of destruction of its intrinsic structures. It would appear in many cases, especially in children, that the epiphyseal cartilage is the structure which brings this process to a halt, so that it is possible to have acute necrosis of a diaphysis of a long bone with perforation at both its epiphyseal ends. This appears to take place less often in adults; and, in fact, it is in adults that the joint-ends themselves are most often primarily involved. This is not meant to imply, however, that it may not be possible to get involvement of the entire length of a long bone, and practically total destruction of its structure. Softening and separation of joint cartilage is practically always secondary to the other process. In those cases which begin in the epiphysis proper, the disease is usually apparently primary in the joint, and is usually mistaken for some affection of the joint proper. In fact, epiphyseal separation occurs in some of these instances before men become alert as to what has really happened. If now patients survive the violence of what has been already described, there is shown a tendency toward encapsulation of the abscess, the formation of a sequestrum, and even the spontaneous separation of the same.

*Second Stage.*— The second stage is thus constituted: Almost coincidently with the occurrence of suppuration there takes place, around the limits of the acute infectious process, a proliferation of tissue, which may be regarded as an acute granulation process by which protection is afforded; and, if sufficient time is thus afforded, we have the rapid formation of new osseous tissue, produced by multinuclear osteoblasts, with which the affected bone is studded. So soon as this process begins there occurs also a lively absorption of material between the dead and the living tissue, by which even within a comparatively few days a considerable amount of loosening of necrotic tissue is produced. The second stage then, should the disease go so far, is characterized by production of a quantity of new tissue whose effect is to wall off the scene of conflict and death from the surrounding tissue. When once this has occurred, the prognosis, so far as the patient's life is concerned, is very much improved, although the local destruction may be very serious. The numerous abscesses within the infected area are likely to coalesce with time, and we may finally have as a result one long tubular abscess extending from one epiphysis to the other. Should there fail to be a distinctly significant connection, we shall at least find both the bone marrow and the spongy bone infiltrated with pus. If the periosteum has been separated, we shall then get a sequestrum whose dimensions correspond with those of the infected bone; should, however, the periosteum not be loosened, then the necrosis will probably be central and more or less circumscribed. The degree to which the rigid osseous tissues are capable of yielding under these circumstances is simply astonishing. It is in this stage that we have often those remarkable enlargements which occur within a comparatively short time, and produce most striking discrepancies in size between the healthy and the diseased bones. So long as the periosteum remains unbroken and unyielding, the pain, of course, will be intense and agonizing. Spontaneous subsidence of pain is practically an evidence of spontaneous giving way of tissue, by which tension is relieved. When this occurs, we will find almost always a similar yielding at the epiphyseal lines, the cartilage being rapidly melted down and converted into necrotic tissue. Epiphyseal separation may take place in any of the long bones. A similar yielding of sutures in the flat bones is also known, — for instance, a purulent diastasis of the tripartite suture entering into the formation of the acetabulum. Spontaneous yielding of the outer or inner table may also be seen in the sternum, or in the bones of the skull. One expects, of course, under these circumstances to find the joint structures sadly compromised, the capsule distended with pus or pyoid products, the cartilages ulcerated and displaced, the ligaments macerated and yielding, and usually the whole joint so compromised that its function is permanently lost.

*Third Stage.*—The third stage is the period of efforts at spontaneous repair. By a process of liquefaction in the direction of least resistance, there is a natural effort at elimination of the sequestrum. This may be a process extending over months, and may be accompanied by so much other disturbance as to completely ruin a limb or bone for further function. In neglected cases we often see several sinuses leading down toward the central sequestrum, each of which makes an effort in its direction to permit escape of that which nature is trying to eliminate. It is not to be held that pus has the property of destroying bone. The spontaneous disposition of bone under these circumstances is due to the action of phagocytes, the writer thinks, *in toto*. There may be some reason to think that cartilage left to float in pus may diminish in size; but bone, never.

Once the sequestrum be eliminated, an extraordinary amount of activity is usually displayed to fill up the defect thus left with granulation tissue, which shall subsequently become firmer, perhaps ossify. It is in this tissue that we are so likely to have a secondary tubercular infection, which shall undo finally all the good that nature unassisted might accomplish.

### SYMPTOMATOLOGY.

In a general way, the signs and symptoms of these infectious lesions in bone are common to almost all the varieties, and are extremely significant when only read and construed aright. We have already indicated that it is the young and the rapidly growing, also the marasmic who are, by virtue of said conditions, predisposed to attacks of this kind. Moreover, we have indicated that the most common causes are over-exertion, mechanical strain, and exposure. Granted that these conditions have conspired in the given case, the signs and symptoms will probably be about as follows: Patients complain first of exhaustion, followed quickly by pain that may speedily become agonizing. This is accompanied by an introductory chill with high fever, after which the general character of the disease rapidly assumes a typhoid aspect. Evening temperature may rise quite high, to be followed by some morning remission. The spleen is usually enlarged, the tongue dry, the bowels disturbed; frequently we have to do with a fetid diarrhea. The sensorium is affected and children usually early become delirious. The pain, which is at first vague, usually quickly focuses in that particular bone, or in those bones, which is or are to be the subject of the acute infectious process. As the pain increases in intensity we get a more and more significant tenderness, which becomes frequently exquisite. Usually before the tenderness is extreme, we get a characteristic reddening and swelling of the affected parts. With all these there will also be characteristic muscle spasm, by which certain posture signs will be produced, and there will be extreme pain when the peculiar positions thus assumed are even in the slightest degree disturbed. In consequence of this, the limbs — for this will usually be seen in the limbs — are drawn up; and every effort to overcome these flexures or contractures will be followed by intense pain. The more acute the process, the more vivid inflammation and edema of the adjacent parts. Thus it may happen that within forty-eight hours we have not merely swelling, but actual edema of the part involved. This edema should always be regarded as a pathognomonic sign when coming on in this way and with this rapidity, and may be practically always regarded as indicating the presence of pus in the depths beneath. Should, now, sufficient time have elapsed, we may in addition to the swelling, the edema, and the livid redness, get the fluctuation which will be afforded by parosteal abscesses, which is still further evidence of the infection going on within the bone. It is rare to have all this disturbance, confined within diaphyseal limits, without more or less participation of the neighboring joints. Of course, when the disease is primary in an epiphysis, the corresponding joint will be early involved. Here the symptoms and signs will not be different from those of an acute purulent synovitis; only in proportion as the bone itself is involved, we will have a much more significant degree of pain. Should a period of several days have elapsed before proper attention is given to such a case, it may be found that epiphyseal separation either has already occurred, or may occur on the slightest handling, such as is necessary for examination or operation. Not infrequently the pus evacuated from these cases is of foul odor, which appears to be often given to it by an admixture of putrefying fat masses.

So far only the symptoms peculiar to the bone affection have been rehearsed. It is necessary to add that to this picture, already often bad enough, we must append a further list of symptoms pertaining to the septic consequences of thrombosis and metastatic infections. Most unfortunately, this disease is frequently so acute and so rapid that even within the first day or two there is not only affection of the tissues comprising the bone, but extensive thrombosis of the veins either inside or alongside the bone, with purulent degeneration of thrombi and the rapid onset of the symptoms of genuine pyemia. To be sure, patients may die of septic intoxication before sufficient time has elapsed to permit of the formation of secondary abscesses. Yet that death may result from a true pyemia is only too well known. Other septic infections may occur in less classical manner,— as, for instance, septic pneumonia, metastatic meningitis, pericarditis, nephritis, etc. In fact, the writer scarcely recalls any apparently spontaneous infectious process which can be followed by death from so many causes, or which is so beset by dangers if not promptly attacked, as this under consideration.

So far but little attention has been given to acute infectious periostitis. Its causes are essentially the same; so also its symptomology and its possible dangers. There is only this to be said, that, as a rule, these symptoms and disturbances are a little less severe than those caused by infection within the depths of the bone; in other respects it runs a similar course, although spontaneous escape of pus, being more easily permitted by accident of location, is more likely to occur.

One need never be surprised in connection with these cases, to find other disturbances, either adjacent or distant, which in the absence of clear pathological views are quite likely to be misinterpreted.

With regard to the rapidity, of course, characteristic of this disease, one must acknowledge that all grades are met with between those fouldroyant cases which pursue a fatal course within thirty-six hours from the first sign of the disease, to others which pursue a much milder course, which extend over several weeks, and finally make a partially spontaneous recovery at

the expense of sinus formation, extrusion of sequestra, periosteal thickening, functional impairment of joints, and perhaps chronic ill-health.

Just here the writer would like to mention two or three illustrative cases, which he will very briefly report.

One case was that of a young lady of about twenty-two, who seems to have been taken with an acute infectious periostitis involving all the main long bones of both lower extremities, which quickly followed exposure during menstruation and consequent cessation of the menstrual flow. There was acute sympathetic involvement of all the lower joints; and she was treated for a number of weeks for acute inflammatory rheumatism. When, two or three months later, she came into my hands, there were found extensive collections of pus; and it was necessary to make long incisions over each femur and over each tibia, the incisions being nearly twelve inches in length, extending down to the bone, which was found denuded, the overlying periosteum being separated by more or less pus with some loose, unhealthy, granulation tissue. Here the radical use of the sharp spoon, combined with packing and repeated dressings, extending over a long period of time, finally secured the readhesion of the altered periosteum to the bone, of which, fortunately, none had died. Her limbs were left crippled, however, and she came near yielding up her life as the result of a mistaken diagnosis.

A girl of fourteen was taken with acute symptoms of the above general character, referred to the upper end of the left femur. These followed over-exertion. She also was treated for acute rheumatism; but, her symptoms becoming rapidly worse, she was put on the cars to be sent to the Buffalo General Hospital for suitable treatment. When she left her home, her limbs were of the same length; when she reached our hospital, the left limb was two inches shorter than the right. Spontaneous separation of the upper epiphysis of the femur had occurred as the result of the journey, and it was only by an immediate and proper resection with removal of the sequestrum, that is, the head and neck of the femur, that her life was saved.

A little boy of ten, enjoying the first good skating of the season, exerted himself to an extreme degree, sat down upon the ice to rest, got home in pain and with commencing fever, became delirious that night, and suffered intensely for a number of days with agonizing pain in one leg, which he would not allow to be touched or moved. He, too, was treated for acute rheumatism, although swelling and edema rapidly took place, with a tenderness disproportionate even to acute rheumatism. His life was spared; but he was treated for rheumatism until several sinuses had formed, and until the lower end of the shaft of the tibia began to protrude through an opening made for its spontaneous extrusion. The homeopaths who had charge of him finally acknowledged their incompetency; and the case was carried a hundred miles to Buffalo for treatment. Only one long incision over the shin was required in order to lift out from its bed the tibial shaft, entirely loosened, bathed in offensive pus, and its exposed end blackened by exposure to the air.

These, of course, are extreme cases; and yet I could make out a list of at least a score of them which have come under my own personal observation. The majority of these cases are met with in the lower extremity. Perfectly analogous or parallel cases, however, could be quoted in which the upper extremity was involved. In 141 cases, collected by Helferich, the tibia was involved in 66, the femur in 45, the humerus in 20, the radius in 6, the fibula in 4. This is a proportion which will be not widely departed from in the experience of those who have seen much of this disease.

It will be quite proper to stop here for a moment to speak of a similar infectious process involving the short and spongy bones, like those of the cranium, the tarsus and the carpus. While, to be sure, the affection is much rarer in these localities, it may pursue essentially the same course, as result of which we have periosteal separation, as well as speedy yielding and loosening of the ligaments which bind these small bones together, extensive swelling, edema, and later fluctuation overlying the affected area, while clinically the symptoms above mentioned will be repeated, varying only according to the part involved. There seems to be less tendency to pyemic disturbances or to wide dissemination of infectious products in these cases. In consequence, we hear much less of death in these instances. Locally, however, they may be equally destructive. These are the cases usually regarded as acute caries; but it is well to insist that their etiology is practically the same.

Cases of this general character which pursue a mild course are frequently the unknown causes, or at least the unrecognized causes of deformities which come later into the hands of orthopedists or of general surgeons for rectification. Subluxations, complete dislocations, deformity due to apparently spontaneous fracture — these are among the conditions met with, for which only clear pathological knowledge can afford an explanation. The so-called distention luxations are naturally spontaneous, and are in effect to be always explained by some process of this general character. These are met with particularly at the hip and at the shoulder. Another form of similar deformity is produced by first a loosening, later a regeneration along epiphyseal lines, as the result of which we have deformity simulating subluxation. Roser has described also another variety of luxation, permitted by an overgrowth of the restraining ligaments, which appears to be permitted by a protracted hyperemia due to active disease, as the result of which these ligaments become relaxed or elongated, with resulting condition much resembling that of an inflamed joint. Deformity is also produced by persistence of muscle cramp or contractures due to the violence of the acute disease. If these be allowed to remain too long unattended to, there will be fixation, also with more or less subluxation. Most serious joint deformity may be produced in this way. Again, by atrophy of certain groups of muscles, corresponding to the areas externally affected, there may be produced, at least, change in shape, with more or less loss of function and persisting deformity. Finally, deformity may be produced in still another way, by those actual disturbances of the growth of bones which may lead either to that form of atrophic elongation first described by Ollier, to which I have elsewhere devoted some attention, or to an absolute arrest of development by which a relative shortening of limb is produced.

One should perhaps stop here to rehearse some of the unusual or accidental incidents met with in some of these cases. We may have, for instance, subperios-

teal hemorrhages in the vicinity of the epiphyses, with perhaps complete detachment of the membrane. Just whence the hemorrhage comes is difficult to say, although the epiphyseal tissue itself may be intensely vascularized. Again, the periosteum may appear very differently along different areas of the same and involved bone. One may see it intensely congested at one place, and quite blanched or anemic at another. So one may find quite limited or small subperiosteal collections of pus; and it is worth knowing, that these may be distinct or multiple, and that to open a single collection does not necessarily imply that the entire trouble is thus relieved.

Along with the osteoperiosteal congestions, particularly the peri-epiphyseal or epiphyseal, one may observe also striking lesions among the neighboring muscles. Sometimes these are so circumscribed as not to be easily recognized. They may be even limited apparently to a comparatively small group of muscle fibres; they may consist of white points, or form white lines extending through the muscle tissue. Frequently the white points will be found to be minute collections of pus, but not invariably so. Sometimes the white lines represent linear abscesses, as though the path of infection had been limited to a given bundle of muscle fibres. Perhaps these signs are seen more often in the tibialis anticus and in the biceps of the thigh than in the other muscles. These muscular lesions appear at times to be something else than purulent degenerations. Such spots may even be found in the heart muscle in fatal cases, in which case the ventricular portions are those most involved. Here the condition is one rather of an acute myocarditis in limited patches. When these places are examined histologically, it will be found that we have to deal with an interstitial inflammation, extending sometimes into a genuine suppuration, sometimes stopping short with tissue necrosis.

In the liver and the kidneys, miliary disseminated white patches are often found. The lungs are seldom primarily involved; they may show hemorrhages, or conditions of that character.

Still another rare event, but one several times noted, to which allusion has been made especially by Gangolphe and Devars is the possibility of epitheliomatous degeneration of the fistulous passages remaining after spontaneous evacuation of some of these collections of pus. The cancerous process seems to begin at the external opening, and to extend slowly down toward the medullary depths.[4]

[4] The malignant degeneration of osteomyelitic foci has been recently quite elaborately dealt with by Devars (De la Dégénérescence Cancroïdale des Anciens Foyers Ostéomyélitiques, Thèse de Lyon, 1894), who reaches, briefly, the following conclusions:

The fistulæ persisting after osteomyelitic attacks are occasionally the site of malignant degeneration, the epitheliomatous being the most common of all the forms. This seems to be, perhaps, another expression of the well-known fact that old ulcers and cicatrices take on the same kind of degeneration, the form under consideration being either an internal extension or manifestation of the same lesion. These foci do not appear equally susceptible, nor to the same degree. Old tubercular granulations give place to papilliform vegetations, which are frequently difficult to separate — at least on first appearance — from the lesions of an epitheliomatous ulcer. Malignant degeneration occurs not infrequently in the cavities containing sequestra, which are also emptied by persistent fistulæ. Devars has collected 39 cases of intraosseous epithelioma, most of the patients being in the middle years of life when attacked.

These epitheliomata appear sometimes as primary lesions, sometimes as secondary; in other words, they quickly succeed to the original trouble, or they develop by slow processes, as in the old ulcer. They develop always slowly, and may produce lesions quite concealed from external view. Secretions from these sources have usually a peculiar fetid odor, which to those familiar with it may even be diagnostic. As in all malignant neoplasms, the course of the disease is unfavorable. Nevertheless, the prognosis is not so bad in and of itself, so far as life is concerned, although it necessitates the ablation of the limb. If, on the other hand, some bone of the trunk be involved, the prognosis is bad in every respect. In most of the cases the neighboring lymph nodes are involved. If not soon treated after this has occurred, prognosis is naturally worse.

Treatment must be thoroughly radical, amputation, if possible, being the only resource; and Devars has found a fair percentage of his recorded cases apparently cured by this measure. The entire thesis is well worthy of study.

Gangolphe has also called attention to the horrible fetid character of the discharge from some of these cases, which persists in spite of irrigation and of all but the most radical measures. Although this has not yet been worked out bacteriologically, it is probable that this fetor is due to the activity of some extraneous organism belonging to the class of saprophytes.

Another phenomenon noted in some of these cases has been a peculiar eruption such as we see during other infectious diseases — an evident manifestation of septic poisoning, consisting usually of wine-red plaques, sometimes raised above the surface as in urticaria. These points are not painful; they disappear under pressure, and run a very variable course. It was in 1858 that Guebler first called attention to the existence of these eruptions, which have since been studied by many investigators. In October of 1892 Bouchard announced to the Académie de Médecine the existence in cultures of the microbes which often cause these conditions, of two toxines, which he called "ectasine" and "anectasine," by reason of their peculiar vasomotor action. The first promotes vascular dilatation and diapedesis; the second paralyses the vasomotor dilators. Curiously, these two substances, of such contrary effects, seem to be produced by one and the same microbe, namely, the bacillus pyocyaneus. It is known also, as Arloing has shown, that the filtered cultures of the staphylococci contain a toxine which is a vaso-motor excitant. Gangolphe holds that the peculiar eruptions seen in some of these instances are particularly due to the effects of these particular toxines.

I have not yet mentioned fat embolism as one of the complications of the fulminating forms of these bone infections. The possibility of its occurrence, however, must not be forgotten; it is not frequent, but its gravity is extreme when it occurs. The first evidences of occurrence of fat embolism will probably be met with in the lungs, in the shape of rapid and embarrassed respiration. Lannelongue has insisted on certain other pleuro-pulmonary complications occurring usually during the third or fourth day of this disease, it being possible to have a unilateral (even a bilateral) pneumonia complicated possibly with adhesions; running an atypical course; frequently, but not necessarily, fatal; of short duration; not materially influenced by ordinary methods of treatment.

Albuminuria is also a not infrequent complication, while effusions in the pericardial or pleural sac occur sometimes without any warning whatever.

One of the most striking phenomena in connection with this disease pertains to the recurring character of certain cases. There is every evidence, both experimental and clinical, now at hand to prove that, particularly in the bones or beneath the periosteum, is it possible for collections of micro-organisms to lie latent or dormant for more or less long periods of time, their activity being re-awakened by accident, or by coincident infection, or by that lowering of vital resistance which is so often seen in connection with wasting disease or starvation; and there are clinical cases on record to prove that there have been concealed in the bone for twenty years such collections of organisms,

which retain their virulence but hold it in a latent form. We have little to compare with this except the known properties of tubercle bacilli; and I know of no other disease in which this outbreak is anywhere nearly so striking as in the cases here alluded to. I have repeatedly seen instances which amply convinced me of such possibility. For instance, they give a history such as this: A young lad goes through an attack of acute osteomyelitis of the tibia. The disease often, if early recognized and operated on, apparently subsides; the limb heals with considerable scar, and everything goes well for years, until during an attack of scarlet fever, or typhoid, or after a fracture or some other untoward event, the old bone area becomes again sore, a fresh bone abscess is formed, and perhaps requires a repetition of the previous operation. Or, if this does not occur at exactly the site of the previous trouble, it occurs in the same bone within a short distance. I have at this moment in mind a young woman upon whom I have four times operated within a few years for this trouble, breaking out each time in a different portion of the left tibia, whose leg when I first saw her was already extensively scarred with the results of previous similar manifestations. This does not depend upon my evidence alone, but has been spoken of independently by several different writers. I have no explanation to offer for it, but desire to insist upon the clinical recognition of the fact.

It may seem somewhat at variance with the generally received ideas of the activity of micro-organisms which can produce such virulent disease, to think that these activities may be so long held in abeyance in certain instances. For the argument of diminished virulence of bacteria, we have as yet no satisfactory explanation; but there is nothing stranger about their capability of retaining the power of life and growth for years inside the human body, than there is in the fact that grain from the ancient Egyptian burying places should retain its power of growth when planted to-day.

### SPECIAL FORMS.

Let us pass now from general considerations to a hurried consideration of two or three distinct or special forms. It is well worth our while to ask whether the different organisms which may produce this disease may call forth any such distinctive features, clinically or pathologically, that one may recognize their individual presence; in other words, whether special features may be assigned to distinct organisms. We are not yet in position to answer this elaborately, and yet certain things we may affirm. For instance, those cases of acute bone infections which occur during puerperal fever, or in conjunction with erysipelas in other parts of the body, are in almost all instances due to the streptococcus. The forms which are due to the pneumococcus are distinguished rather by a predominance of joint complications and by a lesser tendency to subperiosteal abscesses or to sequestrum formation; while clinically their course is more rapid, their symptoms more acute, and, when recovery follows, their duration is relatively short, while they show a prompt tendency to cicatrization and repair. This form may occur not alone during the course of a pneumonia, but even without pneumonia and without traumatism, as a manifestation of primary infection. The forms due to, in whole or in part, the presence of the bacillus pyocyaneus are more likely to show the peculiar eruption already spoken of, while the odor from the discharge of these cases is usually pre-eminently unpleasant. Of the staphylococcus forms, or those mixed with streptococci, it is hard to state anything very definite. The staphylococcus aureus seems to be the organism at fault in the most rapid and malignant cases. Nevertheless, they may be found in the milder, although here usually with some other forms in combination. It would seem that in the post-febrile cases — for example, those following typhoid or scarlatina — we are more likely to meet with the streptococci alone or in relative abundance.

I may add to this statement another, that whereas in 1883 Rodet described an organism of osteomyelitis which was for three or four years separated and given an identity of its own, we now know that this was an error, and that the organisms which he found were simply those now recognized as so common, namely, the staphylococci.

Of the cases following typhoid, variola or diphtheria, I have nothing to say in particular, save that they do not necessarily go on to destructive suppuration. Multiple periostitis with considerable thickening is one of the rare complications of typhoid. One such case I recall in my own practice: Some years ago a young lad had nearly convalesced from his typhoid fever, when he was taken with symptoms to which I was at that time at first a stranger. These proved to be evidences of most painful inflammation of the periosteum covering the long bones of both lower extremities, extending upward, apparently by continuity of tissue, over the pelvis, and even up onto the lumbar vertebra. A more appealing picture of distress or of anxiety lest somebody should rudely jar his bed, or step heavily in the room, I have never seen and cannot imagine. This was my first introduction, years ago, to the surgical complications of these continued fevers, since which I have, of course, seen many illustrations. His periosteal complications ran a somewhat prolonged course without even a sign of the presence of pus, and his tenderness slowly subsided until, finally, he was able to use his limbs again. This will be the probable general course of certain cases occurring during these continued fevers and exanthemes, and I need scarcely say more about them.

The one particular form which I wish to describe, in addition to what has been already said, is that which finds description, or even allusion, in very few works, or even careful monographs and general articles. It is a form to which my attention was first called by the writings of Kiener and Poulet, and should be known as "acute tubercular osteomyelitis." It might also be called "acute tubercular panostitis." It corresponds to the ordinary forms of tubercular ostitis as do the most rapid and destructive miliary forms of pulmonary tuberculosis to the ordinary cases of consumption. There is no doubt but what the entire bone marrow, and, in fact, the entire integrity of one or more bones may be destroyed as rapidly as that of the lungs. It is a type of disease which runs a most acute clinical course, though never fulminating, which is equally destructive but less painful, in which there are perhaps more external disturbances with less tenderness than in the ordinary suppurative forms of this disease. The periosteum is likely to be more thickened, and we are quite likely to have more edema and swelling of the entire limb. Some years ago I had to amputate at the shoulder-joint an arm, all of whose bones were in-

volved in the most acute thinkable process of this kind. Why the condition did not disseminate I do not pretend to explain; but I would say that with the removal of the upper extremity, the patient quickly recovered and regained his usual health. On dividing the bones, one had in this specimen the most beautiful and typical picture of acute miliary tuberculosis of the bone marrow and the spongy-bone structure. I take particular pains to bring this form before you, because I know that it has received very insufficient description, and I am anxious that the possibility of this rare condition should be borne in mind.

### DIAGNOSIS.

I need say but little in regard to the diagnosis of this type of disease in addition to what has been already said. I have deliberately reported a number of cases mistaken in the early stages, or until too late, for rheumatism. In my experience, the average general practitioner nearly always makes this mistake; and it is particularly to warn him against it that I would disseminate such information as is contained in this paper. To the best of my knowledge and belief, rheumatic conditions never suppurate. In nearly all of the cases to which I have called your attention, suppuration occurs early, sometimes very promptly; and by this means alone it would seem as if error in diagnosis could be avoided. It scarcely seems necessary to go into an elaborate differentiation between the two conditions because I am confident that this mistake has so often occurred simply from ignorance of the fact that we have such a condition as infectious osteomyelitis of acute type, and I do not wish to take up your time.

### TREATMENT.

There is but little to be said concerning treatment, but it needs to be emphasized with all the power possible. We have in these forms of disease acute infections whose tendency is toward tissue destruction and suppuration within deep and pent-up cavities. The intense and agonizing pain which characterizes most of them is caused by the fact that this excitement is going on in spaces enclosed by rigid walls, while the generally grave nature, the sometimes overwhelming typhoidal character of the symptoms is due to the intensity of the process, the extreme toxicity of the bacterial products — in other words, to the intensity of the auto-infection; and the frequently grave and often fatal complications are due to the anatomical relations of the veins and lymphatics coursing through and alongside of the bones. With all the emphasis that I can bestow, I want to urge that the treatment of these cases be essentially surgical and promptly so. Remember that death has been known to occur within thirty-six hours from the first unpleasant symptom, and remember that this might have been avoidable had operation been performed within the first twelve hours. What now is necessary? Anesthesia, and incision with a firm hand, not merely through the skin, but to the bone, and by all means through the periosteum. These incisions can usually be made at such points of election as shall cause a minimum of disturbance to other important structures; but it may be necessary to expose the shaft of the tibia, for instance, from one end to the other by an incision extending from knee to ankle, which shall freely expose the bone proper; and if here ample explanation be not afforded for the intensity of the symptoms and pain — explanation in the shape of exudate, of pus, or of infectious products — then the bone itself must be opened with the same freedom and the same purpose in view. These are cases where, after exposing the bone, it is perfectly justifiable to use a large bone drill to perforate at different points into the marrow cavity, as one would introduce the hypodermic needle into the soft parts, searching for pus. The thickening that may occur even within a few days will sometimes be astonishing. One need never hesitate to go with a sterilized drill into the depths of every accessible bone. So soon as anything but healthy bone marrow be revealed by these punctures, the chisel should be substituted for the drill, and the medullary cavity should be widely and mercilessly exposed. Ordinarily pus will be forced out through the drill opening even before the withdrawal of the instrument. With this guide, the chisel should be used until every pocket of pus has been widely opened and until sharp spoons and irrigator nozzles can be introduced freely, so that the parts can be absolutely cleansed from all pent-up suppurative products. It may possibly be enough to open the medullary cavity of a long bone near its upper epiphysis, and then near its lower; and then to draw through this instruments or plugs by which it can be thoroughly cleaned out. But, when once the patient is anesthetized and this procedure has been begun, the surgeon should never stop until he has completely evacuated every particle of infectious matter. The same is true of parosteal abscesses. One who is not familiar with these cases can scarcely conceive of the relief to pain which is hereby afforded, nor of the conversion which is so speedily effected of a grave septic case into one of mere extensive and open incision, but with the parts so exposed that there can no longer be any possibility of retention of pus or resorption of poisonous products. The cavities thus made are left widely open, it being much safer to allow them to heal by granulation than to attempt to close them prematurely. Extensive scars result from such radical operation; but not only are lives thereby saved, but limbs in more or less shapeliness, and joints in completeness of function, which would otherwise be lost — hopelessly lost.

Note. — The interested reader is referred especially to the monographs of Ullmann, "Beitrige zur Lehre der Osteomyelitis Acuta" (Wien, 1891), with its admirable bibliography; and Jangolphe, "Maladies infectieuses et parasitaires des Os" (Paris, 1894); also to an article by Garré, "Einige seltene Erscheinungsformen der akuten infektiosen Osteomyelitis," in Kocher's *Jubiläum Festschrift*, 1891, p. 43.

## A SELF-RETAINING DRAINAGE CANULA FOR PREVENTING SCAR IN CERVICAL ABSCESS.[1]

BY F. M. BRIGGS, M.D.,
*Surgeon to the Boston Dispensary.*

In the treatment of abscess of the neck, the avoidance of resultant scar is of great importance to the individual. While a scar in other parts can be disregarded, the exposure of the neck to constant inspection, and the undue prominence here of any appreciable scar, gives an additional consideration; for we have to consider not only the question of effecting a cure, but also that of leaving the least possible scar as a result.

Two years ago, the writer [2] reported three cases of

[1] Shown with five cases at the meeting of the Boston Society for Medical Improvement, February 4, 1895.

[2] Boston Medical and Surgical Journal, January 17, 1893, p. 34.

large cervical abscess treated by making the cut from one-fourth to three-eighths of an inch in length. The result was a cure with a little scar in two cases, and three small round cicatrices in one case. This latter was an extensive, suppurating cervical adenitis, extending from the ear to the clavicle, on one side, in an otherwise healthy male adult. Three short cuts were made at various times, as necessary. At one period of the case the neck was full of branching sinuses, which were treated by a method which will be spoken of later. After a tedious treatment of over three months, healing finally took place, and the man now has three imperceptible scars. He has been, and is, in fine physical condition.

Since the above report I have followed out the same treatment in similar cases. The results have been good, but there has been one defect in the method. In most cases the skin heals, but the abscess cavity does not. The cavity refills (usually with a serous fluid), and frequent reopening of the cut may be necessary before healing finally takes place. This has been a serious objection, for healing is delayed by the constant refilling of the abscess, and the patient naturally objects to a, perhaps, daily cutting.

As scar is limited to the cut through the skin, it follows that the shorter the cut the smaller the scar. Where skin unites by first intention, it not infrequently shows a slight line of cicatricial tissue; where it heals by granulation the amount of cicatrix is often large, and where, as is sometimes the case, the cicatrix hypertrophies and we have the keloidal scar, the disfigurement may be very decided.

If, in treating an abscess, a cut is made dividing the whole, or nearly the whole of the inflamed area, the contents evacuated and the cavity packed, we are doing all that can be done to bring about healing by granulation, and are doing just that which *will* leave a scar. The treatment of abscess is a question of drainage; and the reason why a long cut is effective is because it gives free drainage. If drainage is the only consideration, such treatment is unquestionable; but if the resultant scar is to be considered, it is bad treatment. When we see, as we do, necks covered with old cicatrices, some depressed, some bunched in keloid, usually of a different color from the rest of the skin and always a disfigurement to the individual, certainly any treatment which cures the condition and which prevents such a result is very much to be preferred.

Aspiration and setons are two methods which have been used with the object of avoiding scar. Having had no personal experience with either of them, I can only say, on general principles, that aspiration drains at once, but does not give subsequent drainage, and that in many cases this is essential before healing can take place; that a seton drains partially, but that the drainage cannot be as free as is often necessary; and that both of these methods consider only one point — the scar — but do not dispose of the other, the very important question of drainage.

I have recently had Messrs. Leach & Greene of this city make a little instrument which covers both of these points satisfactorily. This is a self-retaining drainage canula and is as shown in Figures 1 and 2. It consists of two surfaces of silver, curved laterally, bent outward, and jointed at the angle. The cut through the skin being made (one-eighth of an inch), the knife is pushed into the abscess. Upon its withdrawal the canula is inserted, as in Fig. 1. When the joint is reached the external arms are closed. This reverses it. The internal arms open, dilating the tissues in the vicinity of the cut and retaining the canula within the cavity, while the external arms come together and make a tube (Fig. 2). A projection at the end of each external arm prevents it from falling into the abscess cavity, and it is fixed *in situ*. It is removed by seizing one of the external arms and withdrawing it until the hinge is reached, when, by spreading, it is again as in Fig. 1, and easily slides out.

FIG. 1.

FIG. 2.

The canula can be cleaned and sterilized, and gives free, continuous, and, if necessary, permanent drainage through a skin cut of barely one-eighth of an inch. It reduces the cut to an undoubted minimum, gives surgical drainage, and leaves the least possible resultant scar.

Of the following thirteen cases, all but two, were treated at the Boston Dispensary during my recent service there.

| No. | Diagnosis. | Location. | Canula Inserted. | Canula Removed. | Canula Reinserted | Time in Healing. | Age. | Remarks. |

* By patient — see notes of case.

From these cases it will be seen that abscess of a single gland, and simple, non-glandular abscess healed in one week or less. (Case 8, which disappeared after the canula was removed, undoubtedly healed in a few days, for the abscess was progressing as favorably as any of the others at the last visit.)

Case 3, whose photographs showing the appearance before and after treatment are here given, had, as will be seen, a multiple glandular abscess involving the front of the neck. The whole cavity was emptied and drained through one canula, inserted at D, and healing followed in ten days, leaving a slight inflammatory hardness, surrounding and defining the limits of the original triple-walled cavity. This slowly disappeared, and a second photograph taken two months later shows his present conditon. There is no scar. Knowing where the canula was inserted, I can detect, by the most careful inspection, a very minute white line; but no one, who did not know the point of insertion, could distinguish it from the trifling blemishes which the patient has on other parts of his face and neck.

Abscess before evacuation

Same case two months later.

I have encountered the greatest difficulty in the multiple glandular inflammations, where the glands are only partially broken down. In the treatment of such cases there is a very important question for consideration, namely: Should these glandular masses be thoroughly excised at once, or is the surgeon justified in waiting?

The writer hopes to discuss this question in a later communication; but it is beyond the scope of the present paper to do more than refer to it, and to give the clinical history of five such cases treated upon the theory that immediate excision is not necessary. These are Cases 1, 6, 7 and 11, and the case already referred to as reported two years ago.

This latter was a case of gradual, extensive breaking down of both superficial and deep glands on one side of the neck in an otherwise healthy individual. I allowed the process to take its course, making short incisions when indicated, and effected a cure with no scarring. This man has been perfectly healthy since, and there is no reason to think that he will not continue so.

Case 1 of the above table was similar, but not so extensive. Three superficial glands and some of the deep ones were involved. The total inflamed area was about two and a half inches in diameter. As this case is illustrative of the various points to be considered, I will describe it in detail.

The patient, female, age twenty-five, married, and the mother of one healthy baby, presented herself at the Boston Dispensary, December 7, 1894, with a large inflamed glandular mass on the left side of the neck, over, in front of, and behind the sterno-cleido muscle. She had first noticed it about three weeks previously. December 14th pus was present in quantity, and a canula was inserted at the thinnest point. It was removed December 17th, and from that time on for fourteen weeks there was the same tedious treatment that I think must be necessary in all similar cases treated by this method. The cavity closed down to a deep sinus, which discharged a small quantity of pus daily, and which showed no tendency to heal.

January 16th. Pus had formed at another point about one and a half inches distant from the first incision. I inserted a canula, and at the same time reinserted a canula in the original opening.

January 19th. Both canulas were removed. The second cavity slowly closed down to a sinus which connected with the first by a deep and tortuous tract. The connection was shown by injecting corrosive solution; when thrown into one opening, it came out of the other. The probe went in for about two inches, but could not be made to follow round through the connecting passage. The sinus ran well under the sterno-cleido mastoid.

February 7th. I treated the sinuses by the same method that I had previously used and with equal success. It consists in rapid but gradual dilatation with olive-pointed urethral bougies, curetting the sinus thoroughly, and giving injections later. I started with a No. 11 bougie and went up, one after the other, to No. 15. This went through with considerable pressure. I then introduced a small, sharp curette and scraped the lining walls on all sides. Iodoform and oil was injected.

February 9th. Tincture of iodine was injected into each sinus. This was followed by a sharp inflammation and profuse suppuration, but it had the desired effect. There was a free discharge of pus for about seven days, which then gradually diminished.

February 25th. Another abscess had formed lower down on the neck. It was superficial and healed very quickly. The canula was left in for three days.

The case showed final healing, that is to say, complete closure of sinuses, some fourteen weeks after the first canula was inserted.

April 7th. The patient reported for inspection. There were two, small, depressed, scarcely noticeable scars, which I think will be almost invisible in a few months.

Case 6 disappeared at the end of five weeks, not cured. This was a case of a small mass of partially broken-down glands, back of the sterno-cleido. At the last visit there was a deep sinus.

Case 7, a child, age one year, had both sides of the neck entirely filled with inflamed glands. I first saw her February 5th, when the glands on the left side were wholly broken down; those on the right side partially so. Two canulas were inserted on the left side and one on the right side. They were removed three days later. Healing occurred in ten days on the left side, but it was three weeks before the right side was in normal condition.

Case 11 is still under treatment. This was a mass of partly broken-down glands under the right ear. A canula was inserted February 28th, and was pulled out on the dressing, by the patient herself, the following day. It was pulled out with the inner arms open, and the cut was torn to three-eighths of an inch. There was very little subsequent suppuration, and the glands instead of showing abscess formation have been slowly disappearing. There is a sinus about one inch in depth. It may be that in this case a radical operation will be necessary later on, and that the glands will have to be cut out; but before doing this I shall give the patient at least eight weeks more. I think, however, that the adenitis will disappear spontaneously, or that further suppuration will occur, and allow of the insertion of another canula. At present, absorption is evidently going on. The swelling has diminished fully one-half in size, and the patient is in good physical condition. The final result will be reported in any event.

Before concluding, I wish to call special attention to the following details:

(1) The knife should be narrow-bladed (not over an eighth of an inch broad), and very sharp at the point. It should be pushed through the skin, well into the abscess and an even cut made; that is to say, the internal opening should be the same size as the external. The canula should be inserted as soon as the knife is withdrawn.

(2) The abscess cavity should be emptied at once by slow, firm compression. This is said to be bad surgery. I have yet to see a bad result from it. The immediate emptying of the cavity places the walls in the best condition for rapid healing, and subsequent distention is prevented by the free drainage afforded by the canula.

(3) As a rule, I do not syringe. This is indicated in only three conditions: (*a*) Where the cavity needs sterilizing. (*b*) Where solid *débris* is present and will not come out. (Both of which are uncommon in my experience.) (*c*) Where a sluggish healing process calls for a stimulus or an irritant. This comes at a later period of the case.

For sterilizing and for washing out *débris* I use corrosive (1 to 2,000 or 1 to 4,000) or creolin (one or two per cent.). For a stimulus, iodoform and oil; and for an irritant, tincture of iodine.

(4) The dressing should be moist sterilized gauze, and in applying it, the bandage should be carried around the forehead by a number of turns, as well as around the neck. If carried around the neck alone, the dressing moves with every motion of the head, rubs over the canula and causes much irritation of the cut.

(5) In removing the dressing the very greatest care should be taken that it does not stick to the canula; for the skin is tender, and if the canula is adhering to the gauze, it can be easily pulled out with the inner arms open, tearing the skin, and enlarging the resultant scar.

As a rule, the canula should be left in three days, but I have taken it out in twenty-four and in forty-eight hours. It may have to stay in more than three days. It is impossible to lay down an invariable rule on this point. The principle of the treatment depends upon free, continuous drainage, and the canula should be taken out when it is evident that this is no longer necessary. This decision lies wholly with the surgeon. Any one who is familiar with these cases can tell at a glance whether further drainage is needed, or whether healing ought to take place if the cavity is left to itself.

Persistent sinus should be treated as already described.

In conclusion, where the case is a multiple, partially broken-down, glandular inflammation, the patient should understand clearly at the outset that the treatment may extend over a period of many weeks, and that a radical operation may be the final outcome. But from the results which I have obtained in such cases, I think that in any similar case the patient can be assured that there is good reason to expect a favorable result, and that if this does occur the neck will not be disfigured.

In cases where full suppuration is already established, in both glandular and non-glandular abscess, the result is very satisfactory. It is remarkable to see the inflammatory process subside in a few hours under the constant drainage, and to see a, perhaps, very large abscess entirely healed in one week. It is even more satisfactory to see the same case a few weeks later and to try to find the point where the canula was inserted.

A Medical Appointment for a Woman. — A woman doctor, Madame Touransin, has been appointed Medical Officer to the Lycée Fénélon, in the place of the late Dr. Dujardin-Beaumetz.

## A TEST OF THE ACCURACY OF CLINICAL MEASUREMENTS OF THE LENGTH OF THE LEGS.

BY THOMAS DWIGHT, M.D.,
*Parkman Professor of Anatomy at Harvard University.*

To take accurate measurements on the living with a tape-measure is admittedly difficult. What is worse is the uncertainty as to how great an error is likely to occur even when considerable care is exercised. This doubt is annoying in surgery and in medico-legal medicine. The fact that the legs, which most frequently come into question, are often of different lengths, complicates the matter. It is to be understood that I am speaking of clinical, not of anthropological measurements. As for obvious reasons it is not practicable, even *post mortem*, to institute a series of tests of the accuracy of measurements by disarticulating the legs and remeasuring them, we have to resort to some roundabout method.

In my researches in the dissecting-room of which the results were given in the Shattuck Lecture,[1] I measured before dissection the length of the legs in two ways. First, from the top of the great trochanter to the ground, and, second, from the anterior superior spine of the ilium to the internal malleolus. The former may seem the best guide to the length of the leg but it presents such great difficulties in execution that I consider the other more trustworthy and have relied on it alone in the following tests. It may not be amiss to mention a point of technique in finding the starting-point. If one feels without method for the prominence supposed to be caused by the anterior superior spine of the ilium, it is very easy to mistake for it a part of the crest. The finger should be laid on the crest and carried forward till it has rounded the superior spine. As soon as this is passed, by pressing upward the finger easily recognizes a definite point.

After dissection I measured the greatest possible length of the femur and the length of the tibia, including the malleolus, but not the spine. The test which I now make public is to compare the differences between the combined lengths of both bones with the differences obtained before dissection. Let it be remembered that we are not now discussing the difference between the legs but are trying to determine the accuracy of the measurements made in the flesh. If we find, for instance, that the distance from the spine of the ilium to the inner malleolus is the same on both sides, and then after dissection find that the combined length of the right femur and tibia precisely equals that of the left ones, the presumption is strong that the original measurements were very accurate. The difference between the results I have called the error. Thus, if the first measurements show that the right leg is six millimetres longer than the left, and the bones show that it is only two millimetres longer, the error is four millimetres. If the first measurement shows that the right leg is six millimetres the longer, and the bones show that the left is the longer by two millimetres, I have added the differences together and called the error eight millimetres. I am not at all sure that in this last point the method is the proper one; but I have adopted it because, by making the error appear as large as it possibly can, it is the severest test of the accuracy of the original measurements.

[1] Boston Medical and Surgical Journal, 1894, vol. cxxxi, p. 73.

I have applied this test to 73 bodies with the results shown in the following table:

| Error, in mm. | Times. |
|---|---|
| 0 | 8 |
| 1 | 10 |
| 2 | 12 |
| 3 | 9 |
| 4 | 7 |
| 5 | 11 |
| 6 | 2 |
| 7 | 3 |
| 8 | 6 |
| 9 | 7 |
| 10 | 1 |
| 11 | 2 |
| 13 | 1 |
| 18 | 1 |
| | 73 |

The average error was almost half-way between four and five millimetres; but a better judgment is formed by analyzing the table. Thus it appears that 30 times (that is in 41 per cent. of the cases) the error was either absolutely *nil*, or less than three millimetres, which in such coarse work may be called a negligeable quantity. Only four times did the error exceed one centimetre. In the worst case, in which the error was 18 millimetres, the original measurement made the left leg one millimetre the longer, while the left bones were the longer by 19 millimetres. I cannot help thinking that by a blunder .1 was put in place of 1. in recording the original measurements; but, be that as it may, this method shows a greater accuracy in measurements made with a tape-measure before dissection than I, at least, was prepared for.

# Clinical Department.

## A CASE OF CASTRATION FOR HYPERTROPHIED PROSTATE.[1]

BY M. F. GAVIN, M.D.

This operation is still *sub judice*, and the history of this case, recently operated upon, may be of interest to the profession.

C. G., sixty-nine years old, a widower, entered Boston City Hospital, May 5, 1894, with the following history: Frequent and scalding micturition for five years, occasional pain over pubes, never any retention or dribbling. Examination by rectum showed a large, dense, symmetrically enlarged, smooth prostate, size of a large orange, occluding to considerable degree the rectum, the finger-tip reaching with difficulty the upper edge. The catheter was passed easily until the prostate was reached, which was surmounted with difficulty. The residual urine was five ounces, was acid and contained pus, some bladder cells, a trace of albumin, and very few renal elements. In five days the patient was discharged with directions to return to the hospital for catheterization weekly.

For four months the patient followed this treatment, but the symptoms increased rapidly, and constantly recurring pain made more frequent catheterization necessary, and he was taught the use of the catheter with poor success, the prostatic urethra being too difficult for the patient to pass the catheter through. He finally came to hospital with absolute retention which had existed for twenty-four hours, with great pain, distressing tenesmus, coated tongue, tremulousness, and prostration.

[1] This paper will appear in the Boston City Hospital Reports, Sixth Series.

A No. 9 Coudé catheter was passed with difficulty, and several ounces of cloudy urine withdrawn. Its specific gravity was 1.010, reaction alkaline and no albumin was present. Catheterization had to be performed every four hours, day and night, because of the irritable condition of the bladder, which was quieted by morphia. Pain was still a prominent symptom, and the patient was unable to pass water at all. This condition continued for nearly three weeks, when the urine was still cloudy, acid, 1.012, albumin a trace, and pus was found in the sediment. Castration was performed, and about eight hours after operation the patient had the first voluntary micturition for three weeks. Sixteen hours after the operation catheterization was needed. Voluntary micturition continued during the next day, and a second catheterization was demanded about forty hours after operation. From this time on no catheter was needed, morphia was omitted, and voluntary micturition, unattended by pain, continued. There was no more tenesmus or discomfort. At the end of a week the sutures were removed from the incisions, the wounds healing firmly. The prostate was then diminished markedly in size and consistency. The patient's nervous symptoms were quieter and disposition much more cheerful.

During the second week the patient was up and about the ward in clothes, passing his water during the day about every three or four hours, and three or four times a night. The force of the stream was increased. The character of the urine was unchanged except that there was a little less pus. The urine chart then showed a polyuria, as much as 120 ounces being passed in twenty-four hours, the average being about 98 drachms. Three weeks after the operation the prostate was diminished one-half, and in five weeks was only one-fifth of the size before operation. The patient was then discharged. The urine was then 70 ounces in twenty-four hours, acid, albumin a trace, pus much less in quantity, residual urine three ounces.

The patient reports from time to time at the hospital. He is grateful and enthusiastic, free from pain or discomfort, passes water every four hours during the day and two or three times at night. The residual amount is two to three ounces and is clear, specific gravity 1.010 to 1.014, albumin trace. Patient has gained thirty pounds since leaving the hospital. Prostate is now about one-sixth of the size before the operation.

This case has considerable interest in many ways; it goes to show that permanent benefit does follow the operation of castration for hypertrophy of the prostate. When contrasted with the many other operations that have been suggested, it has much to commend its use. It is rather repulsive to the average man to think of the loss of his testicles, but when we consider that this operation is only called for late in life, when the activity of those organs, to say the least, is on the wane, it must lose much of the repulsiveness that has been urged against this operation. The operation is a simple one and does not entail much risk to life. Of course it is only for a certain class of cases that this operation is called for — persons unable to follow out a systematic course of palliative treatment; where the passage of a catheter is attended with the loss of blood or great pain; where obliged to work and exposed to the changes in the weather, and where the liquor habit prevails.

The subject of this operation had tried the palliative treatment faithfully without any gain; in fact, he was losing flesh and strength. He was told of the different operations — perineal drainage, suprapubic cystotomy, prostatectomy, and castration — but was willing to allow us to use our better judgment. When we think of the suffering that follows hypertrophy of the prostate and how difficult it is to reach even to afford relief, living with a disorganized condition of the bladder and later the kidneys, any remedy ought to be gladly welcomed by the surgeon. I have been greatly impressed with this case and the result that followed the operation.

The suffering of a woman with advanced ovarian cystoma is no greater than that of a man with an enlarged prostate and its consequences, and if ovariotomy is done to relieve the one, why not castration for the latter?

## Reports of Societies.

### SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

CHARLES L. SCUDDER, M.D., SECRETARY.

REGULAR Meeting, Wednesday, March 6, 1895 DR. M. H. RICHARDSON in the chair.

DR. ROSWELL PARK, of Buffalo, read a paper on

#### THE ACUTE INFECTIOUS PROCESSES IN BONE.[1]

DR. J. C. WARREN: I am very much pleased that Dr. Park selected this subject for discussion this evening. I feel that the disease has not been understood by the general practitioner, and not only by the general practitioner, but a large number of surgeons have not and perhaps do not now appreciate the important bearing of this process on bone disease. Many of these cases, in fact the majority of them, are spoken of as necrosis, as if necrosis were a disease and not a sequel of disease, the process itself going unrecognized. The reason the general practitioner does not recognize the disease is because the teaching has been inadequate; and many of these bone affections have consequently been classified, as Dr. Park has already told you, with a number of acute types of disease. Many of them were fatal in their nature as bone typhoid, acute rheumatism, etc. They often run a rapidly fatal course, and I have no doubt many cases reported as blood-poisoning, typhoid fever, etc., were cases of acute osteomyelitis not recognized. On the other hand, the surgeon has not recognized the disease because he has not seen it in its early stages. I think it is remarkable to find how in a long hospital experience one comes to a realizing sense of the fact that one sees so few examples of acute osteomyelitis in its early stages, and the reason is because the doctors do not send the cases into the hospital for treatment. It is just as it was a few years ago in appendicitis. The hospital did not get these cases. It may be that we have an epidemic of appendicitis here, a larger number of cases than elsewhere; but this winter in the Massachusetts Hospital during my term of service there were something like forty cases of appendicitis in the hospital at one time. The general practitioner has begun to recognize the disease, and to send it promptly to the surgeon for treatment; and so I hope it will be eventually with acute osteomyelitis. If we can by

[1] See page 425 of the Journal.

such papers as Dr. Park has presented to-night enable the general practitioner to diagnosticate the disease, then we shall begin to see the disease in its early stage, and perhaps be able to rob future pathological museums of large collections of dead bone, etc., which adorn so many at the present time. I say it is rare for the surgeon to see these cases. I can only recall a comparatively few typical cases of acute osteomyelitis. I remember one which I saw in private practice, which I did picture for acute rheumatism, and for which I gave salicylate of soda. I might as well confess that I made just such a mistake as I deprecate in the general practitioner. A young man after going on a few days with symptoms of acute rheumatism broke out with suppuration in other joints, and died of septicemia in a very few days. An autopsy was refused; but I have no doubt in my mind that that was a case of multiple osteomyelitis terminating in septicemia or pyemia. I have seen two cases of acute osteomyelitis which were recurrent; one was in the space perhaps of about ten years, and the patient came in with the symptoms at the most typical part of the body, namely, the epiphyseal line of the femur, the patient groaning with pain all night. A large incision was made down to the periosteum which did not appear to be very much affected. An opening one and a half inches long by one inch in width was made; the bone chiselled out very freely. I was interested in the condition which I found in the interior of the bone at that time. There was no pus, but there was a dark, bloody, brownish-colored mass of softened cancellated bone, evidently tissue in a state of putrefaction from an acute septic process. This was curetted out and disinfected, as I thought at the time, thoroughly. The symptoms were relieved for the time being, but the disease reappeared. The temperature rose slowly; and finally a second operation was performed. I found then that the septic process was creeping slowly up the bone very much as in the carbuncular types of inflammation in the soft parts, foci of pus showing here and there.

That case eventually led to the so-called spontaneous fracture of the bone which Dr. Park has mentioned, and also had subsequently what I thought to be a secondary tuberculous infection of the tract. The patient through all this refused amputation, and finally came out victorious and has since been married. In another case I saw a return of the disease at the age of fifty, where there had been a history of acute osteomyelitis at the usual period, about twenty years of age. This case was diagnosticated as a case of neuritis by two very able physicians in its earlier stages; but as the swelling and inflammation in the thigh proceeded, it became evident that there was fluctuation, that an abscess was forming, and I was sent for. After inquiring into the case and finding a scar on the thigh low down in the customary place just above the knee-joint, I made the diagnosis of osteomyelitis. There was one especially interesting point in connection with that case. I made several free incisions, the patient refusing to take ether. The pus that was discharged was very foul indeed, of a grumous, brownish color. The shaft of the bone was as smooth and polished as marble and stood out in bold relief in the centre of this abscess. The patient was in poor condition, and as soon as the opening was made his condition became worse; and as I had predicted, he died in three or four days of acute septicemia.

The reference made by Dr. Park to the secondary tubercular infection of old pus-cavities is a very important one, and of especial value in point of view of treatment. These cavities, although the sequestrum has been discharged, do not in many cases tend to heal. With removal of the dead bone the cure has not been effected by any means. The bone is enlarged. A section through the bone shows a tortuous sinus with an ivory induration of the bone around it, and we have a bone fistula which remains perhaps for a life-time; although it may not cause any active suppuration it is a weak point, a nidus for infection. Tubercular infection, I think, is common; and many of the so-called cases of scrofulous bone disease are really complications of this original acute infective process. A large number of cases come to out-patient wards, particularly young children who are in that state of debility which makes them so fit subjects for this form of bacterial infection; many of these cases are looked upon as cases of acute suppurative synovitis or tubercular disease, white swelling of the joint, perhaps of more or less acute nature. Koplick and Van Arsdale have called attention to this type of disease, in many cases of which the abscess instead of involving the shaft of the bone, either breaks through the epiphyseal lines, or develops in the epiphysis primarily, on the epiphyseal side of the epiphyseal line, and in that way involves the joint. Of course, the joint may be involved in a typical case finally; but it is much less common, as you all know. So that in these cases we want to recognize an acute infectious process and the importance of perhaps not merely making an opening in the joint to let out the purulent serum, but to follow the point of suppuration up to its fountain source in the bone. Cases of multiple osteomyelitis have been recognized as a type of osteomyelitis by most writers and care has been taken to differentiate them from the metastatic abscesses which occur in pyemia. A broader view of these cases perhaps would be to classify them with pyemia, because a more minute examination shows that we have not only abscesses in different bones in the body, but we have the ulcerative endocarditis type of inflammation, which shows that other systems beside the osseous system have been involved in the disease; but there are certain typal cases which I think are as well expressed clinically by the name multiple osteomyelitis, or better explained in that way than by the name "pyemia," where we do not have the general infection of the system in a hap-hazard sort of way, and which ran a much less malignant course.

In regard to treatment I can only say when we have got a case of acute osteomyelitis of the virulent type it is just as grave a disease as appendicitis and ought to be treated as promptly; but we have not got quite to the point of looking upon it in that intense way which our young doctors and surgeons do appendicitis. I think the time is coming when it will be recognized, and when surgeons will consider it much as they now do cases of abdominal surgery. I hoped Dr. Park might say something about the treatment of necrosis, which is, of course, the part which we usually have to content ourselves with, and some of the methods of healing of large bone cavities which are formed as a result of the disease, and possibly give us some information as to his experience with decalcified bone, and what conclusions he has come to as to the best way of dealing with these sometimes large abscesses with tortuous sinuses boring in various directions, and, in fact,

forming a suppuration which is perhaps as difficult to disinfect as the Augean stables themselves.

Dr. E. H. Bradford: Dr. Park's paper deserves not only our welcome but our best thought; more so perhaps than the gentlemen here realize or Dr. Park himself. His work is that of a leader in the study of the pathology of bone, an investigation much needed. It will be admitted that at the end of the nineteenth century, although we have accumulated a great deal of knowledge as to the classification of diseases of the liver, kidneys and the larger organs, we know but little of diseases of the bones. The fact is, clinical observers have collected a greater amount of experience than the pathologists have been able to digest, and the busy practitioner has had too little time to devote to purely scientific research in this difficult branch of pathology. Investigations such as Dr. Park has brought to our attention are of the greatest value, not only for the interesting facts collected, but as a stimulus to further research. As he says, there are a great many questions that need to be answered. The whole matter of bacteriology demands study, especially as to the causative relation of germs to diseases of the bone. Is it true that osteomyelitis may appear shortly after typhoid fever, due to the bacillus of typhoid fever; and is it true that the same can happen after pneumonia? I can add one case to those referred to by Dr. Park, where acute osteomyelitis in the ankle followed pneumonia in a healthy boy, an interval of two years being dotted by a number of acute attacks of pain and swelling, culminating finally in complete destruction of the cuboid. There are other clinical facts which Dr. Park hardly had time to pay attention to, which present themselves for study. Why is it that acute osteomyelitis affects boys rather than girls? Why is it that it attacks between the years of ten and twenty more than later? and why does it attack by preference the lower end of the femur? These questions are all of importance, and we certainly owe Dr. Park all the thanks for bringing them so clearly before us.

Dr. Bradford showed a number of specimens of bones representing caries and osteomyelitis; also a specimen of sarcoma of the spine presented to the museum by Dr. Everett Flood, of Baldwinsville. The particular interest in this specimen is that, although the sarcoma had disorganized the cord and portions of the vertebral bodies, the intervertebral substances were swollen to an unusual extent, but apparently not involved by the sarcomatous process.

Dr. H. C. Ernst: I can add very little to the summary Dr. Park has given us of the etiology of this process, but it does not appear to me that it is quite so definitely settled as some suppose in a number of the points presented. One of them in particular is illustrated by what are spoken of as post-typhoidal abscesses in which the typhoid bacillus is found. It is quite possible, of course, that it may occur there; but this is only an illustration of the sort of process Dr. Bradford has just mentioned, the occurrence of acute osteomyelitis following an attack of pneumonia. The conclusion that because a bacterium occurs in a given situation it is therefore the cause of the process with which it is associated, seems to me to be entirely fallacious, and has in the past led to many erroneous conclusions, and will, I dare say, in the future if a serious protest is not entered to stop it. In the first place, we know in the laboratory nothing in regard to the bacillus of typhoid fever that induces us to believe that under any conditions it can be made to produce suppuration. Therefore, why should we believe that because it occurs in an abscess it has taken on an entirely new function? We forget that the methods of bacteriology are of the most imperfect kind, and we know that practically the whole of the modern science was started by the introduction by Koch of the solid nutrient media; and we may look forward to some advance of the same sort in the future in regard to the etiology of these various processes. In such an instance as this of the typhoid abscess we have neglected largely one of the broadest fields of investigation; and so far as I am aware in these processes no attempt has ever been made to study the occurrence of the anaerobic bacteria; whether in these processes there do not occur other varieties of bacteria which will develop under anaerobic conditions and whether they have something to do with the etiology rather than forcing ourselves to the conclusion that the typhoid bacillus has taken on a new function. A second point is that possibly the physicians will not in the future be obliged to send their cases to the surgeons constantly in these processes, because, as it would appear, very considerable advance has been made in the study of the toxines of the staphylococci and the streptococci that certainly are the most common etiological factors in the production of acute osteomyelitis, and the laboratory experiments give promise of the possibility of protection against or the arrest of attacks of this sort by therapeutic agents derived from the cultures rather than by surgical interference.

I have listened to the paper with the greatest possible pleasure, and I can only join in what Dr. Bradford has said in thanking Dr. Park.

Dr. R. H. Fitz: I may be allowed to say a word or two from the medical standpoint. It is obvious that physicians should bear in mind, after hearing such a paper, that, although the bones of the body are supposed to be especially the province of the surgeon, they may originate symptoms which apparently are remote and of more general character than concern the bones in particular. For many years the bone marrow has been looked upon as an important part of the blood-making apparatus closely allied, both in structure and function, to the lymphatic system. Its systematic examination shows that it, like the latter, quickly reacts to infectious agents, presenting a variety of consequent changes, not only those to which Dr. Park has referred, but degenerative changes also, attributable to milder degrees of infection. The physician should, therefore, appreciate that he may find anatomical changes localized in the bone marrow, although the symptoms may be conspicuously those of a pyemia or septicemia, with but ill-defined localizing symptoms — a very important consideration with reference to treatment.

Dr. Park referred particularly, in speaking of etiology, to the importance of the association of traumatism, or of local disturbances of nutrition with a general and perhaps a concealed source of infection. I remember many years ago that Dr. R. M. Hodges emphasized the frequency of osteomyelitis not only among young boys, but especially among very active young boys; in his experience cases being frequent in the summer among boys diving from wharves. Of course, this may represent merely a coincidence, but it is significant that the disease is not especially limited to those who are run down or subject to suppurative processes.

With reference to the relation to rheumatism. I have no doubt that Dr. Park will agree with me in considering that the terms acute rheumatism and osteomyelitis are to a certain extent indefinite, especially as regards the relation of results to causes, and that with the advance of our knowledge we may find that each term has been applied to the action of the same agent or agents, the one representing a milder, the other a severer result of infection. The search is constant for a more exact etiological classification, both for diagnosis and treatment; and, therefore, in behalf of the general practitioner I would say that at the time he may be thoroughly justified in calling his case acute rheumatism, appreciating that it is a mild degree of infection and need not feel called upon to seek the aid of the surgeon until the severity of the symptoms indicate that the integrity of the bone marrow is seriously threatened.

Dr. A. L. Mason: I should like to express the great pleasure with which I have listened to Dr. Park's paper, affording, as it does, so clear an explanation of the painful symptoms with which we sometimes meet toward the end of acute fevers, especially typhoid I should say, and in pseudo-rheumatism. The cases, however, which fall into the hands of physicians I think are not so many, because these bone symptoms do not arise until late in convalescence or even perhaps many months after the patient has had the acute infection which gives origin to the bone inflammation. I presume this also is the reason for the fact Dr. Park has alluded to, that in the text-books and works on fevers little mention is made of this subsequent condition. I am quite sure that in 1878, when periosteal inflammation following typhoid first came to my notice, very little was known about it as a sequence of fever. The case in point was one of prolonged typhoid with sub-periosteal suppuration. The patient was operated on by Dr. Hodges, by incision through the periosteum, and recovered without loss of bone. At that time the matter was entirely new to me and since then, until recently, there has been very little information relating to it in medical text-books. The point which Dr. Park has referred to with regard to the non-suppurative nature of rheumatism I think is an important one. Rheumatoid cases which have been admitted to the hospital and which have shown suppuration have seemed to me improperly classified as rheumatism, since suppuration probably never occurs in true rheumatism.

Dr. H. L. Burrell: The paper which Dr. Park has presented has interested me very much indeed, and many of the clinical pictures which he has presented I recognize. I should beg to protest against the position taken by Dr. Fitz as classifying acute rheumatism with acute osteomyelitis. Acute osteomyelitis, as I have seen it, is an imperative disease; if there is a word which expresses the pathological condition it is a jugulation of the bone, and unless the periosteum is slit up and tension relieved the bone is killed. It is a condition in which it is wrong to wait, and I am very glad that Dr. Park takes the ground that immediate operation is necessary. There is one question that I would like to ask Dr. Park. As I have met these cases — extremely ill, delirious, with very high temperatures — and have been called upon to operate, in making the extensive incisions that are necessary to expose the bone there comes a time when it becomes a question how much the patient will stand. In one instance where I was practically forced into an ablation of the whole shaft of the tibia, finding the periosteum stripped from the shaft of the bone and the bone lying bathed in pus, I lost the patient from shock. That has suggested to me that in these severe cases if we satisfied ourselves with simply draining at first and then did a secondary operation later when the patient was stronger, that perhaps we might save ourselves the disaster of an occasionally immediate death following the operation.

Dr. Park: I have been very much gratified at the discussion that has been evoked or provoked by the paper. I assure you that I read a paper here with no little diffidence, and I am glad to have found something which has been of interest to you. After all, as I think of what I have read, I want to assure you that the subject has been by no means fully covered. There is a great deal more that could be said which I could not say at such a time, and I regard this little essay as only an introduction to the subject of acute infections in bone. It carries one insensibly to similar troubles in and about joints which has been covered by Dr. Townsend of New York.

There are two or three matters upon which I would like to say a word. Why do boys have this trouble oftener than girls? And why particularly between the tenth and twentieth years of life? I have tried to impress that the predisposing causes, so far as externals are concerned, are fatigue and exposure; and these are two causes to which boys are more liable than girls, and boys between ten and twenty more liable than boys below ten years of age. Still I would like to cite an illustrative case occurring, this time, in a girl, but showing the influence of fatigue and exposure: A girl about fifteen years of age who lived at Niagara Falls went skating one day in winter, had no idea how far she went or how tired she was, but got so tired that she sat down upon the ice and cooled herself off in that way; after repeated exposure she got home lame and tired. The next day she was taken with all the signs and symptoms of acute osteomyelitis of the upper end of one femur. The case was treated at her home, part of the time under homeopathic, part of the time under regular auspices, always as acute rheumatism. After three and a half weeks she was so evidently in need of something more than had been done that the suggestion was to take her to the hospital in Buffalo. When she left her home the mother assured me the limbs were of the same length. When she reached Buffalo one limb was two inches shorter than the other. On resection of the hip, the joint end of the bone was found lying loose in a cavity which contained pus. There had been suppuration in that epiphysis. It shows how complete and how speedy this epiphyseal separation may be.

As illustrating also the effect of fatigue in predisposing to infections, there is the somewhat classic experiment which your bacteriologists could tell you about better than I can. Take the experiment with the ordinary domestic rat, which ordinarily is immune to anthrax. Put that animal in a cage with a turning-wheel and keep him working until he is tired out, and you can easily infect him with the germ. It shows the influence of fatigue and exhaustion in predisposing to bacterial infection. I think there is a lesson to be drawn from that in the liability to acute osteomyelitis (and to other infectious diseases) after exposure. The

germs may be in the system or near by where they can infect it, but are not likely to do so unless some one of these conditions obtain.

There is one condition on which I would like to speak which is still *sub judice;* we need more exact information about it. That is the very rare periostitis albuminosa, described by the French school of surgeons, regarded usually as merely a separation of the periosteum of the bone by albuminous or gelatinous material, for which in time past there has been no explanation; of which I have seen one or two cases and which some of the later pathologists suppose to be an expression of this same condition, save that the organisms have either been killed off or perished before the disease is attacked by the surgeon. There is opportunity for considerable research and study in settling a moot point concerning its etiology.

In regard to the treatment of necrosis, etc., the operation itself, of course, requires no consideration here, but I would like to say this about the treatment of the cavities. Nature makes an effort to extrude the sequestrum by provoking a formation of granulation tissue around it and at the ends, furnishes by ulceration an escape for a certain amount of discharge, granulation tissue replacing the bone and finally breaking down, usually by secondary infection, and thus forming the fistulous passages which permit often spontaneous escape of bone. Now the cavity in which the sequestrum lies is lined with this granulation tissue. It is provoked by the presence of this foreign body, this sequestrum. If the surgeon contents himself with cutting away enough bone to remove this, he takes away from that cavity, although he gives greater possibility for escape of discharge, the real exciting cause for further granulation by which it might be healed up. I think the thing for the surgeon to do is to introduce a desirable substitute for this sequestrum. I think the reason why so many of the cavities which we pack with gauze heal better is because the gauze packing serves as a stimulus and substitute for the sequestrum.

I think that many of these cases of necrosis are liable to the possibility of secondary tubercular infection. I am glad so good an authority as Dr. Warren agrees with me in that. It is a feature of the question which I think is not usually nor sufficiently noted in the books and general articles. At present I have a great deal of faith in guaiacol as an antidote to the tubercular process, and I am using packings composed for the most part of iodoform gauze or some such material, which is soaked in balsam of Peru to which is added about ten per cent. of guaiacol, perhaps with iodoform in addition to that.

Lastly, if you will permit me to so far digress as to pay a compliment: the subject with which I have dealt to-night is one I have long been forced to deal with as a teacher; and while I knew students needed that kind of knowledge, they could not get it in any standard text-book at that time. Not until recently has any adequate description of this condition crept into any English books. I am glad to say that in the new work which has just been issued by Dr. Warren, of this city, it finds adequate mention and description, and I think this is but one of the many valuable features which that book contains. I consider his monograph on "Surgical Pathology" a monument to himself and a very great credit to the profession in the community from which it emanated.

THE BOSTON

# Medical and Surgical Journal.

THURSDAY, MAY 2, 1895.

## THE THIRTEENTH CONGRESS OF INTERNAL MEDICINE.

Among the interesting papers read at the Thirteenth Congress of Internal Medicine just held at Munich, April 2–5, 1895, was one by Heubner, of Berlin, on the "Results of Sero-Therapy in Diphtheria." It was discussed by Widerhofer, Kohts, von Ranke, von Mering, and others.

Heubner (referee) indulges in the usual exhibit of statistics to prove the advantage of the antitoxin injections over all other methods of treatment. Thus, to quote his words: "Sero-therapy has caused in the city of Berlin a notable lessening of mortality. In 1894, before sero-therapy, there were 517 deaths in 1,332 cases of diphtheria (39 per cent.); since the employment of sero-therapy, out of 1,390 cases we have had a mortality of only 21 per cent. The mortality has then diminished about one-half since we have adopted the antitoxin treatment."

The presence of the Löffler bacillus is to this writer the criterion of true diphtheria, and all false membranous affections resembling diphtheria but devoid of this bacillus are simply *diphtheroid.*

The success of the antitoxin treatment depends on its early commencement rather than on the apparent benignity of the affection. The febrile symptoms are less marked under sero-therapy, and the pulse is less frequent. Early treatment diminishes the chances of albuminuria, causes the local symptoms sooner to decline, the false membranes to become detached and fall off sooner than under the old treatment, and when they fall off they are seldom reproduced. Cases subjected to sero-therapy in good season are remarkably exempt from laryngo-tracheal complications. Out of 16 cases where the larynx was invaded from the first, the disease was arrested and recovery followed in nine.

Out of 181 cases of pure diphtheria recorded by this authority, all that were treated by the serum injections on the first and second days got well; and of

those treated on the third day, two only succumbed. In only three of these 181 cases was there any relapse; nine presented symptoms of cardiac weakness, and 12 had partial paralysis. In a few of these cases, an erythematous eruption followed the injections. There was in no case any swelling or suppuration at the point of injection.

Preventive injections were practised on 64 children; two of these were afterwards attacked with diphtheria and one succumbed.

"If," says Heubner, "we compare the observations before and since the introduction of antitoxin, we have to note in favor of the new treatment two important modifications: diminution of the fever, and early expulsion of the false membranes; these facts support the views of those authorities who accord a truly specific value to this treatment. The other characters noted in the course of cases of diphtheria the last year might rigorously be attributed to the 'epidemic genius,' since they have been very generally observed; in reality, it must be strange, to say the least, if the relative benignity of these late epidemics has everywhere coincided exactly with the institution of sero-therapy with no relation between these facts but one of mere coincidence."

Baginski, of Berlin, stated that from the 15th of March, 1894, to the same date, 1895, 525 cases of diphtheria had been treated with antitoxin at the Friedreich Hospital; at first Aronson's serum was employed, then that of Behring. The epidemic which prevailed then was one of the gravest; for during the months of August and September, when the supply of serum had run out, the mortality was 52 per cent., while during the four previous years it had been successively 50 per cent., 33 per cent., 36 per cent., and 42 per cent., the average being 41 per cent. Of these 525 cases, corresponding to the period during which sero-therapy was employed, the mortality only attained the figure of 15.81 per cent.

From a clinical point of view he holds that it is incontestable that sero-therapy exercises a marvellous action on the general state of the diphtheritic, if not from the first day of the injection, at least from the second or third day, provided that the quantity injected is sufficient. These are summed up in a comparatively mild run of the disease, and a prompt return of the appetite and strength. There is, notably, a speedy return of the temperature to the normal. The local processes are more speedily arrested under sero-therapy than under any other treatment.

Baginski agrees with Heubner as to the advantages of early treatment by antitoxin. The mortality of those treated from the first day of the disease by antitoxin was 2.5 per cent.; of those treated from the second day, 10 per cent.; of those treated from the third day, 14 per cent.; of those treated from the fourth day, 23 per cent.; of those treated from the fifth day, 35 per cent.

Among the secondary effects imputable to sero-therapy, were noted the abscesses observed in seven cases where the injection was made deeply into the muscular layers; in the pus of several of these cases no pyogenic bacterium could be found. In 15 cases, erythema multiforme followed the injections, but the speaker did not attribute this complication to the sero-therapy; in fact, long before this treatment came into vogue, diphtheritic erythema was known.

Baginski does not attempt to explain the action of the serum, but believes that the efficacy of the remedy is now sufficiently established empirically.

Widerhofer, of Vienna, in summing up his experience with antitoxin in the hospitals of Vienna, finds a diminution of the mortality of diphtheria by more than one-half since the introduction of sero-therapy. In 130 cases he has used preventive injections with good results, none of these persons contracting diphtheria, though previously exposed. In two other series of cases the preventive injections were practised, and with nearly identical results. No local treatment was used conjointly with the injections; in a few cases of heart weakness, small doses of digitalis, strophanthus or strychnine were given to sustain the circulation. Bronchitis and catarrhal pneumonia, as complications, had been very infrequent since the precaution was taken to give the patients moist, instead of dry, air to breathe by the constant evaporation of water in the wards.

Von Ranke, of Munich, spoke with enthusiasm of the success of the antitoxin treatment in the hospitals of Munich; the mortality had been lessened by more than one-half since the use of sero-therapy. In his estimation antitoxin arrests the spread of the disease and grave cases soon become mild under its use. Sero-therapy is an excellent adjuvant to intubation in laryngeal cases. Kohts, of Strasbourg, also testified to the benefits of sero-therapy in opposing the extension of the pseudo-membranes. He prefers to combine its use with local antiseptic treatment. From the point of view of mortality, he does not, however, find that sero-therapy has furnished results superior to the older methods of treatment. It was admitted, however, that the statistics furnished by Kohts were relatively meagre, and that in almost all his cases, the treatment by antitoxin was instituted late.

Seitz, of Munich, spoke of the greater frequency of erythema since the use of sero-therapy, and thought this complication for the most part due to the injections.

Von Mering, of Halle, said that at Halle out of 74 cases of diphtheria treated by antitoxin from the second day, only four died. The mortality which before had been 28 per cent., was reduced to five per cent. No complication of any gravity had followed the injections. With this statement all the other speakers agreed; only it was affirmed by one or two that the paralytic sequelæ were a little more frequent after sero-therapy.

It was thought by one of the speakers (Vierordt, of Heidelberg), that the favorable results attending the new treatment might be in part due to the benig-

nity of epidemics the past year or so; people were more than ever frightened at the name diphtheria, and the mild cases (such as used to be kept at home), were now sent to the hospitals. Moreover, it should, he thought, be remembered that the local antiseptic treatment has been used more perseveringly and with greater success by physicians of late years.

It will be seen that there was at this discussion, participated in by some of the most careful observers among the German clinicians, almost entire agreement as to the efficacy of the antitoxin treatment in reducing the rate of mortality in diphtheria. There was also a general consensus that thus far no serious complications or sequelæ imputable to the antitoxin serum have attended the injections.

## ANTI-STREPTOCOCCIC SERO-THERAPY.

ANOTHER application of sero-therapy has gone on record. It is the treatment of erysipelas, puerperal septicemia and other diseases due to the streptococcus, by injections of the serum of animals rendered immune to the streptococcus infection.

The curative serum is prepared on the same general principles as the antitoxin of diphtheria. Hares, then a horse, are vaccinated against the streptococcus. The serum of these immunized animals is used first upon animals which have been inoculated with the streptococcus, and with results so favorable as to warrant the application of the same treatment to human diseases caused by that baneful microbe.

At the meeting of the Société de Biologie, February 23, 1895, Roger reported a case of puerperal fever treated by Charrin and himself with streptococcus antitoxin: "Despite the gravity of the infection," he says, "this woman got well in forty-eight hours."

At the session of the society held March 30th, he reported another case of puerperal septicemia treated in the same way and with the same success.

"What struck us particularly in both cases," he adds, "was the prompt amelioration of the general state, the sense of comfort experienced a few hours after the injections, and the speediness of the convalescence."

Roger subsequently treated a case of erysipelas in the same way, and with equally good results. The patient was an infant three weeks old, suffering from erysipelas of the left side of the face. Five cubic centimetres of the antitoxic serum were injected under the skin; this was attended with a fall in the fever and a diminution in the extent of the erysipelas, and at the end of four days the child was well. This case, Roger observes, is the more interesting from the fact that the erysipelas of new-born infants is almost always fatal.

In still another case, the serum was injected in a woman, who twenty days after her confinement was attacked with a pseudo-membranous streptococcus-angina, with high temperature (between 39.7° C. and 41.3° C.). The pulse was rapid, feeble and irregular (148 per minute); the heart-beats had the fetal rhythm. The patient received 60 c. c. the first day in two injections, and 30 c. c. the second day. Thirty-six hours after the first injection, the temperature fell from 41° C. to 38.3° C., and twenty-four hours later it became normal.

These facts present the greatest interest, and suggest the ultimate extension of this treatment to other and still more grave cases of streptococcus-infection. The injections are said to be perfectly innocuous.

## ANNUAL REPORT OF THE BOSTON BOARD OF HEALTH.

THE twenty-third annual report of the Boston Board of Health for the year from February 1, 1894, to February 1, 1895, contains, as usual, some interesting statements. The death-rate, calculated on the basis of a population of 501,000, was 22.98 per 1,000 inhabitants. This is 1.04 less than that of the previous year, and the lowest since 1890. Last year pneumonia caused the largest number of deaths; this year consumption resumes its usual place as the principal factor in the city's mortality. The deaths from consumption numbered 1,425, 12.36 per cent. of the total mortality. The deaths from pneumonia numbered 1,119, or 9.71 per cent. of the total. Diphtheria became epidemic during the year, causing 817 deaths, and its increase was noticeable in every month of the year over those of 1893. It assumed an epidemic form in the last week of September, reached its climax about the first week in December, and gradually fell off at the end of the year. It will be of interest to note in future reports what effect the medical inspection of public schools, as well as the use of antitoxin and the early treatment and isolation of cases discovered by the application of the culture test, have upon the prevalence of this disease. It is fair to expect a decided diminution in its fatality, and ultimately in its frequency.

It is stated that during the past four years diphtheria has shown an increasing tendency in Boston — the rate per 1,000 inhabitants being .505 in 1891, .881 in 1892, .976 in 1893, and 1.630 in 1894. Of the other contagious diseases reported during the year, the deaths from scarlet fever, typhoid fever and measles were respectively less than the year previous. The increase in diphtheria and cholera infantum raised the number of deaths due to zymotic causes to 2,357, an increase of 315 deaths of this class over the previous year, or a percentage of 20.46 to the total mortality. The deaths of children under five years of age were also increased to 4,108, or 35.66 per cent. of the whole number of deaths. This is the highest per cent. since 1887, and the highest number of deaths for any one year on record. The increase of deaths of children was due to diphtheria, cholera infantum, and an unusually large number of enteric diseases, the result of malnutrition.

At the commencement of the year small-pox had

made some headway in the city. In was totally suppressed in May, there having been 77 cases and 22 deaths.

The report concludes from the comparatively low death-rate, and the deaths due to constitutional, local, developmental and violent causes, numbering 9,140, over which little or no control can be exercised by health regulations, that the health of the city is in a fairly satisfactory condition.

The Board, as has been previously stated, hopes soon to have a supply of antitoxin serum from its own laboratory, which will be furnished free to the public institutions and to the poor of the city. It has under consideration a proposition for extending this distribution at cost price to the well-to-do and to the health authorities of the smaller communities forming part of what is known as the Metropolitan District.

The fifty physicians selected by the Board for medical inspection of the public schools began their work November 1, 1894. The reports of these inspectors, for the months of November and December, show that 4,962 pupils were presented to them for examination; and 564 were found to be too ill to remain in school for the time being; 212 were suffering from contagious diseases; 43 were suffering from diphtheria; and 131 were too ill from troubles in the eyes and ears to be in school. Diseases in the throat were most prevalent, and were found in 1,749 pupils. Diseases of the eye, ear, and spine occur sufficiently often among the school children to warrant a more careful examination to detect those who may be suffering from mild forms or early stages of such diseases. School children often suffer serious and unrecognized disadvantages by reason of mild forms and early stages of these ills which would not generally be seen and appreciated by the teachers; nor could this be reasonably expected of them.

The Board of Health purposes to pursue this system of inspection as far as it may be found to be agreeable to the school management and profitable to the highest interests of school hygiene.

There is good reason to congratulate the Board and those connected with it upon the work accomplished by it during the year, for the welfare of the city of Boston.

## MEDICAL NOTES.

A Hahnemannian Hospital for the Insane. — According to the *Medical News*, the Pennsylvania Legislature has before it a petition signed by 20,000 Philadelphians for the establishment of a Hahnemannian Hospital for the Insane.

A New Treatment for Prostatic Hypertrophy. — It is stated that at the recent German Congress of Internal Medicine, Reinert, of Tübingen, reported three cases of prostatic hypertrophy which had been considerably relieved by the ingestion of a preparation of the prostate glands of animals.

A Grewsome Discovery. — According to the New York *Times*, an investigation of the cause of the prevalence of contagious diseases in the schools of New York City has disclosed the fact that out of 112 school trustees 23, or a little less than 20 per cent., are undertakers; a fact which the *Times* says would be amusing were it not so tragical.

The Regulation of Antitoxin in Europe. — The German Government has ordered that antitoxin shall not be offered for sale in the German Empire before being submitted to the Institute of Infectious Diseases at Berlin. After examination the Institute will stamp on the bottle the date and number of the sample. This went into force April 1st. A similar proposal is now before the French Legislature.

Transposition of the Heart, Liver and Spleen. — George S. Dixon, M.D., reports in the *Medical Record*, April 20, 1895, a case of transposition of the heart, liver and spleen, in a boy sixteen years of age, of Russian parentage. The case was shown before the Pediatric Section of the New York Academy of Medicine, February 14, 1895, and the transpositions verified by Dr. A. Jacobi.

Burns due to Intense Cold. — M. Raoul Pictet has described the "cold burns" experienced by himself and his assistants during investigations at low temperatures. In some cases the skin is first red, then blue, and subsequently the area of the injured spot extends to nearly double what it was originally. There is a painful itching sensation in the surrounding tissues, as well as at the affected spot, and healing usually takes five or six weeks. In more serious cases the skin rapidly becomes detached, and there is a long and stubborn suppuration, the wound remaining open for more than six months in one instance after a drop of liquid air had fallen on the hand.

A Sterilized Bill of Fare. — The physicians of the government of Podolia, says *La Médecine Moderne*, recently held a meeting to devise measures to be taken against the cholera. Like every self-respecting medical meeting, this one was concluded by a banquet, of which the following is the *menu*:

Vodka bactéricide et hors-d'œuvre immunisateurs.
Bouillon stérilisé.
Roastbeef aux phagocytes, sauce serum No. 3.
Dinde rôtie, immunisée, contre le choléra des poules,
aux marrons stérilisés à l'étuve.
Glaces préparées au lait stérilisé dans des appareils
centrifuges et servies dans des boites Petri.
Fruits de l'arbre de la science du bien et du mal.
Vins Pasteurisés. — Vin blanc filtré sur bougie Chamberland.
— Bière et porter en cylindres hyalins. —
Champagne ayant subi la quarantaine à Riga.
Café, liqueurs et cognac pour parfaire la désinfection.

Lay Comments on a Lithopedion. — The *Journal of the American Medical Association* is responsible for the following interesting conversation: A surgical operation was recently performed at the Religio-Medici General Hospital at X——, for the removal of a lithopedion from an adult male. The operation was successful as to the delivery by laparotomy of the fetal remains, but the parent did not survive. Two ladies travelling in one of our public conveyances were over-

heard discussing the singular operation. One of them remarked: "So odd, was it not, and in a young man at that." — "Yes," replied the other in a subdued tone of voice, "and a bachelor, too."

## BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — During the week ending at noon, May 1, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 58, scarlet fever 38, measles 166, typhoid fever 13.

The American Pharmacy Fair. — An American Pharmacy Fair, the first of its kind ever attempted in America, will be held in Mechanics Building from May 1st to May 25th.

The Keeley Bill. — The Committee on Public Charitable Institutions have reported adversely to the bill proposing to compel the employment of the Keeley cure at the Massachusetts Hospital for Inebriates.

Child Insurance in Massachusetts. — On April 30th the Massachusetts House of Representatives, by a vote of 149 to 23, refused to order to a third reading the bill to prohibit insurance of the lives of children under ten years of age, thus ending the matter for the present session.

Dr. Forster appointed Surgeon-General. — Lieutenant-Colonel Edward Jacob Forster of Boston, Medical Director First Brigade, M. V. M., has been appointed Surgeon-General by Governor Greenhalge, in place of Brigadier-General Herbert L. Burrell, retired.

The Suffolk District Medical Society. — At the annual meeting of the Suffolk District Medical Society the following gentlemen were elected officers for the ensuing year: President, John G. Blake. Vice-President, Francis H. Brown. Secretary, Herbert L. Smith. Treasurer, Edward L. Buckingham. Librarian, B. J. Jeffries. Member of the Nominating Committee of the Massachusetts Medical Society, W. L. Richardson. Committee of Supervision: F. Minot, S. L. Abbot. Committee on Social Meetings: G. A. Leland, E. Reynolds, P. Thorndike, John Dane. Censors: H. F. Vickery (Councillor), F. B. Harrington, R. W. Lovett, E. O. Otis, George Haven.

## NEW YORK.

Leprosy. — One case of leprosy in New York and two in Brooklyn have recently been reported. While all were in different families all three occurred in colored lads who were born in the West Indies. The New York case has been sent to North Brothers Island, and the patient is stated to be in an advanced stage of the disease.

A Young Mother. — One day last week at the Court of Common Pleas, in a suit for damages against a landlord, there was presented the novel spectacle of a woman of fifty accompanied by a married daughter thirty-seven years of age, and the mother looked about as young as the daughter. She stated that she had been married at the early age of twelve, and that her child was born when she was only thirteen.

A Centenarian. — Mrs. Catharine Scott, who is believed to have been the oldest woman in Brooklyn, died at her home in that city on April 21st. She was a native of Ireland and her age is given as one hundred and three. But for a fall three months ago in which she suffered a fracture of the thigh, she would probably have lived several years more, as she always enjoyed excellent health. Despite her great age it is stated that she had not a gray hair, and that she was able to read without glasses. She had had three daughters and one son, and the last surviving daughter died about three months ago at the age of sixty.

A Contagious Hospital for Paying Patients. — A project has been set on foot for the erection of a hospital for the treatment of patients suffering from diphtheria, scarlet fever, and other contagious diseases, who are able to pay for their accommodations. It is designed especially for those attacked with contagious diseases while stopping in hotels and boarding-houses. The bill for the incorporation of the institution has now passed the Legislature, and the site for the proposed building in East 16th Street, near the Willard Parker Hospital, has been surveyed. The prime mover in this very useful and practical philanthropic work has been Mrs. John B. Minturn, who has contributed $25,000 towards it. In addition $36,000 has been subscribed by others, and there now remains but $14,000 to be raised to complete the $75,000 endowment fund required. It is hoped that the building may be erected during the coming summer, and be ready for occupancy in the autumn.

Tenement-House Reform. — The tenement-house reform bill which recently passed the Legislature has been sent to Mayor Strong for his approval, and on April 25th he gave a public hearing in regard to it. Among those who spoke in favor of it were President Wilson and Dr. Cyrus Edson, of the Board of Health, and Richard Watson Gilder, the President of the Tenement-House Commission, who stated that it was the result of the most careful and painstaking investigation on the part of the Commission and was probably as good a bill as could be framed at the present time. Among the vital points in the bill are the provisions forbidding the covering of more than 75 per cent. of any tenement lot with buildings, instead of 78 per cent., as at present, and permitting the Board of Health to condemn an unsanitary tenement. The principal objections to the bill came from contractors and builders, who claimed that in many of its provisions it was impracticable and theoretical, and that it would largely increase the cost of tenement buildings. The mayor thanked Mr. Gilder for his arduous labors in behalf of tenement-house reform, and stated that he would approve the bill, though he might possibly suggest some minor changes in it.

## Miscellany.

### A COMPLIMENTARY DINNER TO THREE NEW MEDICAL BARONETS.

THE *Medical Press and Circular* gives a rather amusing account of the "complimentary dinner" given to Sir John Erichsen, Sir Russell Reynolds and Sir John Williams, at the Criterion in London on the 27th ult., which it characterizes as "but a qualified success." The account shows that if the art of after-dinner oratory among British medical baronets is not in a high state of cultivation, at least one British medical journal cannot be accused of timidity in criticism. The account runs as follows:

"The proceedings were opened by the Chairman, Lord Reay, who, in a speech of inordinate length, which might have done duty as an introductory lecture at one of the medical schools, was understood to propose the health of the guests of the evening. The resolution was spoken to by Sir Henry Thompson, who, much to the disappointment of his old pupils, was inaudible, and failed to make any impression or to relieve the monotony of the proceedings. Dr. Champneys, who had been selected to champion the cause of Sir John Williams, spoke distinctly and scored the first success of the evening. Sir John Erichsen, in reply, delivered a speech which was full of pathos and stirred to a marked degree the feelings of the audience. Sir Russell Reynolds spoke with his accustomed fluency and precision, and illustrated his remarks with numerous appropriate and amusing anecdotes. Sir John Williams was lachrymose to a degree, and was clearly unable to rise to the occasion. The proceedings terminated with a speech by Sir William Broadbent proposing the health of the Chairman, who took advantage of the opportunity to inflict on the remnants of the company another oration."

### A SUCCESSFUL OPERATION FOR PURULENT PERICARDITIS.

SURGICAL intervention in pericarditis is so rare as to render the case operated by Eiselsberg, and reported in the *Wiener klin. Woch.*, for January, 1895, of especial interest. The case was that of a boy of seventeen who developed a purulent pericarditis after a stab-wound of the pericardium. Puncture of the pericardium having been performed several times without relief, the surgeon decided upon incision. The cartilage of the fourth rib on the left was resected, and the thickened pericardium exposed. After exploratory puncture it was opened by a transverse incision four centimetres in length, and two litres of a sero-purulent fluid were evacuated. The cavity was washed out with warm salicylated water, the borders of the pericardial incision stitched to those of the wound, and two drainage-tubes inserted. Complete recovery took place in four weeks. Examination of the exudate showed the presence of an organism resembling the colon bacillus, but it was of course impossible to say whether its presence was primary or the infection took place through the wound. The writer insists upon the importance of suturing the pericardium to the lips of the wound, the advantages of which procedure in preventing infection of the pleura are evident.

## Correspondence.

### THE GOOD OLD TIMES.

JAMAICA PLAIN, April 29, 1895.

MR. EDITOR: — The following item clipped from a Boston daily paper dated August 15, 1865, and sent me by a friend, may interest your readers as it did me:

THE "GOOD OLD TIMES." — The *Worcester Spy* prints a genuine curiosity, in a doctor's bill, dated no longer ago than 1830. The price of a visit in those days was fifteen cents, but when the conscientious physician took one ride to see several patients he divided the price among them, so that the most frequent item in the bill is "to part visit, 8c." The charges for medicine range from five to twenty cents, and the highest amount in the column is "to sundry medicine, compound tincture, and tin box, 30c." The total of the bill, which is for constant attendance and medicine for a period of eight months, the visits averaging as often as once a week, is less than five dollars.

Though the services of our profession are by no means rewarded at their full value even at the present day, we may yet be thankful that we did not practise in the "good old times."

Very truly yours,

ARTHUR P. PERRY.

[It would be interesting to ascertain, if possible, the amount of the necessaries of life which the fee of 1830 would purchase, such information being essential to a fair comparison. How far the greater purchasing power and the lower scale of living would go to make up for the comparatively small size of the fee is an open question.— ED.]

### RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 20, 1895.

| Cities. | Estimated population. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | | Infectious diseases. | Acute lung diseases. | Diarrheal Diseases. | Diphtheria and croup. | Measles. |
| New York | 1,956,000 | 913 | 386 | 14.63 | 21.56 | 2.20 | 5.80 | 3.41 |

| Pittsfield | 18,802 | — | — | — | — | — | — | — |
| Everett | 16,585 | 11 | 6 | 36.36 | 9.09 | — | — | — |
| Northampton | 16,331 | 4 | 2 | 25.00 | — | — | — | — |
| Newburyport | 14,073 | 6 | 0 | — | — | — | — | — |
| Amesbury | 10,920 | 2 | 0 | — | — | — | — | — |

Deaths reported 2,861; principal infectious diseases (smallpox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 322, acute lung diseases 570, consumption 319, diphtheria and croup 124, measles 40, diarrheal diseases 40, typhoid fever 34, scarlet fever 27, whooping-cough

25, cerebro-spinal meningitis 14, erysipelas 9, malarial fever 6, small-pox 3.

From typhoid fever Philadelphia 10, New York and Brooklyn 4 each. Pittsburg 5, Boston and Cleveland 2 each. Washington, Cincinnati, Lowell, Lynn, Lawrence, Brockton and Quincy 1 each. From scarlet fever New York 10, Brooklyn and Pittsburg 4 each; Chelsea 2, Philadelphia, Boston, Nashville, Cambridge, Lynn, Lawrence, and Salem 1 each. From whooping-cough New York 6, Brooklyn 5, Boston 3, Cincinnati, Providence, Worcester, Springfield, Lawrence, Northampton and Clinton 1 each. From cerebro-spinal meningitis New York and Everett 4 each; Washington, Worcester, Somerville, Chelsea and Waltham 1 each. From erysipelas New York 5, Brooklyn 3, Boston 1. From malarial fever New York 3, Brooklyn 2, Philadelphia 1. From small-pox Cincinnati 2, Philadelphia 1.

In the thirty-three greater towns of England and Wales, estimated population 10,591,530, for the week ending April 6th, the death-rate was 21.1. Deaths reported 4,280, acute lung diseases (London) 427, whooping-cough 93, measles 53, diphtheria 51, diarrheal diseases 38, scarlet fever 21, fever 17, small-pox (Derby) 1.

The death-rates ranged from 10.9 in Croyden to 33.0 in Bernley; Birmingham 26.9, Bolton 23 6, Bradford 19.3, Gateshead 20.7, Hull 25.5, Leeds 21.9, Leicester 23.1, Liverpool 24.9, London 19 0, Manchester 26.4, Newcastle-on-Tyne 16.9, Nottingham 15.4, Portsmouth 20.0, Sheffield 20 7, West Ham 15 7.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530 for the week ending April 13th, the death-rate was 20.5. Deaths reported 4,160: acute diseases of the respiratory organs (London) 368, whooping-cough 108, measles 68, diphtheria 68, diarrhœa 50, scarlet fever 26, small-pox (Birmingham) 1. The death-rates ranged from 2.4 in Cardiff to 28.2 in Preston, Birmingham 25.5, Bradford 18.2, Halifax 17.8, Hull 22.9, Leeds 19.0, Leicester 16.7, Liverpool 24.1, London 19.3, Manchester 24.6, Newcastle-on-Tyne 20.1, Norwich 20.4, Nottingham 19.8, Portsmouth 16.1, Sheffield 19.8, Sunderland 18.9, West Ham 18.2.

## METEOROLOGICAL RECORD.

For the week ending April 20th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | Direction of wind. | | Velocity of wind. | | Weather. * | | Rainfall in inches. † |

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 20, 1895, TO APRIL 26, 1895.

### PROMOTIONS.

LIEUTENANT-COLONEL DALLAS BACHE, deputy surgeon general, to be assistant surgeon general with the rank of colonel, April 18, 1895.

MAJOR DAVID L. HUNTINGTON, surgeon, to be deputy surgeon general with the rank of lieut.-colonel, April 18, 1895.

CAPTAIN WILLIAM C. SHANNON, assistant surgeon, to be surgeon with the rank of major, April 18, 1895.

By direction of the president the retirement from active service April 18, 1895, of COL. JOSEPH R. SMITH, assistant surgeon general, is announced.

Leave of absence for six months, with permission to go beyond sea, to take effect upon his relief from duty at Fort Columbus, New York Harbor, is granted CAPT. WILLIAM P. KENDALL, assistant surgeon.

## BOOKS AND PAMPHLETS RECEIVED

Annali di Medicina Navale, Gennaio, 1895. Anno 1. Fascicolo 1.

Nervous Disease in Early Syphilis. By G. Frank Lydston, M.D. Reprint. 1895.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING APRIL 27, 1895.

M. W. BARNUM, assistant surgeon, ordered to examination for promotion, May 15th next.

J. E. PAGE, assistant surgeon, ordered to examination for promotion, May 15th next.

F. G. BRATHWAITE, assistant surgeon, ordered to the Naval Hospital, Norfolk, Va.

T. C. WALTON, medical inspector, ordered as delegate to American Medical Association, Baltimore, Md.

S. H. DICKSON, surgeon, ordered as delegate to American Medical Association, Baltimore, Md.

## SOCIETY NOTICES.

THE WARREN CLUB.— A regular meeting of the Club will be held at 80 Marlborough Street, on Tuesday evening, May 7, at 8 o'clock.

Dr. John T. Bowen: "Modern Theories and Treatment of Eczema."

Dr. Paul Thorndike: "Points in the Treatment of Strictures of the Deep Urethra."

W. E. PAUL, M.D., *Secretary*.

AMERICAN ASSOCIATION OF MEDICAL EDITORS.— The Annual Dinner of the American Association of Medical Editors will take place Monday, May 6, 1895, at the Equitable Building (ninth floor), Calvert and Fayette Streets, Baltimore. A Business Meeting will be held at 6.30 P. M., at the same place. Members may bring guests upon purchase of tickets for them. Banquet tickets, $5.00. Those expecting to attend will please write *immediately*, stating number of tickets desired, to

WILLIAM B. CANFIELD, M.D.,
1010 N. Charles Street, Baltimore, Md.

## RECENT DEATHS.

MOSES REUBEN GREELY, M.D., M.M.S.S., died at South Weymouth, April 24, 1895, aged sixty-seven years.

CHARLES PARKER SPALDING, M.D., M.M.S.S., died in Lowell, March 25, 1895, aged forty-six years.

NATHAN FRENCH, M.D., M.M.S.S., died at Malden, April 27, 1895, aged eighty-four years.

KARL THIERSCH, M.D., died in Leipsic, April 28th, aged seventy-three. He had been professor of surgery in Leipsic since 1867. His contributions to surgical progress were many and important, and his method of transplantation of large pieces of skin, "the Thiersch grafts" is one of the most valuable of recent surgical procedures.

KARL LUDWIG, M.D., the eminent physiologist, died at Leipsic, April 26th, aged seventy-nine years. He had been professor of physiology in Leipsic since 1865, and for the preceding ten years had held the chair of physiology in Vienna. He was the inventor of the kymograph, and the importance of his work and that of his pupils to physiology can hardly be over-estimated.

GEORGE CUPPLES, M.D. (Edin. and Paris), died at San Antonio, Texas, on the 19th of April, in his eightieth year. He had practised in San Antonio for upwards of fifty years. He was buried on Sunday, the 21st inst., and the body was followed to the grave in San Fernando Cemetery by probably the largest procession of mourners ever seen in the city of his adoption.

Dr. Cupples was president of the State Medical Association in 1874 and again in 1878. He was a skilful and courageous surgeon. He was the first to introduce into Texas anesthetics — ether first and chloroform afterwards. He was the first in the United States to perform the extirpation of the tongue for cancer, by Nunnelley's method, and to perform the operation of ovariotomy in a child under eight years of age, and to perform Freund's operation for the extirpation of uterus and ovaries. He was the first in Texas to amputate at the hip-joint and knee-joint with success.

Dr. Cupples first became connected with the naval service, having enlisted as staff assistant surgeon in the Spanish service, in 1836. In 1838 he resigned, and in August of the same year he graduated from the University of Edinburgh, studying also in the hospitals of London. He then went to Paris, where he studied until 1843 for the purpose of occupying an official position in the hospitals of France. In 1844 he sailed for America, coming direct to San Antonio from Paris. During the Mexican war he enlisted in Hay's second regiment of cavalry and served throughout that struggle as a surgeon. When the civil war began he entered the Confederate army as first surgeon of the seventh Texas regiment of mounted volunteers, serving in the campaign of New Mexico. In December, 1862, he was appointed medical director of the Eastern Military District of Texas and continued in charge until he was ordered to join Sibley's brigade in Louisiana. The following summer he served as senior chief surgeon of division, and in June, 1864, as medical director and inspector of the cavalry corps of the Trans-Mississippi Department up to the close of the Red River campaign. He gave his parole at San Antonio at the surrender.

### OBSERVATIONS ON DIPHTHERIA.[1]

BY J. H. McCOLLOM, M.D.

It is generally supposed that diphtheria is a disease of modern times, but Aretæus, a Greek physician of Cappodocia, wrote a description of a disease similar to diphtheria in 111 A. D. In the sixteenth century the disease was prevalent to a greater or less extent, according to written statements of the physicians of that time. In 1821 Bretoni wrote the first full and elaborate account of the disease. After that time, until 1847, the disease did not seem to attract much attention among the physicians of the Continent. In 1847 an outbreak of diphtheria occurred in England, which was traced to its origin at Bologue, and was known as the "Bologne sore throat." Since that time diphtheria has been more generally recognized and more carefully studied; and for this reason, although diphtheria is somewhat more prevalent at the present time than formerly, yet the apparent increase is due in a measure to the better recognition of the disease.

Diphtheria was first recognized in Boston in 1859, in which year there were 19 deaths from this cause, reported. From what is known of the disease to-day it seems reasonable to suppose that if 19 deaths from a so-called new disease were reported, there must have been many cases of the same disease that were not recognized. The following year there was only one death from this cause reported in Boston. Since that time the death-returns have shown a gradual increase in the number of deaths. In 1863 and 1864 in Boston, with a population of 186,526, there were 106 and 108 deaths respectively. From 1865 to 1875 there were very few deaths from diphtheria. In 1875 the number of deaths from this disease increased to an alarming extent, from 72 to 420. In 1881, there was quite a severe epidemic of the disease in this city; the deaths for that period numbering 601, giving a rate per 1,000 of the living of 1.657. Since 1881 the number of deaths from diphtheria has varied from 232 to 817 each year. The number of cases reported in 1894 was 2,019, with 817 deaths. The death-rate from this disease per 1,000 of the living for 1894 was 1.630, while that of 1893 was .976. The most marked increase in the cases of diphtheria in 1894, as compared with that of 1893, occurred in the last six months of the year.

In England the increase of the mortality from diphtheria has been much more marked in the larger towns than in the rural districts. In London this has been more particularly noticeable. For instance, during 1871 the death-rate was .10 per 1,000 of the living; while in 1890 it was .33 per 1,000.

Dr. G. B. Longstaff, in a paper on the "Geographical Distribution of Diphtheria in England and Wales," shows that in the past few years there has been an increase in urban districts as compared with the rural. For the purpose of this investigation the twenty-six years from 1855 to 1880 were divided into three periods, and the districts into dense, medium and sparse. In the first period, 1855–60, in which the death-rate from diphtheria per 1,000,000 for the whole country was 182, it was found that the rate was 123 in the dense districts; 182 in the medium districts; and 248 in the sparse districts. In the period from 1861 to 1870 the death-rate from diphtheria per 1,000,000 was 163 in the dense districts; in the medium, 164; in the sparse, 223. In the period from 1871 to 1880 the rate in the dense districts was 114; medium 125; and the sparse districts, 132. It will be seen from this that in the period from 1855 to 1860 the death-rate from diphtheria per 1,000,000 was twice as great in the sparse districts as in the dense; that from 1871 to 1880 there was a difference of only 18 between the death-rate of the sparse districts as compared with the dense districts.

It is now generally conceded that imperfect drainage and unsanitary conditions should not be considered important factors in increasing the frequency of this disease. Twenty years ago diphtheria was considered to be a filth disease; but careful investigation of the course of epidemics in various parts of the world and the discovery of the specific organism of this disease have proved the fallacy of this opinion. In an epidemic of the disease occurring a few years ago, in a neighboring city, investigated by the State Board of Health, it was found that in localities where the hygienic conditions were good, where the drainage was perfect, the disease was much more prevalent than in localities where there was not sufficient drainage and the most marked unsanitary conditions existed. An analysis of the cases of diphtheria reported in Boston for five years from 1888 to 1892 shows that in the crowded and poorer localities of the city the disease was not so prevalent as in the better portions of the city. For instance, in Ward 16, with an average population of 213 to the acre, the morbidity was much less than in Ward 25 with an average population of seven to the acre. Elevation above tide-level in this city does not seem to have any bearing upon the prevalence of the disease. As an illustration of this point, a comparison of that portion of East Boston the elevation of which is only a few feet above mean low water, with that in which the elevation is much greater, shows that the disease was much more prevalent, for five years, in the latter than it was in the former.

The discovery by Klebs of the bacillus of diphtheria in 1883 and the investigations by Löffler a year later placed the etiology of diphtheria upon a scientific basis. The result of these researches shows conclusively that diphtheria is distinctly an infectious disease; that it never originates spontaneously; and that it is a local disease; that the constitutional symptoms are due not to the presence of the organism in the blood, but that they are due to the toxine caused by the growth of the bacillus. The term diphtheria should only be applied to those cases in which the bacillus exists. All other cases of disease of the mucous membrane of the mouth and throat characterized by the presence of a false membrane should not be considered as diphtheritic in their nature. The diagnosis of diphtheria, particularly in the milder cases, is impossible without a bacteriological examination. In the milder cases the appearance of the membrane has nothing distinctive on which to base a diagnosis. The term "pseudo-diphtheria" has been used to designate cases of sore throat where there is a membrane, but in which the bacillus of diphtheria is not found. In these cases the streptococcus pyogenes and the staphylococcus pyogenes aureus and the albus have been found.

[1] Read before the Clinical Section of the Suffolk District Medical Society, February 20, 1895.

Much has been said regarding the liability to error in technique, in making cultures, in cases of membranous sore throat. While it is perfectly true that in certain instances where there is an extensive membrane in the throat, diphtheritic in its nature, through some error in technique the bacillus is not found, yet the chance of failure is not so great as to invalidate to any appreciable extent the accuracy of a bacteriological diagnosis. In a mild case of diphtheria, with very little membrane the liability to error is very slight.

In regard to the manner of taking cultures, there is this very important practical point. Experience has shown that the bacilli on the exposed surface of the false membrane frequently die, so that if the wire is passed simply over the surface of the membrane the result, so far as the bacillus of diphtheria is concerned, will be negative; but it may be positive so far as other organisms are concerned, as streptococci and staphylococci. It is, therefore, necessary to pass the wire either through the membrane or along its edges, and then inoculate one tube. It is also well to inoculate a second tube with the secretions from the throat near the site of the membrane. If this is done, in every instance, the liability to error will be very much diminished.

A second very important point is, that the patient should not use any disinfecting gargle for at least an hour before the culture is taken. The result of the investigations of Dr. Park in New York showed that while antiseptic gargles did not restrain the growth of other bacteria they did prevent the growth of the bacillus of diphtheria.

Much has been said regarding the existence of a bacillus morphologically similar to the bacillus of diphtheria, found in the throats of healthy individuals, and it has been claimed that this organism is a productive source of error in bacteriological diagnosis. Investigations, however, have shown that this organism does not interfere to any considerable degree with the accuracy of the diagnosis.

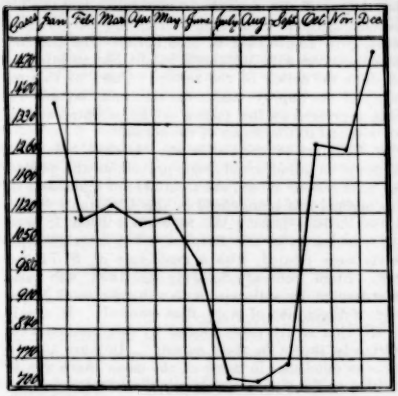
The examination of 70 non-diphtheritic throats made at the bacteriological laboratory of Harvard Medical School showed that the existence of this bacillus was not sufficiently frequent to be an element of error in bacteriological diagnosis. In the cultures from these 70 throats bacilli of many varieties were found; but in no instance was an organism seen that with care would be likely to be mistaken for the bacillus of diphtheria. In cultures made from the throats of 60 patients in the Children's Hospital, some of whom had been exposed to diphtheria, but in whom there was no clinical evidence of disease the bacillus of diphtheria was found in only one instance. It would seem from the result of these 130 cultures that the pseudo-diphtheritic bacillus cannot be a source of very great error. The bacillus of diphtheria may become after a time non-virulent and in this condition may remain in the mouths of patients who have had diphtheria for a long time; but it is reasonable to suppose that it may at any time acquire virulence, and therefore should be regarded as an element of danger.

The bacillus of diphtheria is a straight or slightly curved rod with rounded ends. Irregular forms are very frequently seen. As it is a pathogenic organism it grows more rapidly at the temperature of the blood than at a lower temperature; and for this reason it is important for the purposes of diagnosis to place the inoculated tube in an incubator over night. This organism grows readily on all the usual culture media. It has been claimed that this bacillus will not grow on potato prepared in the usual way, but careful and extended experiments have shown conclusively that although the growth is very slight and that irregular forms are quite common, yet at the end of forty-eight hours a thin film, which can be seen by careful inspection, forms on the surface of the potato. The growth of the needle culture in gelatin is not sufficiently characteristic to be of any very great importance from a diagnostic point of view. Milk is an exceedingly good culture-medium for this organism, and therefore may be a source of infection. The best culture-medium for diagnostic purposes is Löffler's mixture, composed of blood serum three parts, with one part of bouillon containing one per cent. of peptone, one per cent. of grape-sugar and one-half of one per cent. of sodium chloride. Upon this culture-medium, at the end of twenty-four hours, moderate-sized white colonies will appear, while other bacteria will not have developed colonies to any considerable extent.

Welch and Abbot found that this organism died after an exposure of ten minutes to a temperature of 58° C. (138° F.) This has an important bearing on the subject of disinfection by heat.

In regard to streptococci throats, it is a question just how infectious they are. That they are infectious to a slight degree is reasonable to suppose; but thus far experience has shown that their degree of infectiousness is much less than that of diphtheria.

One very important factor in the spread of diphtheria is the existence in cats and dogs of diphtheria. The disease manifests itself in cats and dogs not by the existence of marked membrane in the throat but by the condition of the lungs simulating pneumonia. The animal has a peculiar strident cough; has anorexia and loses flesh rapidly. At the bacteriological laboratory, recently, cultures taken from the throats of a cat and a dog that had been exposed to diphtheria revealed the presence of the bacillus of diphtheria. This organism disappeared from the throat of the cat in about two weeks; as the dog was killed, no further investigation could be made.



The bacillus of diphtheria in the case of the lower animals is a trifle longer than that found in human beings; but it has the same cultural peculiarities and is as virulent as that in human beings.

Cows may have diphtheria, and when suffering from the disease may be a source of infection.

Klein, in a report to the Local Government Board of London, traced an epidemic of the disease to milk from cows that gave unmistakable evidence of being ill of diphtheria. Small areas of false membrane were found on the teats of these cows. Cultures made from these lesions contained the diphtheria bacillus. Cats fed on the milk from these cows contracted diphtheria. While there is no positive evidence that the milk in the udder contained the germ of the disease, there is every reason to believe that the milk was contaminated by the hands of the milkers.

The influence of mild cases of diphtheria in the public schools has a marked effect on the prevalence of the disease in this community. In one of the primary schools, a short time ago, where there had been an outbreak of diphtheria, four children were found attending school who gave unmistakable evidence of having diphtheria. The chart which gives the num

ber of cases of diphtheria reported in this city, by months, for ten years, shows that when the schools are in session the number of cases is much greater than during vacation time.

The result of the investigations of 500 cases of suspected diphtheria examined at the bacteriological laboratory of the Harvard Medical School proved conclusively the importance of a bacteriological investigation in cases of a doubtful nature. Of these 500 cases, diphtheria was found to exist in 133 instances, or 26.6 per cent. These investigations did not embrace the well-marked characteristic cases of diphtheria, but comprised those in which a diagnosis, so far as the clinical appearances were concerned, would have been impossible without a bacteriological examination.

Since the 1st of November, 1894, by an agreement of the Board of Health with Prof. H. C. Ernst, physicians have an opportunity to send cultures to the bacteriological laboratory of Harvard Medical School for examination. From the 1st of November, 1894, to the 1st of February, 1895, 1,846 cultures were examined, and of this number in 462 instances the bacillus of diphtheria was found. In 1,292 instances the bacilli were absent, and in 92 cases there were no growth. In regard to cases in which no growths were found, it may be said that this result is due to some error in technique. Allusion would not be made to this were it not for the fact that some physicians seem to think that when there is no growth that therefore the case is not one of diphtheria. Such is not the fact. In a culture taken from any throat there should always be a growth of some sort, if proper precautions are taken. In addition to the question of diagnosis the time when the bacilli disappears from the throat of a person who has been ill of diphtheria, and the time when this person ceases to be a source of danger to the community, can only be established by a bacteriological examination. The benefit of these bacteriological examinations is evident from the fact that in November and December, when these examinations were commenced, the number of reported cases of diphtheria was about 18 daily. They have now diminished to an average of about 11 a day. On the other hand, from November, 1893, to January, 1894, the disease showed a gradual increase from November to December and from December to January. The result of these investigations has proved that statistical compilation on the epidemic spread of diphtheria, as well as on the character of epidemics of this disease, cannot be considered reliable unless based upon bacteriological examinations of all cases of suspected diphtheria.

In regard to the treatment of diphtheria by the ordinary methods, very little need be said; thus far clinical experience has shown that in severe cases where there is a general infection of the system very little is to be hoped from the usual modes of treatment. When there is laryngeal obstruction, intubation and tracheotomy relieve the dyspnea, and frequently save life; but are powerless for good when there is a general infection of the system with the toxic principles derived from the growth of the diphtheria bacillus. A diphtheria patient dies from one of three causes: either from laryngeal obstruction or from toxic infection or from failure of the heart, due to the peculiar effect of the toxine of diphtheria on the nervous centres. To relieve the two latter symptoms, or, to speak more correctly, to prevent their occurrence, many things have been advised.

Peroxyde of hydrogen has its advocates. A weak solution of corrosive sublimate in the form of a spray has been tried; douching the mouth with hot water either pure or containing a certain amount of salt has been advised. The use of strong caustics must be deprecated, for they only destroy the mucous membrane and offer a favorable nidus for the extension of the disease. The experiments of Roux and Yersin show conclusively that the bacilli of diphtheria, as a rule, will not grow on intact mucous membrane. In these experiments the fauces of a certain number of guinea-pigs were painted with a virulent culture of the bacillus of diphtheria without any result. It was not until the mucous membrane was wounded that it was possible to infect these animals with diphtheria.

At the present time the attention of the profession, both in this country and abroad, is directed to the treatment of this disease by the use of serum from animals rendered immune to diphtheria.

Some three years ago Behring commenced his investigations upon the action of the antitoxins of diphtheria. These investigations have been conducted continuously up to the present time. Since 1891 Mr. Roux has pursued his investigations in the treatment of diphtheria by antitoxin; at first on animals and then on children. At the present time he states that the investigations in all essential points correspond to those published by Behring and his co-laborers.

The animals that are to furnish antitoxin are rendered immune against diphtheria, that is to say, they become accustomed to diphtheria, so that the diphtheritic toxine has no effect on them. The toxine is prepared by cultivating virulent diphtheria bacilli in bouillon for one month, at a temperature of 37° C. or 98.5° F., so that the poison may accumulate. Before commencing to prepare the toxine the virulence of the diphtheria bacilli must be tested by its effect on guinea-pigs. A procedure requiring less time has been advocated by MM. Roux and Yersin. This method consists in growing the cultures in a current of moist air. It must be borne in mind that in the preparation of antitoxin the bacilli of diphtheria are not used, but the substance caused by their growth,

the specific poison, caused by them, is used. Toxine thus prepared should be of such a virulence that one-tenth of a cubic centimetre should kill a guinea-pig weighing 500 grammes in from twenty-four to forty-eight hours.

Fränkel first rendered guinea-pigs immune against diphtheria by injecting pure cultures of the diphtheria bacillus which had been sterilized at 70° C. Since then Behring has recommended a mixture of toxine and Gram's solution of potassic iodide.

MM. Burger and Wasserman arrived at satisfactory results by growing a culture of the diphtheria bacillus in a bouillon made from the thymus gland. This culture had been exposed to a temperature of from 65° to 70° C., during a quarter of an hour.

The method which has given the best results is that used by MM. Roux and Vallard in their researches on tetanus. This method consists of the addition of three parts of Gram's solution consisting of iodine one part, potassic iodide two parts, and water three hundred parts to one part of the toxine. The injection is to be repeated after a few days, and either the dose of the mixture must be increased or the proportion of Gram's solution diminished. A little later the toxine can be given pure. It is sometimes necessary to omit the injection for a time, if the animal is losing in weight.

Dogs have been rendered immune against diphtheria by many experimenters, among the number Bardach and Aronson. Sheep and goats are quite sensitive to the action of the diphtheritic poison. The immunization of milk animals, as cows and goats, is of particular interest from the fact that the milk of these animals has a certain antitoxin power.

Of all the animals capable of furnishing great quantities of the anti-diphtheritic serum, the horse is the most easily rendered immune. He bears the toxine much better than any of the animals to which allusion has just been made. By injecting gradually increasing doses of the toxine at various intervals, the horse in two months and twenty days is rendered immune; that is, he can receive from 200 to 300 c. c., according to his weight, of toxine of definite strength without disturbance. The serum from this animal has a protective power of 50,000, that is to say, a guinea-pig resists the inoculation of one-half a cubic centimetre of a virulent diphtheria culture if it receives, twelve hours previous, an injection of the antitoxin equal in amount to a fifty-thousandth part of its weight. The curative action of the antitoxin has not been satisfactorily explained, but it appears from numerous experiments that this agent does not destroy the toxine, but that its remedial power is due to stimulation or some other special action on the tissue cells.

In some of the experiments made for testing the action of antitoxin, diphtheria was caused in female guinea-pigs by rubbing pure cultures of diphtheria bacilli on the excoriated surfaces of the vulvæ. In these cases the pigs recovered if the serum was injected before the inoculation, otherwise they died. A membrane was formed, at the point of inoculation, but there was very little constitutional disturbance. After the second day the false membrane became detached and repair of the mucous surface commenced. In these experiments the protected animals received one ten-thousandth part of their weight of serum.

The most interesting experiments to the physician were those in which guinea-pigs and rabbits were inoculated in the trachea. Guinea-pigs inoculated in this way died in three days, if not protected by the serum. When inoculated with diphtheria cultures, after having been injected with the serum, they did not contract diphtheria, if the dose was sufficiently large. The animals injected with toxine, after the serum treatment, gave no evidence of diphtheria. The presence of streptococci with diphtheria bacilli had an injurious effect on the action of the serum. Cases of this nature did not improve under the treatment because the cells depressed by the poison of the streptococci did not respond to the action of the serum.

In February of 1894 after the beneficial effects of antitoxin on animals had been proved, as the preceding brief *résumé* shows, the treatment of diphtheria by this method was commenced in the Children's Hospital in Paris. During the four years from 1890 to 1893, inclusive, in this hospital, 3,971 cases of diphtheria were treated, with a death-rate of 51.71 per cent. From February to July 24, 1894, 448 cases were treated, by antitoxin, with a death-rate of 24 per cent., a diminution of more than one-half. It should be said that all the cases treated by this method were extremely severe in their nature. It must also be borne in mind that in many of the cases there was in addition to the diphtheria infection a streptococcus infection which, as has been shown, has a nullifying effect on the action of antitoxin. The effect on the local lesions in the throat was similar to that observed in the experiments on guinea-pigs. MM. Martin and Chaillon have found, that of 120 children treated by antitoxin, 54 did not have albuminuria; 12 had this symptom one day, and 54 had it during the whole course of the disease. It seems, therefore, evident that the use of the serum diminished the action of the diphtheria poison on the kidneys, and therefore considerably diminished the frequency of albuminuria.

In the Children's Hospital in Berlin from 1891 to 1893, there were 1,081 cases of diphtheria treated, with a mortality of 38.9. From the commencement of 1894 to March 14th, 86 cases were treated with antitoxin, and the mortality has fallen to 13.2 per cent. Since the middle of March, 1894, according to the statement of Virchow in *La Semaine Médicale* of December 12, 1894, 303 of 533 cases of diphtheria admitted to the hospital were treated by antitoxin, with a death-rate of 13.5 per cent. Of the 230 who were not treated by the serum 47.82 per cent. died.

The following table compiled by Dr. Sims Woodhead shows the result of treatment by antitoxin in different cities. The whole number of cases treated was 2,237, with an average percentage of deaths of 20.2. The average percentage of deaths in cases reported to the Board of Health of Boston for the past ten years is 29.38. When the percentage of deaths from diphtheria in Boston for 1893 is compared with the average percentage in Woodhead's table, it is found that there is a diminution of 12.29 in cases treated by antitoxin, the former rate being 32.49 and the latter being 20.2. It will also be seen, from this table, that the percentage of deaths when antitoxin was not used was 45.6, while that where antitoxin was used was only 23.95, a diminution of nearly one-half.

So far as is known, there has been no injurious effect from the use of antitoxin. In some instances there has been a slight redness about the region of the injection; but this has not been sufficient to cause any annoyance. In a few cases a slight general erythe-

matous blush has appeared, which disappeared in a few hours; and in some instances there has been a marked attack of urticaria.

Dr. Morrill, in the *Boston Medical and Surgical Journal* of January 24, 1895, says that in the Children's Hospital, for the purpose of securing immunity, 50 children were given five cubic centimetres of antitoxin. In no instance was there any injurious result following the injection. Urticaria was noticed in four instances; slight diarrhea in seven; temporary increase in micturition in nine; anorexia and slight vomiting in four; well-marked tenderness over the site of the injection in two; erythema around the puncture in three. In one case 45 cubic centimetres were injected, but the child died sixty hours after the first dose. The autopsy proved that the patient died from a broncho-pneumonia and that the death could in no way be attributed to the injection.

RESULTS OF SERUM-THERAPY IN DIPHTHERIA.

A few words should be said regarding the manner of using antitoxin. In order to arrive at any satisfactory conclusions, it is all important that in every instance where antitoxin is used, there should be a bacteriological examination of the throat. It is also important that the urine of the patient should be examined for albumin before and after the injection. The dose for procuring immunity, according to some observers, is three cubic centimetres for any age over three years, and a half of that for younger children. For a cure of the disease during the first two or three days, under two years of age, ten cubic centimetres; from two to ten years of age, fifteen cubic centimetres; over ten years of age, twenty cubic centimetres. After the third day, in a severe case, a larger quantity may be used with positive advantage. If the disease does not seem to be ameliorated by the first dose a second should be given in twelve hours.

Roux states that his practise has been to give twenty cubic centimetres of serum to each patient on admission to the hospital, and the same quantity, or half the same quantity, according to the severity of the case, twenty-four hours afterward; and if the pulse and temperature still remain high, the same dose is repeated. He also adds that the smallest dose that he ever gives, in the first stage of the disease, is twenty cubic centimetres, and frequently, in severe cases, two or three times as much. There seems to be no doubt from the accounts published abroad as well as from the experience in this city that antitoxin is a remedial agent, of very great efficacy, in the treatment of diphtheria; that it will cure every case has not been claimed, that it is particularly advantageous in cases of mixed infection where streptococci and diphtheria bacilli are associated, has not been proved; but that it is an invaluable agent for the treatment of diphtheria has been abundantly shown.

One advantage of the treatment is, that after the injection into the back or abdomen there is no interference with the patient; no swabbing of the throat; no tearing of the mucous membrane. It is stated that even in the worst cases that proceed to a fatal end, there is a marked amelioration in the suffering; that the dyspnea is relieved to a certain extent. If the patient dies, his death is comparatively painless.

In regard to the kind of syringe that should be used, it must be said that the common subcutaneous syringe is not adapted for the purpose, because it cannot be properly sterilized by heat. Koch's syringe, which consists of a detachable rubber bulb, a glass barrel and a needle, is the most satisfactory instrument for this purpose. The barrel and steel needle can be put in a test-tube in the bottom of which a little cotton is placed, the tube plugged with cotton, and then put in the oven of a cooking-stove and kept at a temperature of 150° C., for half an hour or more, or until the cotton is slightly singed. A syringe prepared in this way will remain sterile for four or five days.

In conclusion it may be said, that antitoxin has now been in use for about one year, and that to-day the reports regarding its remedial power are made more favorable than they were ten months ago. It is, therefore, self-evident that in antitoxin we have an agent, that, while it will not cure every case of diphtheria, will have a very marked and decided effect in diminishing the death-rate from this disease.

## CRITICISM ON THE USUAL METHOD OF MEASUREMENT OF CHEST-EXPANSION IN LIFE-INSURANCE EXAMINATIONS, AND STETHOKYRTOGRAPHICAL STUDIES OF THE BILATERAL EXPANSION OF THE CHEST.

BY RICH. HOGNER, M.D., BOSTON, MASS.

MEASUREMENTS of thorax circumference on inspiration and expiration have a long time played a certain rôle in determining the condition of the lungs; but they have been put to no more universal use than in life-insurance examinations, where, as a rule, they have been and yet are compulsory.

The life-insurance companies have their questions to be answered by the examiner, such as: "Girth of chest under vest, forced expiration? Same, forced inspiration? Circumference of chest on full expiration In forced inspiration? How many inches does the sub-

ject measure without coat, round the chest, at the armpits, during forced inspiration and expiration? Is the expansion of the chest normal?" etc. These questions must be answered with exact figures or with more or less varying replies, such as, "of normal condition," "of ordinary expansion," or a simple "yes" or "no" — words usually clear enough, but in this case leaving altogether too much scope to individual opinion. In any case the answer must be based upon some kind of measuring, either with an instrument (measuring-tape, spirometer, thorakometer, etc.), or by the eye.

The above quoted questions seem to have gained favor the world over, for they are common to the Old and to the New World's most celebrated life-insurance companies; and yet they are far from being satisfactory, for what physician does not know that the changes in the lungs most to be feared, the tuberculous, begin in the apices (therefore high above the nipples, and considerably over the plane of the armpits), also that the total (that is bilateral) capacity may be "normal," while a greater or less part of the lungs is functionally incapacitated? The respective questions, therefore, involve too little, but they could not well be phrased otherwise, in view of the methods at present used.

As to these the thorakometer and compass, also the spirometer and pneumatometer are impractical, while the latter two are in some cases injurious to the health; for which reason the measuring-tape is generally used, which, however, cannot be comfortably and reliably placed any higher than the level of the nipples or thereabouts. Because the measuring-tape — which is unsatisfactory — cannot be placed higher than in one plane of the lungs which has so little to do with tuberculosis that it is only attacked in the last stages, the companies have inquired after the condition of the chest at this level, concerning which physicians waste their time in answering. By what has already been said, it can be seen that tape measurements of the "chest's deepest inspiration and expiration" are illusive and should not therefore be employed, especially in such an important examination as that in question. If one may draw conclusions from an unreliable method, the life-insurance company has to take greater risk and the insured person secures less justice. With life-insurance companies, the rule which governs shoemakers cannot apply: "that the certain pay for the uncertain"; but as a result of present measuring — methods of the expansion of the chest — it happens not infrequently that some of the insured ones receive "a clear paper," which is not deserved, while others get "a poorer certificate" than they should justly receive.

I may be permitted to add further criticism on the method of employing measuring-tapes in examination of the chest expansion.

The method of this measuring with the tape is, as is well known, to place the tape around the "patient's" thorax, from behind, forward, at the height of the nipples; to adjust it as it lies horizontally or somewhat symmetrically on corresponding points, and with the ends or points of contact so placed on the breast, that making fast the zero point, one can at once read its expansion upon the graduated tape. While the examiner tries to hold the tape with an even tension, the person examined breathes in and out as vigorously as he is able, whereupon the band or tape adapts itself as well as it is possible for it to do. The "patient" must, of course, stand as immovable as a statue and in some certain position, but there is no existing rule for this. He is allowed to raise one or both shoulders; bend his head — like a Chinese porcelain image — back at inspiration, forward at expiration; hold his hands on his hips, or let his arms hang down loosely; if only he will stand still and sigh — the deeper the better — without the examiner appearing to have the least idea what great differences of results occur in different positions. But, furthermore, it sometimes happens that with "weak eyes" and poor light, the examiner, after the deep inspiration has been made, moves one hand in order to fix the maximum point with the fingers, and then after the deep expiration, moves the other hand to fix the minimum point, in order after the band has been removed, to read between the fingers in some better lighted part of the room the difference between inspiration and expiration. Can any greater uncertainty in a physical method be imagined, any greater lack of scientific exactness?

He who has undergone observingly, such a measuring of the chest's power of expansion, has not failed to feel the uneven pressure of the measuring band at inspiration and expiration, owing to the fact that the examiner nearly always holds the band more loosely at inspiration and draws it more tightly at expiration, unconsciously suggesting that it is meant for the company's sake (if done in a life-insurance company's interest) and for the applicants to obtain the greatest possible difference; a phenomenon somewhat like "table moving," when the predisposing thought "it must move" is the power that unconsciously sets both arm and hand muscles and consequently the table in motion.

The *first* defect in tape-measuring is, therefore, that it lacks an unvarying, unbiassed pressure.

The *second* lies in the fact that the tape band often glides more or less easily, according as the skin is smooth or rough, dry or moist, in which latter case, it sometimes will not move but presses the skin.

A *third* defect is that the tape-measurement only records the bilateral total chest-girth. Therefore, one cannot measure the right and left side at the same time each by itself; and yet this is often necessary, for reasons easily understood. Who has not had experience with the vicarious functions of the organs, or how if one organ is sickly or weakened, its mate works so much the harder? For instance, in the case of inflammation of the lungs, the well lung becomes overworked for the sake of the sick one, etc. Therefore, by the use of the measuring-tape, one can easily gain a great bilateral difference between inspiration and expiration, displaying thus a great sum of capacity even when the expansive power of one lung is lowered, but when the well lung was obliged to bear so much greater share of the burden of respiration and to work so much more. To seek to measure the power of dilatation of the two halves of the chest with the measuring-tape, first the one from the processus spinosus to the middle of the sternum, and then immediately after the other half, and then to compare the results so obtained, is in the highest degree uncertain (even if the almost impossible case should arise in which every tape-measurement should be accurate); for what guarantee is there that one breath is drawn precisely as deeply as another. It is more probable that

after a very deep first breath, the lungs are in a sort of apnoe, and the one following is so much the more superficial (because the necessity for respiration this second time, thanks to O-surplus, is so much less); and the second tape-measurement in this case gives too low a result.

The custom of measuring on a level with the nipples seems passing strange, just as one is surprised that in many blanks, not a word is to be found about the height at which the measurement shall be taken, precisely as if it made no difference about the plane.

When we know that tuberculosis first attacks the apices, and that the more diseased a part of the lung is, just so much more the healthier parts must work, it is easily understood that the coefficient of expansion on the mammillary plane will be, not only relatively too high, but also, perhaps, really greater where there is a mild affection of the apex of the lung than if the person in question were healthy. A great degree of expansion in the mammillary plane may, therefore, be rather a "memento" than a proof of healthy lungs. Why then not take the measures upon the supra- and infra-clavicular regions, or in their immediate vicinity? Simply because it cannot be done with the measuring-tape. The forward springing posterior and anterior axillary folds are so many hindrances for the measuring-tape, which it cannot gauge so easily as the smooth path round the mammillary plane, and carries the measuring-tape sidewise, upward against the upper chest aperture; the tape rolls up more or less, or "cuts in" under the arms and is hindered then in its movements; so that, even if the measuring be not wholly impossible, it will be at least more unreliable.

From this it will appear that the method of measuring the chest-expansion with tape is to be rejected. It does not conform to the exact requirements of science, and therefore should not hold the prominent place it does at present, in so many cases of chest measurement, namely, in life-insurance examinations. There is no doubt, on the contrary, that measurements of the thorax expansion may be of great service in making a perfect diagnosis for the final decision as to the condition of the lungs, if only a practical and reliable method of examination were adopted. I have, therefore, sought to construct a little autographic instrument which might possess the advantages denied to the measuring-tape, namely, the stethokyrtograph, the description of which is to be found in the *New York Medical Record* of the 8th of March, 1894, to which you will permit me to refer you.

If it has been demonstrated that the tape, in measurements of the chest-expansion, as a rule, gives unsatisfactory and unequal results, it cannot, however, be denied that an experienced hand may in favorable cases get results approximately good enough to control other measurements. After a number of tape-measurements (for the purpose of getting the right sense in the hands), I have, therefore, made the following comparative measurements between the tape and the stethokyrtograph, in order to test the accuracy of the latter.

### COMPARISON BETWEEN THE RESULT OF MEASUREMENT OF CHEST-EXPANSION WITH THE MEASURING-TAPE AND WITH THE STETHOKYRTOGRAPH.

It can be set down *à priori* that a critical and conscientious measuring of the chest with the measuring-tape will give a lower result than with the stethokyrtograph, for, as has been before maintained, the measuring-tape clings more or less to the body, and so has even on a dry skin a greater resistance to overcome than the gimp which with the exception of the back, comes only tangentially into contact with the fourteen small metal discs.

On the other hand, the stethokyrtograph would seem to give too high a result, because the gimp slides on the discs three, five, seven or nine millimetres distant from the surface of the body. The weight of the cylinders often presses down the discs into the skin and lessens the height; a large part of the gimp nearly touches the skin of the chest; the "ends of the chain," the two stationery discs, lie lower than the nearest movable discs; the gimp cuts into the back more than glides; all of which conditions, however, clearly reduce the apparently too great result obtained by the use of the stethokyrtograph.

If the results of the measuring-tape, often too low,[1] be compared with those of the stethokyrtograph, the latter are found to be just as much higher as one would suppose the correct ones to be. Also, if the results with the stethokyrtograph should have been too high, this signifies nothing. The most important point is that they give reliable comparisons of the two halves of the chest, between the respective expansive capacities of the lungs; and this they seem to do.

A computation from Table 7, "Comparison of Bilateral Measurements, etc.," shows that the results with the stethokyrtograph were as follows:

MALES.

| | | |
|---|---|---|
| In 16.2% cases, | . . . | .5– 9 mm. less than with tape. |
| 2.7% " | . . . | the same as with tape. |
| 56.7% " | . . . | .5–10 mm. greater than with tape. |
| 13.5% " | . . . | 11.0–20 mm. " " |
| 8.1% " | . . . | 22.0–27 mm. " " |
| 2.7% " | . . . | 36 mm. " " |

FEMALES.

| | | |
|---|---|---|
| In 23.8% cases, | . . . | 1.0–11 mm. less than with tape. |
| 0.0% " | . . . | the same as with tape. |
| 31.0% " | . . . | .5–10 mm. greater than with tape. |
| 34.5% " | . . . | 10.5–19 mm. " " |
| 3.4% " | . . . | 26 mm. " " |
| 3.4% " | . . . | 31 mm. " " |
| 3.4% " | . . . | 44 mm. " " |

Or collectively, with 66 comparisons of 37 males and 29 females:

| | | |
|---|---|---|
| In 19.7% cases, | . . . | .5–11 mm. less than with tape. |
| 1.5% " | . . . | the same as with tape. |
| 45.5% " | . . . | .5–10 mm. greater than with tape. |
| 22.7% " | . . . | 10.5–20 mm. " " |
| 6.0% " | . . . | 22.0–27 mm. " " |
| 3.0% " | . . . | 31.0–36 mm. " " |
| 1.5% " | . . . | 44 mm. " " |

The stethokyrtograph's superiority has thus been in 45.4 per cent. cases .5–10 millimetres; or, if one will, in 68.1 per cent. cases one centimetre on the average, depending certainly on its superiority in sliding.

Convinced of the reliability of the stethokyrtograph by thousands of measurements with it, I will now quote only the results of these measurements in

### THE BILATERAL (TOTAL) CHEST-EXPANSION.

The results have been arranged in tables,[2] in order to facilitate reference to them, Nos. 1 and 2 containing 517 persons each (of whom 315 are men, 202 women). Nos. 3 to 6 each contain 636 persons (401 men, 235 women) of varying ages, from three years to nearly ninety years; of unequal height, from that of the dwarf to that of a giant almost; also of different

[1] This is only a question of the critical and self-evident examinations.

[2] For lack of space, the tables, with one exception, have been omitted.

occupations, though the majority of them belonged to the country population. As lung-tuberculosis has been uppermost in mind, the persons have been placed in four principal groups, according to the condition of the lungs, namely: "Sound," "Sound, with prolonged sound of expiration," "Infiltration" and "Consumption." By which is meant that the "Sound" are persons in whose lungs the sound of respiration (in the apices) was softly vesicular and the sound of expiration shorter than that of inspiration; "Sound, with prolonged sound of expiration" are those whose breathing has the same sound as the foregoing group, but in which the expiration sound was at least as long as that of inspiration. Both groups have, as a rule, been "easy-breathing," have not lost breath from running, climbing stairs, etc. The group "Infiltration" includes cases where the sound of respiration — especially expiration — was rough or harsh, the expiration prolonged, and breathing not so easy as in the foregoing groups. Under "Consumption" have been classed those with pneumonia chronica, those with more or less advanced phthisis pulmonis. Other chest diseases, such as chronic bronchitis, heart-failure, a couple of cases of pleuritis, etc., have been met, but were so few in numbers that on the whole they signified little. They have been grouped according to the above principles.

It is scarcely necessary to add that all who have been examined have had to take the position necessary to the use of the stethokyrtograph, that is, they have stood immovable, with the head bent forward, hands resting lightly on the hips, shoulders still, etc., and the breathing has been "deep and slow," as deep as possible without changing the position of the body in any respect.

On examining Table 1, we see the 517 persons divided into six groups, according as the expansion of the chest in the "subclavicular plane" was 80 mm. or more, 70 to 79.6 mm., 60 to 69.5 mm., 50 to 59.5 mm., 40 to 49.5 mm., or under 40 mm., independent of the condition of the lungs.

Few persons (18, or 3.5 per cent.) belong to the first group, of greatest expansion, with ages ranging from eight to sixty years, and the height from that of a child to the average of an adult. No height of 180 cm. or above (5 ft. 11 in. or above) has appeared in this group, neither has any consumption. The majority of persons having the lungs "Sound, with prolonged sound of expiration" are of average height, 170–179.5 cm. (5 ft. 7 in. to 5 ft. 11 in.), and mostly young or in early middle age, that is, from fifteen to twenty or thirty to thirty-nine years old. Of the eighteen here only one was a woman, of good average height and in her "best years."

The next group, 70 to 79.5 mm., contains 27 persons, or 5.2 per cent., mainly like the foregoing group, with the addition that very tall persons (180 cm. or more) are found represented here.

The third group, 60 to 69.5 mm., includes 80 persons, 15.5 per cent. of all examined — persons of all ages, all sizes and of all conditions of the lungs.

The three remaining groups, 50 down to less than 40 mm., with about 25 per cent. each of the number examined, also include persons of all ages, sizes and conditions of lungs.

The question of the expansion of the chest can be answered, according to Table 1 thus:

The greatest chest-expansion in the subclavicular plane, 80 mm. or more ($3\frac{1}{8}$ in. or more), does not accompany developed consumption, and only in exceptional cases "infiltration."

A chest-expansion on the subclavicular plane of 70 to 79.5 mm. ($2\frac{3}{4}$ to $3\frac{1}{8}$ in.) does not accompany developed consumption, but is not infrequent with "infiltration."

A chest-expansion on the same plane, below the last-named limit, can, on the contrary, be met in the perfectly "sound" as well as in those with consumption.

Concerning chest-expansion in the mammillary plane, it may be seen by Table 2 that on the whole it resembles the subclavicular plane, only being upon an average about 10 to 15 mm. higher, according to the anatomical form of the chest, in the majority of cases.

The numbers in the higher groups have, therefore, increased, while those of the lower groups have decreased correspondingly.

In the highest group 80 mm. or more ($3\frac{1}{8}$ in. or more), there is, therefore, no consumption found, but very tall persons (180 cm. or over, 5 ft. 11 in. or over) have gained entrance into this group. The number with "infiltration" has increased.

The next group, 70 to 79.5 mm., contains, on the contrary, several with consumption, and also persons of all ages, sizes and conditions of lungs, precisely like the remaining groups.

The question of the expansion of the chest on the mammillary plane, can, according to Table 2, therefore be answered thus:

The greatest chest-expansion on the mammillary plane, 80 mm. or over ($3\frac{1}{8}$ in. or over), does not accompany developed consumption, but is not infrequent with "infiltration."

A chest-expansion on the mammillary plane, below the last-named limit, can, on the contrary, be met as well with the perfectly "sound," as with those having consumption.

Table 3 shows only that the plurality of chest-expansions belongs to the smallest sizes, 40 to 69.5 mm., but as a rule, higher numbers for men than for women. A noteworthy exception, however, appears in the group of men fifteen to nineteen years old, "Sound, with prolonged sound of expiration," where, in the sub-clavicular plane, a chest-expansion of 80 mm. or over appeared in not less than about 25 per cent. of cases, and in the mammillary plane on the average, an unusually high expansion figured. In the remaining groups, such a high record of expansion has seldom appeared.

Table 4 shows how infinitely varying the total chest-expansion can be in the same group of persons, and in the subclavicular as well as in the mammillary plane; it shows us the records of the lowest limit so low that we might think they represented only the lightest breathing (and yet the examined ones have done their best to breathe as deeply as possible without changing the position of the body), while the figures of the highest limit are so high that they rival the high figures uncritically so often obtained with the measuring-tape. There is no doubt that some of the lower figures could have been raised, if the patient had practised "breathing after command," for many persons seem to find difficulty in breathing calmly and deeply while the physician stands ready to measure the expansion of the chest; but in reality these measurements have been made under the same conditions as

the usual life-insurance examinations, and have, as a rule, been made without previous training of the patient. Besides, there is a class of persons who seem to have a very slight expansion of the chest, even when the condition of the lungs is good; for instance, the very fat, because with them, chest-expansion has been constantly and unexpectedly small, in men as well as women. One often gets the impression from their breathing that they prefer to increase the frequency rather than the depth of their respirations, and that habit finally prevents them from breathing deeply or expanding the chest appreciably which is intensified by a certain change to fat of the outer muscles of respiration *in modo circuli vitiosi*.

It may be specially stated that the lowest chest-expansion never accompanied consumption, either in the subclavicular or mammillary plane; and as to the figures recorded in consumption, they are not so low, and many times are as high, especially in the mammillary plane, as for "Sound." The greatest chest-expansion that has occurred in the subclavicular plane, 104.5 mm. ($4\frac{3}{16}$ in.), was that of a professional runner, especially interesting because his lungs gave out a respiratory sound far from normal physiologically. The man had trained his lungs, and what was lacking in quality was supplied by the quantity of vesicular working capacity. The highest figures in the subclavicular plane have belonged to the group "Sound, with prolonged sound of expirations," and nearly always at all ages (to this belonged the case quoted above), depending, as probably indicated, upon the fact that while these persons are "sound" in their functions, and the demand on the lungs is in proportion thereto, nature compensates the little change which is here represented by "prolonged sound of expiration" by allowing the chest — that is, the lungs — hyperdilatation, as it were, and for day after day. A portion of the lung having a physiological sound of respiration, the expiration shorter than the inspiration, would, for lack of exercise, not be expanded so excessively, as a rule, as a portion with vesicular respiration but with a "prolonged sound of expiration," at least, not before training had come to help it. This tendency to increase the chest-expansion seems to continue so long as the part of the lung beneath is not too diseased. For we constantly find it, as before stated, in the subclavicular plane, for the group "Sound, with prolonged sound of expiration," and quite often in the group "Infiltration"; whereas in the group "Consumption," although the disposition is certainly to be noticed, it is not sufficient for so great expansion of the chest as in the best cases of the preceding groups.

Looked at broadly, the same tendency is detected in the mammillary plane. In the group "Sound" one often gets higher figures than in the subclavicular plane (corresponding, one might think, to the anatomical form of the chest), and therefore in the groups "Sound, with prolonged sound of expiration" and "Infiltration," often higher figures than in the first named; but what is still more noticeable is, the high figures in the mammillary plane for the group "Consumption" show that the chest-expansion was just as high, sometimes higher, than for "sound" persons of the same age.

As to the relation of chest-expansion in the subclavicular and mammillary planes, the latter has generally been 10 to 20 mm. greater in the same person. It has happened often enough, that persons have been found having dilatation in the mammillary plane less than in the subclavicular; and it has often happened that a renewed examination gave the same results, but not infrequently it has depended on the fact that the patient was tired after the first examination, which was always the one in the subclavicular plane. The figures in Table 4 do not always correspond, therefore; and probably the figures in the mammillary plane would often have been 10 to 20 mm. higher if the examination had begun in that plane. The greatest chest-expansion (106.5 mm., $4\frac{3}{16}$ in.), was that in the mammillary plane of a "sound" averaged-sized soldier thirty-two years old, with unusually fine chest, and not especially trained lungs.

Moreover, the tables show that during childhood is established — because of the more movable chest — a comparatively greater chest-expansion; also that a great expansion of the chest may remain (80 mm.) even to the early years of middle life.

By Tables 5 and 6 it appears that the average chest-expansion is not great, and that the difference in the various groups is not so great as *à priori* one would expect. If the chest expansion in the subclavicular plane for groups "Infiltration" and "Consumption" — which have mostly shown 40 to 49.5 mm. — are excepted, then in the rest of the cases the expansion in both planes, on an average, has been 50 to 59.5 mm., with distinct tendency, to be sure, for the consumptives to fall below these figures in the mammillary plane, even. As we have already seen by Table 4, the expansion of all groups fluctuates considerably, above and below these limits. From Tables 5 and 6 it is further seen that the chest-expansion of women in all groups has been, as a rule, lower than of men, which has not prevented some exceptions here and there.

Regarding the expansion of the chest or the bilateral differences between dilatation of the chest with deep inspiration and expiration, as I have already in some regards shown in an article in the *New York Medical Record*, March 3, 1894, p. 264, they seem to vary within considerable limits, in the subclavicular plane from 14 to 104.5 mm. in the groups "sound" and "sound, with prolonged sound of expiration," also from 14 to 81 mm. in the groups "Infiltration" and "Consumption"; and in the mammillary plane from 17 to 106.5 mm. in the former groups, and from 85 to 91.5 in the latter.

The expansion, however, has been in the most of my 517 cases in the subclavicular plane only 50 to 59.5 mm. in the two first groups, and 40 to 49.5 mm. in the second two groups; and in the mammillary plane respectively 50 to 69.5 mm. and 40 to 59.5 mm. The measurements were taken only on Swedes.

The result of these studies of bilateral or total chest-expansion is this, that one cannot, as a rule, draw any conclusions about the condition of the lungs from measurements of the bilateral girth of the chest at the time of deepest inspiration and expiration, or from measurements of the total chest-expansion in some certain plane, be they made on the subclavicular or the mammillary plane, and that such measurements, therefore, should not be taken into consideration in life-insurance examinations, and least of all should they be used as the basis of judgment as to the applicant's place in the "risk scale." The only measurements of the bilateral or total size of the chest which

ought to exist, and which, therefore, ought to be introduced, are in my estimation, those as well in the plane of the axillary folds as in the mammillary plane (or at least in the latter), while the chest is at rest, that is to say, during the faintest respiration; because these measurements give a certain idea whether the normal proportions of the body are ascertained or not, precisely as so often happens in the present life-insurance examinations, that the abdomen is measured to see if it corresponds to the proper proportion between abdomen and body's length, etc. For such measurements the tape is adequate, if critically and carefully used; just as surely it is to be condemned in measuring the expansion of the chest.

If the bilateral (total) measurements of chest-expansion have been cast aside as meaningless, then it remains to investigate whether the "contemporary unibilateral," that is, the "simultaneous single and double-sided" measurements can be of any practical value; but that subject may be left for another paper.

## VAGINAL HYSTERECTOMY AFTER MARTIN'S METHOD.[1]

BY HOWARD A. LOTHROP, A.M., M.D.

VAGINAL hysterectomy is now recognized as a perfectly legitimate operation, and is generally acknowledged to be the most desirable mode of procedure in certain cases, hence, most gynecologists are accustomed to practise one or other of the various methods devised for the vaginal extirpation of the uterus. The earliest operation was performed by the elder Langenbeck; but this route for uterine extirpation failed to receive much attention until 1878, when Freund established certain methods of procedure which still serve as the basis for this operation, although different operators have devised more or less radical modifications.

Having had an opportunity to observe the methods of some of the most skilful operators, the technique adopted by Martin, of Berlin, appears to me as possessing the most advantages, and the reasons for my conclusion I shall hope to make clear later. His early cases date from 1880; but at that time this operation was tedious and attended with considerable risk to life, either from hemorrhage during the operation or from sepsis soon after, while the statistics were far from being encouraging. As performed at the present time by Martin himself, this mode is the most rapid, attended with the least hemorrhage and fewer accidents during the operation, and less liable to be complicated by septic infection during convalescence, than any method I have had the opportunity to follow. My sources of information for this communication, are personal observations and Martin's publications.

The indications for uterine extirpation, according to Martin, I will briefly enumerate as follows:

(1) Carcinoma of corpus or cervix.

(2) Sarcoma.

(3) Adenoma.

(4) Certain cases of prolapse not amenable to other less radical mode of treatment.

(5) Also, wherever the patient becomes a chronic sufferer, or runs the risk of losing life by the non-removal of the uterus, as might occur in: *a*, persistent uterine hemorrhage; *b*, dysmenorrhea persisting in spite of all attempts for relief; *c*, myomata; *d*, certain suppurative conditions of the uterus; *e*, certain cases of rupture of uterus in connection with pregnancy, or as the result of a necrobiotic change.

If feasible, the vaginal route should be chosen; but if not practicable, we should resort to the abdominal method.

The contraindications for vaginal hysterectomy are:

(1) Extension of malignant disease beyond the uterus.

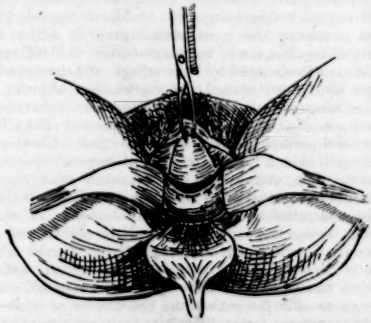
(2) Large size of that organ, particularly if rigid and not pliable; and these points must be determined by the examiner for each individual case.

(3) Presence of adhesions between uterus and other pelvic organs, which render extirpation difficult and wearisome, and may interfere with convalescence, as being the source of hemorrhage and oozing; and furnishing a nidus for a septic infection.

To this last group belong more than fifty per cent. of Martin's fatal cases; and the improvement in his statistics of late is, in part, due to the fact that he is less prone to operate on these cases per vaginam. Hence, given a case where extirpation is indicated, Martin would choose the vaginal route as most appropriate for some cases, the abdominal for others, and the question of choice would depend on his judgment, there being no hard and fast lines to serve as guides.

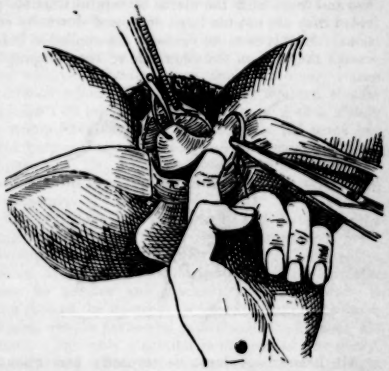
### PREPARATION FOR OPERATION.

On the day before operating the patient should take a warm bath, and a suitable cathartic should be administered. Before undertaking such an operation, all patients should be carefully examined while under the influence of some general anesthetic, in order to determine the exact condition of the pelvic organs, particularly as regards the size of the uterus, the presence of adhesions, and the possibility of any further complications which would contraindicate a vaginal hysterectomy. This opportunity should be taken advantage of, and the vagina carefully cleansed with soap and water and weak antiseptic solutions. All ulcerations of the cervix should be carefully curetted and cauterized if necessary, so as to remove as much source of infection as possible, and then the vagina should be packed with iodoform gauze, which is to be retained until just prior to the operation. If the endometrium is in a septic condition the uterus should be carefully curetted.



Just prior to the operation on the following day, the rectum should be carefully cleansed by enemata, and the anesthetic administered. At this time the vaginal tampons (if any have been introduced) should be removed, and the vulva and vagina made as aseptic as possible by the use of weak antiseptic solutions. The bladder is not to be emptied, but is to remain distended with urine until the operation has been completed.

The only necessary instruments are the following: one perineal and two lateral retractors (after Martin's pattern), two pairs of so-called "bullet forceps," one pair long curved scissors, one pair long-toothed dissecting-forceps, needle-holder, several strong curved needles of different sizes, and a scalpel, catgut of large size serves for ligatures and ties. In addition, a douche apparatus should be arranged on the fountain plan, so that a very small constant stream of boiled water or a solution of corrosive sublimate (1–20,000), can be made to play over the field of operation, the advan-



[1] Read before the Obstetrical Section of the Suffolk District Medical Society, January 23, 1895.

tage of which will be mentioned below. No sponges or clamps of any sort are ever used, thus saving much time and annoyance. There should be three assistants in addition to the one administering the anesthetic.

All hands and instruments having been rendered aseptic, the vulva and vagina as nearly so as possible, the patient is put in the lithotomy position facing a good light. The operator takes his seat in front. While the assistant on the patient's right attends solely to the perineal and right lateral retractors and corresponding leg, the assistant on the left looks after the left lateral retractor with his left hand, while the right holds both the nozzle of the fountain syringe and the "bullet forceps" which have been attached to the cervix, thus constantly irrigating the field of operation and exerting traction on the uterus as may be desired. The hands of the third assistant are free to pass instruments, thread needles, and attend to any wants of the operator that may arise. This small current of water does away with sponges, and many of the operations appear almost bloodless.

The retractors having been properly placed, the first step in the operation consists in applying the "bullet forceps" to the posterior lip, and, without any hesitation whatever, drawing the uterus as far out of the pelvis as possible, so that the cervix will rest on the pubic arch. This renders the field of operation readily accessible, and makes the posterior vaginal wall tenser, showing where the line of attachment of vagina to cervix is to be found. On this line, transversely, the first incision is made, which severs the posterior attachment of the vagina from the uterus. Under normal circumstances this incision would open the cul-de-sac of Douglas; but if there are adhesions, the operator should carefully work his way up between the uterus and rectum, keeping close to the former until the peritoneal cavity is opened. There will be no bothersome hemorrhage, provided the cervix uteri is strongly drawn forward and upward, so as to rest on the pubic arch, and the field of operation constantly irrigated, both of these duties being performed by the right hand of the assistant on the patient's left. The next step is the application of four or five catgut sutures, by means of a small strongly curved needle, to the severed end of the vagina. It is of the greatest importance that these sutures include the free edges of the peritoneum and vagina, as well as the connective-tissue between, the needle coming out about one centimetre from the point of entrance. Thus the hemorrhage is stopped at once, and the connective-tissue spaces shut off from the danger of infiltration. If there should be any hemorrhage from the uterine end of the incision, a large ligature is passed through the cut surface of the uterus, and the ends left long, so as to retract the uterus. Then with the cervix strongly drawn to the patient's right, the left forefinger, as a guide, is introduced into the fossa of Douglas, and sutures are firmly applied to the left side-wall of the vagina just distal to the cervical attachment, and the vagina severed close to the cervix, a small amount of tissue being cut with the scissors after each suture has been applied. Just as was done posteriorly, the peritoneum and vaginal wall are closely approximated. The deeper sutures on the side should be very carefully and firmly tied and left long, so that, after the uterus has been severed, this mass can be pulled down and be securely fixed between the free edges of the

peritoneum and vagina. The important uterine artery, which enters the uterus near the junction of the corpus and cervix, is then first securely ligatured and then severed. The right lateral vaginal wall is cared for in a similar manner; three or four sutures suffice for each side. The higher up in each side the uterus is severed, just so much easier it is to invert that organ later.

The anterior vaginal wall remains to be freed. To accomplish this the cervix is pulled out and down so as to render the parts tense. The lateral incisions are united by one passing around the cervix in front, along the line of vaginal attachment, keeping close to the cervix and merely going through the vaginal wall. With the finger, the bladder (now distended with urine), is carefully separated from the anterior surface of the uterus until the anterior cul-de-sac is reached, and then the peritoneum is opened, leaving the uterus suspended only by the lateral ligament. Peritoneal and vaginal edges are united just as was done posteriorly and on the sides, the bladder being carefully pushed forward and kept from injury; about four sutures serve this purpose.

All hemorrhage having been stopped, the finger is introduced into the posterior cul-de-sac, and the uterus carefully explored as regards size and the presence or absence of adhesions. If small and pliable, it can be readily rotated on the lateral ligaments, and the fun-

dus extracted through the posterior opening, merely by the use of the fingers, or aided by bullet forceps. If large and not pliable, this may be a very difficult part of the operation; and, as further aid, the posterior opening can be kept dilated by means of a spatula, so that traction on the fundus can be accurately applied by means of forceps, while the finger of the other hand pushes the cervix up behind the pubic arch. Pressure over the hypogastrium should never be resorted to.

Three ligatures, applied in the ordinary manner suffice to tie off the lateral ligaments from the uterus, thus completely severing it from its pelvic attachments. If only the uterus is to be removed, they should be applied close to that organ, which is then severed and the catgut left long, so as to control the free ends of the lateral ligaments. In the majority of cases, it is possible, if desired, to remove the ovaries and tubes with the uterus by careful traction, provided they are not too large or bound down by adhesions. In this case the ligatures are applied as before, except they are on the other side of these organs.

All hemorrhage must be stopped; and when assured that there is to be no danger from this source, the edges of the lateral ligaments are carefully pulled down even with the free edge formed by the peritoneum and upper end of the vagina, and then all these free edges united by a continuous transverse catgut suture. If viewed from the abdominal cavity, all we would see at the site of operation is a short transverse line, formed by the approximated surfaces of peritoneum, which readily adhere and serve as a barrier against infection; viewed from the vaginal end a small, puckered, wounded surface over which iodoform has been dusted. No tampon is left in the vagina, nor is any drainage-tube used; and on completing the operation, the patient should be catheterized for the first time.

During the operation the intestines are very rarely seen, and with care there is but slight risk of injury to the bladder or ureters. In well-chosen cases there is but slight risk of hemorrhage, which is apt to be very annoying in cases where adhesions have to be overcome. The secret of rapid and successful removal of the uterus by this method, depends largely upon the ability of the operator to handle the curved needle, while the work is made much easier by remembering the fact that the uterus can be drawn well toward the vulva.

The after-treatment is merely expectant and the danger during this period is that of sepsis. Unless called for by the general symptoms, the wound is not inspected until the fourteenth day, when the stitches, which have not been absorbed, are removed, while on the twelfth day the patient is allowed to leave the bed. A profuse secretion is the signal for vaginal douches. The catheter is used if necessary, and the bowels are moved on the fourth day by enema.

STATISTICS.

Comparative statitsics for different methods by different operators are of but little value as determining the merits of any mode of procedure. Some operate hopeless cases, others weigh the probabilities with the greatest of care before they will risk operation; some tabulate all their cases; others neglect to report failures. From 1880 to 1887, Martin removed the whole uterus per vaginam 106 times, with 14 deaths as result of operation; from 1887 to 1893, 153 times with 14 deaths. Of the fatal cases about one-half were due to sepsis, while embolus, shock, and broncho-pneumonia figure as the remaining more common cause.

Having seen different operators and various methods of vaginal hysterectomy, that of Martin appeals to me as possessing the most advantages. It is the most rapid, requires fewer instruments, the field of operation is not obscured by hemorrhage, and the cut edges are all turned toward the vagina, thus allowing for free escape of all exudation, while the approximated surfaces of peritoneum rapidly adhere and shut off the general peritoneal cavity from infection. Cases must be well chosen for any method of removal per vaginam. The uterus must not be much enlarged, and should be comparatively free from adhesions, otherwise the abdominal route should be selected. If malignant disease has extended beyond the uterus, any procedure is practically hopeless. Given a case where total extirpation is indicated, the vaginal method, when practicable, *as done by Martin himself*, seems to me to offer the patient the best chance of recovery, and to present fewer difficulties for the operator.

## Clinical Department.

### A SUCCESSFUL OPERATION ON A SPINA BIFIDA.

BY SAMUEL BAYARD WOODWARD, M.D., WORCESTER, MASS.,
*Surgeon to City and Memorial Hospitals.*

The large mortality of the surgical interference with spina bifida, whether by tapping, injection, ligation or excision, has been so discouraging that one almost confidently expects on the third or fourth day that gradual rise of temperature indicative of beginning infection of the meninges with its invariable termination.

Not infrequently either does everything apparently progress favorably for even seven or eight days, with the then insidious or sudden change for the worse and the soon following fatal ending.

The favorable issue of the following case under somewhat unfavorable circumstances leads me briefly to report it.

February 18th of this year, I was asked by Dr. E. L. Sawyer, of Barre, to see a child born under his care eight days before. An otherwise well-nourished, perfectly-formed male child had in the lower cervical

region a semi-transparent, thin-walled pediculated tumor the size of a baseball. The pedicle at its junction with the body about two inches in circumference, was covered with apparently normal skin, which also reached about an inch up the cyst wall on every side. The remaining wall was thin, translucent, and where it rested on the child's back discolored and apparently breaking down, while from a minute perforation at its most prominent part was oozing a watery fluid somewhat stained with blood. Pressure, carefully applied, lest the cyst should rupture prematurely, caused no disturbance, nor could the size of the tumor be perceptibly diminished.

As the sac was evidently about to rupture, there could be little question as to the proper course to pursue; and after a somewhat imperfect cleansing of the base of the cyst, chloroform was given, a trocar introduced, and about six ounces of fluid as clear as spring-water withdrawn. The thumb and finger being as closely as possible applied to the base of the cyst to limit the loss of cerebro-spinal fluid, and the child being also kept in a prone position, the sac was then laid open and examined. It was judged that the closure of the sixth and seventh cervical vertebræ was imperfect. With the exception of a small opening at the upper portion of the cleft from which when pressure was removed clear fluid exuded, this cleft was filled with a dark cord, which ran straight across the cyst cavity to the point where was the opening previously described. This cord was of the size of a lead pencil, and seemed to largely consist of blood-vessels, though from various points on its circumference ran in all directions minute nerve fibres to the cyst-wall.

Quilting sutures of silk, one of which surrounded the base of this cord were introduced through skin and sac at the base of the pedicle in such a way as completely to obliterate the cavity. The cyst and redundant skin were removed, and the resulting raw edges carefully approximated by numerous fine sutures. A voluminous dressing of baked gauze carefully bandaged on completed the operation and the child was left to the care of the trained nurse fortunately present. It is needless to say that instruments, hands and sponges were carefully sterilized.

The inaccessibility of this patient to Dr. Sawyer, eight miles from his house over roads almost impassable after the severe snowstorms of the winter, which had prevented him from seeing the mother after her confinement until he went there with me, caused his first visit to be made only on the third day, when the quilting sutures was removed, and his second on the eighth, when the superficial ones were taken away.

A note from the nurse, Miss McGill of the New England Hospital, informs me that the baby slept well, ate well, grew very rapidly, and gave no sign of disturbance from the wound in the neck. The temperature taken thrice daily, reached 101.5° twenty-four hours after the operation, and fluctuated between 99° and 99.7° until the removal of the stitches.

The child is now well, with no sign of the tumor beyond a slightly projecting ridge. Dr. E. H. Baker, of Worcester, who kindly examined the specimen, could find but little in the cord alluded to in addition to the vein and artery, which were of large calibre.

---

A WRITER in the *Southern Practitioner* for May, 1895, speaks of ovariotomy as the "emasculation" of women, evidently using the word in its secondary sense.

## Medical Progress.

### REPORT OF PROGRESS IN GYNECOLOGY.

BY F. H. DAVENPORT, M.D.

#### SUPRAPUBIC FIXATION OF THE UTERUS IN CERTAIN CASES OF RETROVERSION AND PROLAPSE.

DR. THOMAS KEITH [1] describes an operation for cases of intractable retroversion and prolapse which has proved efficacious in his hands. The uterus is pushed up against the abdominal wall with a sound, and a small opening made over the fundus a little larger than sufficient to admit the forefinger. Guided by the finger the right round ligament is seized by forceps, and slowly pulled up with the broad ligament until the ovary is reached. This is brought out with as much of the broad ligament as will come, and the pedicle drawn together by a small silk thread and tied. The stump being held by forceps, the abdominal wound is accurately closed with several sutures, care being taken not to strangulate the stump. This is dried with perchloride of iron, and the ordinary clamp applied on a level with the encircling ligature, so that the tissues do not spread out, and there is thus a slender stump left to separate. In none of the cases has there been a trace of hernia, and no wound has ever suppurated. Dr. Keith has done the operation 34 times, and his son, 17, and all the patients were cured permanently.

The advantages of the operation are, that the uterus being attached only by the right ligament has freer movement than by any other method; there is less risk to life, as there is no invasion of the cellular tissue by needles and stitches; and the fixation is more sure as the ligament is fastened into the wound, whereas simple peritoneal adhesions may become absorbed. The only objection is the loss of one ovary, but one ovary seems to be as useful as two. The right ligament is chosen, because if the left is taken there is generally more tension on the bowel. The advantage over the Alexander is, that the latter has only the round ligament to depend upon, while this has all the tissues that go to make up the broad ligament, and all covered by peritoneum.

#### THE SIMULTANEOUS OCCURRENCE OF CARCINOMA AND FIBROIDS IN THE UTERUS.

Geuer [2] has collected 46 cases of this character from the literature, and classes them as follows: (1) primary carcinomatous degeneration of the myoma; (2) carcinoma and myoma of the body of the uterus; (3) myoma of the uterus, and carcinoma of the cervix or portio. There were 10 cases of the first class, but only four of them can be considered as trustworthy examples of true primary cancer. Of the second class there were 23 cases, of which in only two was the disease secondary in the myoma. In these cases the myoma was submucous.

There were 13 examples of the last group, of which Geuer says that there is little evidence that the myoma is the direct cause of the cancer of the cervix, but like other morbid conditions predisposes to malignant disease. Suspicion of beginning malignant degeneration is aroused when, especially at the menopause, in cases of long-standing myoma, hemorrhage, foul dis-

[1] Lancet, September 22, 1894.
[2] Cent. für Gyn., No. 14, 1894.

charge and loss of strength occur. Diagnosis is confirmed by the microscopical examination of scrapings from the uterus. Vaginal hysterectomy is the most satisfactory operation, as with abdominal hysterectomy secondary infection of the peritoneum is likely to result. This must be especially guarded against by thorough curetting of the vaginal portion, packing with iodoform gauze, and sewing together the lips of the cervix.

PATHOLOGY OF THE UTERINE MUCOSA.

Van Tussenbroek and Mendes de Leon [3] have given a very thorough anatomical and clinical study of this subject, of which the following is an abstract: The diseases of the uterine mucous membrane which by the majority of gynecologists are included under the name of inflammation must be separated into endometritis and pseudo-endometritis.

The true endometritis is histologically characterized by the appearance of leucocytes, which, at first distributed among the normal structures, finally displace these and cause them to disappear. The final result is a small cell fibrillary connective-tissue without glands or surface epithelium. Pseudo-endometritis is histologically characterized by changes in the vessels, which result partly in hyperplasia of the stroma and glands, and partly in atrophy with destruction of the tissues. Both forms of endometritis are, as a rule, confined to limited portions, the microscopical field shows alternately diseased and healthy portions.

True endometritis is characterized clinically, at least at certain stages, by a purulent discharge. Pseudo-endometritis is clinically evidenced by hemorrhages, menorrhagia or metrorrhagia. Sometimes also by profuse mucous discharge. In addition both can be the indirect cause of symptoms referable to neighboring or distant organs.

True endometritis of the corpus uteri (corpus catarrh) is much more common than is usually supposed. It occurs more frequently than catarrh of the cervix. Catarrh limited to the cervix is comparatively rare.

The differential diagnosis between a catarrh limited to the cervix, and a combination of corporeal and cervical catarrh can only be definitely made by the microscopical examination. On clinical grounds one can arrive at a probable diagnosis, if one considers —

(1) That a thin, purulent discharge points to catarrh of the corporeal endometrium;

(2) That with multiparæ cervical catarrhs occur seldom;

(3) That when reflex symptoms are prominent, they point to a pathological condition of the corpus mucosa;

(4) That cervical catarrhs are rare in virgins, and the combination of cervical and corporeal catarrh still more rare.

True endometritis occurs in virgins more rarely than pseudo endometritis; occasionally it is dependent upon previous infectious diseases. The two forms may occur together, in which case they usually follow subinvolution or abortion, where at the same time disturbances of the circulation and infection take place.

Treatment depends upon the intensity of the symptoms. Serious cases of endometritis, as well as of pseudo-endometritis, require removal of the diseased mucous membrane by curetting. Energetic after-treatment is of the greatest importance; where this is neglected, a speedy relapse is likely to occur. It is seldom that treatment confined to the cervix is successful.

[3] Archiv. für Gyn., Band xlvii, 1894.

TREATMENT OF CHRONIC ADHESIVE PELVIC-PERITONITIS.

Under the name "Pelveoperitonitis chronica adhesiva," Martin [4] describes this common affection of the female sexual organs, with special reference to the appropriate treatment. He refers to the opportunity of learning the appearances and results of this form of inflammation from the abdominal operations which are now so common. Less, however, is known about the cause. As regards treatment, Martin says, "No one will attempt more radical measures until medical resources have been tried in vain." As regards massage, the first enthusiasm for this form of treatment has cooled somewhat. Some few cases benefit, more either remain unchanged or are made worse. Where these means fail, there is no doubt that operative measures are indicated. The prognosis of the operative method of treating chronic pelvic peritonitis depends not so much upon the cause of the infection, as upon the character of the lesions found. It will naturally differ widely in cases where the peritonitis is complicated with inflammatory processes or new growths in the pelvic organs, ovaries, tubes and uterus, and where pus-cavities exist in the parametric tissues, from what it is where the condition is merely a more or less complete matting together of the pelvic contents. This last result Martin has found following both septic and gonorrheal infection, and probably also simple catarrhal conditions. The consequent displacement of the uterus is by no means always the most important factor. The obliteration of the tubes, the dislocation and pathological fixation of the often healthy ovaries, the implication of bowels and bladder, and the stretching of the thickened pelvic peritoneum, are usually of more moment than the retro-displaced uterus.

Both ovaries and uterus are often healthy; rational treatment would therefore consist in some method of curing the pelvic peritonitis with preservation of these organs. Both castration and, recently, hysterectomy have been urged and practised for this condition, Martin has found that the separation of the adhesions by operation fills this indication. He has learned, however, by experience that simple separation is a doubtful procedure; hence for five years he has in addition to separating the adhesions stretched the pelvic peritoneum as much as possible with incision of the cicatricial bands if necessary and in addition performed ventro-fixation.

In order to stretch the peritoneum after freeing the organs, Martin uses stroking movements with the fingers in the depth of the pelvis, from behind forwards, employing considerable force. Five times he has cut subcutaneously the fibres of the sacro-uterine ligaments. He then convinces himself of the patency of the tubes and the (macroscopic) healthy condition of the ovaries, and brings them into their proper position. The uterus is then fastened with three silk sutures into the lowest angle of the abdominal wound.

Where the peritoneum is torn and ragged, Martin covers the surfaces with sterilized olive oil which he believes hinders their growing together again.

[4] Zeit. für Geb. und Gyn., Band xxx, 1894.

Of 33 patients treated by this method, 26 had been operated on more than six months previously. From 21 he had late information, and of these 19 were free from pain, and able to work, while in two the improvement had been only temporary. The adhesions had so stretched that the uterus was quite movable, in good position, tubes and ovaries normal to the feel, and the parametrium not sensitive.

### THE OPERATIVE CURE OF SIMPLE AND ADHERENT RETROFLEXION OF THE UTERUS BY THE VAGINAL METHOD.

Dührssen[6] in a long article on this subject gives first the detailed history of 207 operations, and then describes his mode of operation and its results. The principle of the operation is the attaching of the fundus uteri to the anterior cul-de-sac. This can be done in three ways: (1) by fixing the fundus through the unopened vesico-uterine pouch; (2) by opening the peritoneal fold and drawing the fundus down to the vaginal wound; (3) by opening the fold and drawing the body of the uterus down to the vulva. A simple incision in the anterior cul-de-sac suffices in all these methods. The bladder is pushed away, and the highest part of the uterus which can be reached drawn down with a hook or by a strong ligature. A second and a third, each higher than the last, are then inserted, and drawn upon until the fundus appears, when it is sewn into the vaginal wound. The details of the operation should be read in the original. Where there are adhesions they can be reached and separated after the peritoneum is opened as by the third method.

Dührssen says: "All three methods of operation lead to a permanent cure; the first and second with a movable uterus, the third with an adherent one. The term cure does not merely mean that the position of the uterus is normal, but the patient is well; that she is freed from all the symptoms caused by the retroflexion, without in any way compromising any function of the uterus; menstruation becomes regular, and a previous sterility the result of the displacement or its complication is often cured. Pregnancy goes on without trouble, and no difficulty occurs at delivery which can be connected with the operation. The improved position of the uterus persists even after pregnancy and child-birth if caution is exercised."

### THE INFLUENCE OF SEA-BATHS AND PROLONGED IMMERSION ON MENSTRUATION.

Houzel[6] in this article gives some very interesting facts in regard to the effect of sea-bathing upon the generative system of the woman, founded upon the experience of the fisherwomen of Boulogne and vicinity. He refers to the fact that it is generally considered that a woman during menstruation is in a state bordering on sickness, and should observe a strict hygiene, and baths are interdicted. While this may be true of the city women and is a result of our civilization, it is not true of healthy women living a more natural life. For these menstruation is a physiological act, which accommodates itself to the fatigues and the transitions which the necessities of their life impose upon them. Sea-baths far from interfering with menstruation, favor it, prolong the sexual life, and increase their fecundity. The author is of the opinion that if even delicate, neurasthenic women should accustom themselves to take sea-baths regularly, even during menstruation, they would suffer less from amenorrhea and dysmenorrhea, and this function would become regular with great advantage to their general health.

In support of these opinions he calls attention to the habits of the fisherwomen, who are accustomed to remain in the water for hours at a time, thinly clad, submerged to the waist and sometimes to the arm-pits, bare legs and feet, making long marches with heavy baskets on their backs, their clothes dripping wet, in winter and in summer, menstruating or not; and all this without apparently suffering any inconvenience.

He has recorded his observations of 123 of these women as regards puberty, the menopause, their fecundity, and the results on menstruation. All these women were accustomed to go into the water every day, during their catamenia, when pregnant and when nursing. As regards menstruation, not one testified to the least inconvenience from their immersion in the water. Some noticed that their sickness came on without pain when in the water, and that they suffered if they did not pursue their ordinary habits; others flowed more freely; and the testimony was unanimous as to the good effects of the salt water. Nor did this apply alone to those who from childhood were accustomed to the life and began to menstruate under these conditions; even those who began long after puberty felt no ill effects.

The average age of puberty for the 123 women was thirteen years and ten months; and for those who had arrived at the menopause the average age was forty-nine years and a half, giving a length of sexual life of thirty-five or thirty-six years, which is several more than the average. Fecundity, too, is favorably affected. Taking the 63 married women of whom the record is complete, there were 497 children, giving an average of 7.8 children to a household.

Houzel therefore concludes that women can with advantage continue sea-bathing during their periods, provided they have become acclimated to the sea, and have no trouble with the appendages; that they tend to prolong the sexual life, and increase the fecundity in a remarkable manner.

His theory of the action of sea-baths is as follows: At the moment of immersion in the water, the whole economy receives a profound shock; often even somewhat painful. Under the influence of the sudden lowering of the temperature, and of the density of the water, which acts upon the skin by its weight and its salts, almost all the blood of the periphery is thrown back towards the centres; the heart seems to stop; then the pulse becomes small, hard, rapid; hurried respiratory movements succeed a rapid inspiration; the skin grows pale. This lasts a short while, when the equilibrium re-establishes itself, the economy reacts, and accustoms itself to its new environment.

The vessels of the splanchnic organs, sharply dilated by the considerable afflux of blood, react by virtue of their elasticity, to the exaggerated contraction of the vaso-motors of the peripheral vessels, succeeds a sort of temporary paralysis, which dilates their calibre, and the blood flows to the skin, which becomes red and suffused. This kind of gymnastics of the skin and the deep vessels, renders the circulation active in those organs where there is tendency to congestion. The uterus joins with the other organs in this;

[6] Archiv. für Gyn., Band xlvii, 1894.
[6] Annales de Gyn., 1894.

its circulation becomes more free and active, its nutrition more perfect; it gains in vitality, and is able to perform its functions more healthy and easily.

## Reports of Societies.

### CLINICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

J. L. AMES, M.D., SECRETARY.

REGULAR Meeting, Wednesday, February 20, 1895, DR. G. M. GARLAND in the chair.

DR. J. H. MCCOLLOM read a paper entitled

#### OBSERVATIONS ON DIPHTHERIA.[1]

DR. MASON: Dr. McCollom's paper is certainly most interesting, both from the bacteriological and clinical standpoints. The value of the bacteriological test must be regarded as fully established, especially in relation to the mild cases of nasal and laryngeal diphtheria occurring in schools and elsewhere, which otherwise would pass undetected. The more severe types are easily recognized in probably four-fifths of the cases by the clinical appearances. There are undoubtedly severe sore throats, membranous, which have every appearance of diphtheria but which turn out not to be so after bacteriological examination. But there are certain annoyances and inconveniences which occur from the rigid application of the bacteriological test. Dr. McCollom spoke of the pseudo-bacillus and the fact that certain throats, either without or after exposure to diphtheria, may present the Klebs-Löffler bacillus. Where a member of a family is found to carry about the Klebs-Löffler bacilli or the pseudo-bacilli in the throat, with no manifestation whatever of diphtheria, it becomes a serious question as to whether the house should be placarded, the family isolated, the expense of a nurse undergone, etc. It is a practical matter that has arisen more than once, and for myself I do not feel justified as yet, in the absence of symptoms, in putting a family to that expense and trouble, because the only means of determining whether these bacilli are virulent or not must be by the inoculation of animals. That is manifestly impossible in many cases, and in the absence of membrane in the throat, in the absence of symptoms of all kinds it seems to me that we must be guided by the clinical manifestations. The question arises not infrequently in the hospital as to whether a patient with the Klebs-Löffler bacilli who has no membrane shall be placed at once in the diphtheria ward. We have thus far done so. Patients who are not in the least sick, or very slightly so, have been placed in the diphtheria ward with no ill result to themselves thus far; but it is different in families, and it is a matter of serious importance, in which I should like to ask Dr. McCollom's opinion, as to whether it is the duty of physicians under all circumstances to report cases of such mild nature when the Klebs-Löffler bacilli are found, or bacilli having the appearance of the Klebs-Löffler. This may not seem to be a question which would be of frequent practical importance, but I have known of its being brought up.

The value of the use of antitoxin is now well established. At the City Hospital we have had one hundred or more cases treated in that manner, and here again we cannot wait for the culture-test. The patient brought in on the third or fourth day of diphtheria becomes more septic every hour, and the delay of twelve or twenty-four hours may mean death to the individual; therefore it is important that the antitoxin should be injected at the earliest possible moment, the results on the first, second and third days being vastly better than when this substance is used at a later period. As Dr. McCollom said, even in the cases which result fatally after late injection, there is a considerable degree of benefit apparently derived from this source; the children become more comfortable; they may even sit up and seem to be improving, but after two or three days, perhaps, they relapse and die from septic influences or heart failure. As to the disagreeable results of antitoxin, the only one which has seemed to me of any great consequence as a cause of suffering to the patient has been the pain in the joints, like rheumatoid arthritis, which sometimes lasts two, three or four weeks. The urticarial eruption is of little importance.

DR. MORSE: As to the liability of error in a single bacteriological examination of the throat, it seems to me that where the diphtheria bacilli are found it is positive evidence; in a case, however, which is clinically diphtheria, and a single bacteriological examination does not show the diphtheria bacilli, it seems to me that we are not justified on the strength of that one examination in saying that the case is not true diphtheria. For a number of months I followed up every case which came into the diphtheria ward of the City Hospital which gave a negative report for diphtheria bacilli on the first examination, taking swabs every day from the nose and throat until the case left the hospital. In a very large proportion of these cases the second or third examination would reveal the presence of the Klebs-Löffler bacillus, and in some cases the Klebs-Löffler bacillus was not found until the membrane had disappeared. Of course, it is possible that the cases were infected after they entered the hospital, but it does not seem to me that that is the explanation of the majority. So if I receive a negative report on a case of clinical diphtheria, I should not be satisfied with that, but should treat the case as diphtheria, and should want one or two more examinations made before I was satisfied. I am glad Dr. McCollom and Dr. Mason have emphasized the importance of the examination of all sore throats; it seems to me that here is the great use of the bacteriological examination. It is the sore throat which does not look like diphtheria which is liable to confuse. As to the negative examinations in convalescence, it seems to me that one negative report during the convalescence is entirely insufficient, that you should have at least two successive reports. It very frequently happens that one report will be negative, the next report positive, the next day negative and the next day positive, and then perhaps two negative reports. It does not seem safe to fumigate the house until you have at least two negative reports.

As to the infectiousness of streptococcus throats, the Board of Health of New York investigated that last summer, and found it practically *nil*, very rarely being able to trace any infection from one case to another.

When the Klebs-Löffler bacillus is found in the healthy throat, the possessor certainly has not diph-

[1] See page 449 of the Journal.

theria, but I cannot see why he is not as dangerous to the community as is a convalescent case. It is the same bacillus in the same place. The fact that such bacilli may not be fatal to guinea-pigs, is no argument, as it is extremely probable that the Klebs-Löffler bacillus which in one throat is not pathogenic may be virulent when put on a different soil.

It seems to me that in every case of diphtheria antitoxin should be used, whether early or late; and, as Dr. Mason says, we should not wait for the bacteriological test. It should be used at once. It does not seem to me we are going to do any harm, and we do gain twenty-four hours. I see no reason, moreover, why, if you use antitoxin, you should not use other means as well, and not limit yourself to antitoxin alone.

Dr. Withington: Possibly the most useful contribution which I can make to this subject is to speak of the results as I saw them in my own service at the City Hospital during the months of December and January. The cases in which the remedy was used were 91 in number, but 11 of those cases were rejected from the count from failure of the bacteriologist to report the specific germs of the disease in those cases, therefore leaving 80 cases in which the remedy was used. Of those 80 cases, 13 died; and of those 13, two died from scarlet fever which they contracted in the wards of the hospital, and both of them died with clear throats so far as diphtheria was concerned. Therefore these two are not properly to be included among the number of deaths in cases of antitoxin treatment; but as they died after antitoxin injection, I have left them in the list. That gives a mortality of 16 per cent. During the same period of time there were 40 cases of diphtheria in the wards, as shown by bacteriological tests, which were not treated by antitoxin; and they were not treated for various reasons, partly because of the lack of material, partly because of the patients entering moribund in four or five cases; in a few cases because the patients entered very late in the disease, beyond the fifth day from the onset of the disease. As the material was scarce, it seemed proper to withhold it where it did not promise to give good results; but the majority of those 40 cases were those in which the remedy was withheld because the cases were mild. Therefore, the group of 40 cases was a group of selected mild cases, as a whole, and yet the number of deaths among those was 12, or 30 per cent. The group of antitoxin cases, as a whole, were a severer type than those not treated in that way, and the mortality was 16 per cent. Adding all together and including the entire series of cases of diphtheria which appeared in those six weeks, of which two-thirds were treated with antitoxin and one-third without, we had a mortality of a little less than 21 per cent. As Dr. McCollom said, the average hospital mortality has been about 50 per cent. in the City Hospital for a number of years. Assuming that it is from 40 per cent. to 50 per cent., as it is in most large hospitals, we have here a very manifest and striking reduction in the mortality under this method of treatment. In two cases, there were autopsies, and the infection of the system was shown to a marked and surprising degree. Contrary to what we used to be taught as to the migration of the Klebs-Löffler bacilli from the site of the original infection, they were found in the lungs; both patients had broncho-pneumonia, and in the patches of broncho-pneumonia were found streptococci and the Klebs-Löffler bacillus. The same diphtheria bacillus was found in other organs of the body. One of the patients had streptococci in the blood of the left ventricle, and the general toxic infection was very great in both cases. In six of the fatal cases death occurred within forty-eight hours of the first injection, and in four within twenty-four hours. These were cases in which the remedy was used after it was more plentiful than at first and where it was deemed wise to give it in the cases practically hopeless.

Therefore, the numerical results are certainly very promising. The results apart from the question of figures seemed to me very striking. The gentlemen who went into the wards at that time, I think, will admit that the wards bore a very different appearance when that treatment was in force from what they have generally done in years past. Usually in going into those wards one would see a lot of steam being used for the purpose of relieving stenosis of the larynx, and the amount of steam was very much less in patients put early under this treatment. In the second place, the general septic appearance of children with advanced disease, lying in a stupid, comatose way, had very generally given way to a very much brighter aspect of the children, many of them sitting up in their cribs, sometimes sitting up within twenty-four hours of the time of receiving an injection; so that the type of the disease was alleviated as well as the death-rate reduced.

I am very glad that Dr. Mason said a word in favor of still allowing the clinician a little part in the diagnosis of diphtheria. We have been gradually rather crowded to the wall by our friends the bacteriologists, so that we did not dare to express any opinion as to the existence of diphtheria in any case whatever; but there are cases of diphtheria where I think we have a right to an opinion, even though the bacteriologist fails to find the microbe on the first or second examination. Two of the cases were not injected because of a negative report on the first examination. On the second examination, however, diphtheria bacilli were found, but time had been lost and one of these patients died. I have reason to believe if the injection had been made earlier the case might have been saved. Another patient I remember came in with all the symptoms of profound sepsis of diphtheria of the most aggravated type, and lived three days. The first day the report was returned negative; second day negative; the third day, just before he died, the report was, "few Klebs-Löffler bacilli." Another patient was given an injection on the strength of the general clinical picture of diphtheria, membrane being abundant in the throat, and there were two negative reports on the throat. The child was growing sicker, and had profuse nasal discharge. It was thought diphtheria might be present in the nose. Two swabs were taken from the nose, both with negative reports. Finally, for the first time, twelve days after the child entered, we got a positive report on a swab from the nose. In accordance with the ordinary methods of interpretation of reports of bacteriologists, that child would have been assumed to be free from diphtheria all that time; but I am practically sure the child had diphtheria all that time, and the swabs failed to show it. The same thing is important in judging of membranous laryngitis. A case was in the hospital with a strip of membrane on the back of the pharynx, swab taken with negative result; the child choked up, was

intubed, died, and diphtheria bacilli were found post-mortem in the trachea and larynx. The situation of the disease was such that it was not reached by the swab. All these things are evidence that the disease may be overlooked by the most careful bacteriologist, and that the clinical evidence is not to be disregarded.

As to the other horn of the dilemma, what is to be done in cases of the presence of the Klebs-Löffler bacillus without disease, a very serious question comes up. A patient was admitted the other day to the hospital whom I saw first in ignorance of anything about him, and who showed nothing in his nose or throat. I asked him what he was there for, and he said he had the option of being there or in jail. The reason was that he had had diphtheria bacilli in the throat. I suppose he had had membrane in his throat. We had a swab taken, and the report was that there were no diphtheria bacilli present. Inasmuch, as at the same time I had the Klebs-Löffler bacilli in my own throat, as shown by two consecutive daily reports I felt a little guilty that I should be keeping this man there while I myself under the same construction ought either to be in the hospital or in jail. This man had been sent in by the health authorities because of the existence of this microbe in his throat, and we kept him twenty-four hours and discharged him. When the question came as to what diagnosis to put in the record, as he had no membrane and no bacilli, there was no resource but to enter him as having "no disease." I think, while we owe to the bacteriologist an enormous debt for the settlement of doubtful cases of diphtheria, we must still feel that as clinicians we have the right to an opinion, which we like to have confirmed by the bacteriologists.

Dr. V. Y. Bowditch: I have very little to add to what I have already said at the Medical Improvement Society. I have been on duty two weeks in the infectious wards of the City Hospital, and my experience thus far has certainly been in favor of antitoxin. Twenty-six new cases have entered since I came on duty, of which four have died — all four being very severe cases when they came in, two moribund, and one had intubation three times and tracheotomy. All the others with the exception of two are doing very well. Those two I reported on Monday as still doubtful, are better to-day. One is a child who is decidedly septic, fighting his food and treatment and everything, but he developed last night a scarlet-fever rash, and was transferred to the scarlet-fever ward. In the other the amount of membrane is decidedly less this morning.

One point in reference to the immunizing dose is rather interesting. Two nurses who have come down with diphtheria, both having membrane and the Klebs-Löffler bacillus, received immunizing doses three weeks before they were taken. In one case I found that the dose was very small; and in the other I could not find out the exact amount given. Both proved to be very light cases.

Dr. Durgin: I have been much interested in this paper and the discussion. It seems to me extremely important that the clinician and the bacteriologist should agree as to whether this or that patient is dangerous to the public health, and that is the part of this question in which I am most interested. I am frequently asked whether or not some given case should be reported and treated as one dangerous to the public health. For instance, a person who is apparently well, but from some slight irritation seen in the throat a culture is taken and found to contain the Klebs-Löffler bacillus. The question at once arises, What shall be done with this person? In the past we have been accustomed to look upon such person as not dangerous to the public health because we had no knowledge or reason to suspect that the diphtheria bacilli were present. This has been the position of the medical profession up to a recent date. Since, however, the bacteriologist has found that the Klebs-Löffler bacilli are evidence that the patient has diphtheria, and that through this bacilli the diphtheritic patient can spread the disease, we have felt sure that that was the person to put into isolation. We all know that by some unchecked influence diphtheria has continued endemic for years in our city, and we have wondered, in many instances, how the disease could have been contracted. The suspicions which some of us felt that the unrecognized cases were spreading diphtheria, has been fully borne out by the bacteriological work which has been reported to-night. I am constantly in trouble over the cases of diphtheria that continue so long to show the Klebs-Loffler bacilli after the patient has, apparently, recovered. I am importuned every day by the householder, parents and doctors to disinfect and release the patient from isolation. I do not know what to do except to act upon the belief that the patient is a source of danger until the bacilli have disappeared. If it can be shown that the Klebs-Löffler bacilli found in the throat, without coincident clinical appearances, are harmless, then I am ready to pull down the cards, disinfect, and release the patient when the ordinary clinical evidences of diphtheria are gone; but it seems to me that I am not warranted in doing this while the prevailing belief of the medical profession is against it. I was very much interested in what Dr. Withington said about the person who was in fear of the jail. I think I may have seen that patient, a boy who could not be controlled by his mother at home. He had had, according to bacteriological tests, diphtheria; lived at the North End, and was brought into the health office. I looked in his throat, found a little irritation, but no membrane. Professor Ernst is my authority for calling it diphtheria. I tried to have that boy isolated at home, not in jail, but this could not be secured. I then said, "You must go to the hospital," and I secured his admission there. I presume this is the same case; and, if so, two days must have elapsed after the examination by Professor Ernst before the hospital test was made, which gave time for the bacilli to disappear.

Dr. Mason: It seems to be the case that there is clinical diphtheria and also laboratory diphtheria. They usually coincide; sometimes they do not, and then the responsibility must rest either upon the physician in charge, or, if he can shift it on to the health board, it will rest there. The practical difficulty is great. If a man with large interests under his care, who feels perfectly well, accidentally discovers that he has these organisms in his throat, I think we are not in a position to say that the organisms may not be benign; at least, the only way of proving it is by experimentation on animals, and that is practically rarely done. So I do not see how the Board of Health can take the responsibility in such a case of cutting a man off from his business, which may be important, and

subjecting themselves perhaps to great complaint from the individual.

Dr. Withington, being asked if the men on service at the hospital had their mouths constantly watched every day, said he did not think they did. As a matter of curiosity, occasionally it was done, and swabs taken from the mouths of house-officers and from the nurses and articles of wearing apparel; and diphtheria bacilli had been found present in all these situations, but no regular system of watching the throats of the attendants was practised so far as he knew. In his own case he simply happened to find them. He had a trifling indisposition lasting about a day and a half, and after he got well thought he would see what sort of cocci a man had in his throat when he had that kind of throat. A test was made and the bacilli found.

Dr. Withington then read a note bearing on the question from a paper by Dr. Welch of Philadelphia.[2]

After stating that diphtheria bacilli may be present and multiply in the throat without symptoms or lesions, he further adds, that of 330 persons who gave no history of direct contact with diphtheria, eight were found to have virulent diphtheria bacilli in their throats. Of these, only two subsequently developed diphtheria. Bacilli, indistinguishable morphologically or in cultures from the diphtheria bacilli (including the formation of acid in forty-eight hours in bouillon), but entirely devoid of virulence, were found in 24 others of these 330 persons, in most instances in large numbers. Further the "pseudo-diphtheria" bacillus was found in 27 persons. This latter, while morphologically identical with the true diphtheria bacillus, differs from it in respect both of virulence and of mode of growth in certain cultures. So that it appears from this authority, that of 330 persons 8+24 +27, or 54, showed bacilli which were morphologically those of diphtheria; and 32 showed an organism which would have required the experimental test on animals to show whether or not it possessed virulence.

Dr. Durgin: I would like to ask if Dr. Withington or Dr. Mason has seen any case where the Klebs-Löffler bacillus was found in the throat which was in a perfectly healthy state so far as could be seen.

Dr. Mason: The throats have been slightly reddened, no more than many throats are from the use of tobacco or other irritants. I think that the kind of case I referred to may be said to present no positive throat symptoms, and such patients are not infrequently, as I have observed them at the hospital and occasionally outside, in good general health, without fever, and with no symptoms of sickness. It becomes a serious matter to shut them up, placard their houses and subject them to loss.

Dr. Durgin: In a few instances where this question has been asked over telephone, I have advised the physicians to keep the patient isolated for a few days under observation, use gargles freely, take cultures, and if the case cleared up readily not to report it; but I am not certain that I am right in doing so.

Dr. Mason: I should think that was a very judicious way of treating it. The public make no distinction between severe and mild cases, and where houses are placarded they might as well have plague or small-pox within, so great is the prevailing fear of contagion.

[2] Archives of Pediatrics, February, 1895, p. 135.

Dr. McCollom: In regard to what Dr. Mason said about not finding the diphtheria bacillus in cases of clinical diphtheria, it seems to me that this is always due to some error in technique in making the cultures. It sometimes happens that when there is a membrane the first culture may be negative, but the second culture almost invariably will be found to contain the characteristic bacilli. In connection with this there is one important practical point which does not seem to be fully appreciated by the profession. This point is the fact that on the surface of the membrane the bacilli frequently die, and therefore if the culture is taken directly from the surface of the membrane in the majority of cases a negative result will be obtained. If, however, on the other hand, the wire is passed through the membrane or along its edges a positive result is almost invariably reached. It is also advisable to take a second culture from the secretions of the mouth without reference to the site of the membrane. The advantage of this mode of procedure has been satisfactorily proved in a great number of cases examined at the laboratory the past year. It has been found that while the culture from the surface of the membrane did not contain bacilli, that from the secretions of the mouth, did. All false membranes in the throat are not necessarily diphtheritic, and in many instances it is impossible to decide upon the nature of this membrane simply by its appearance. This is notably the case in the membrane appearing in the throat during the course of the scarlet fever. Many cases of scarlet fever in which a membrane appears, without a bacteriological examination would be considered to be cases of scarlet fever associated with diphtheria. As a matter of fact, as has been proved by the examination of a large number of cases, the association of these two diseases is not so frequent as has been generally supposed. In a well-marked case of clinical diphtheria it does not seem to me that it is well to wait for the result of the culture before administering antitoxin; but certainly, if we are to arrive at any definite conclusions regarding the value of this agent, a culture should be taken at the time the antitoxin is administered. If the case does well and the culture shows the presence of the bacilli of diphtheria, we certainly have presumptive proof that the remedy is of use. If, on the other hand, the case does badly and the culture shows diphtheria bacilli and streptococci, or streptococci alone, we have no proof that antitoxin is not of advantage in cases of pure diphtheria. It has been shown in so many instances that a streptococcus infection is not affected in any way by antitoxin, that it is important that this fact should be fully appreciated.

In regard to the presence of the bacillus of diphtheria in persons comparatively well, this is so rare that it does not seem to have any important bearing on the subject. It does seem to me, however, that a person with diphtheria bacilli in the secretions of the mouth is a source of danger to the community, and that he is liable to communicate the disease, of a most virulent type, to other susceptible persons.

While it may be a hardship on the individual to isolate him for a few days, yet the well-being of the community demands it. A person with diphtheria bacilli in his throat is in a similar condition, so far as the community is concerned, to a person with a very slight eruption of small-pox. I think very few people would care to have a person with even four or five

small-pox pustules on his face at large in the community. In the case of adults, with diphtheria bacilli in their mouths, the danger of communicating the disease is perhaps not so great as in the case of children; for instance, a child with a mild attack of diphtheria, so mild that it could not be detected without a bacteriological examination goes to school, kisses the other children, uses the same handkerchief, and may in this way — nay, has — communicated diphtheria of the most virulent type to others. If anything is ever to be done in stamping out diphtheria the disease must be attacked in this direction. The importance of recognizing and isolating mild cases of disease is perhaps shown in no better way than by the history of small-pox in Boston for forty years. For the twenty years from 1852 to 1871 when the mild cases were not carefully isolated, the number of deaths was 1,197, with an average population of 187,969; for the twenty years from 1875 to 1894 when every mild case was isolated, the number of deaths was only 56, with an average population of 405,081.

Nobody pretends to say that mistakes may not occur in bacteriological examinations, but the chances of error are very slight.

In regard to the list read by Dr. Withington, it does not seem to me that it is conclusive; other observers have examined a much larger number of throats of perfectly well people and did not find the bacillus of diphtheria, although a bacillus somewhat resembling that of diphtheria was found. In regard to what Dr. Morse said in reference to two or three negative cultures, I think it is absolutely imperative that there should be, at least, two negative cultures from the nose and two from the mouth in a case of diphtheria before a person can be considered well of the disease.

## NEW YORK COUNTY MEDICAL ASSOCIATION.

At a meeting of the New York County Medical Association held April 15, 1895, a paper by Dr. Thomas R. Savage was read on

### SYMPHYSEOTOMY, WITH REPORT OF A SUCCESSFUL CASE.

The patient upon whom symphyseotomy was performed was a young woman twenty-four years of age, pregnant for the third time. In her first pregnancy the birth was premature, at the fifth month. In her second she went to full term, and craniotomy had to be resorted to. When Dr. Savage was first consulted she had just entered the ninth month of utero-gestation. The child's head presented in the left occipito-anterior position. The measurements taken of the pelvis showed it to be of a decidedly funnel shape, normal in its dimensions at the superior strait, but contracted at the pelvic outlet to a transverse diameter of two and a half inches.

Three weeks before the date of the patient's expected confinement complete dilatation of the os uteri was secured, and she was placed under chloroform. The usual incision for the open method of operating was made, and the pubic joint was found to lie almost three-quarters of an inch from the median line. Dr. Savage expressed his belief that the articulation is commonly found in this situation and quoted Wehlé's statistics of 60 cadavers. In only eight cases was the articulation in the middle; in 40 cases it was to the left, and in 12 cases to the right. The strong subpubic ligament was divided, but no separation occurred at the joint. It was then found that the bones were retained in position by the post-pubic fascia; and when this was severed the joint surfaces sprang apart to the extent of one and three-quarter inches. The wound was packed with gauze, no hemorrhage having occurred. The patient's thighs were then placed upon the abdomen (the knees being still held together), and the child easily extracted with the aid of the forceps.

During its passage the separation of the symphysis did not exceed two and a half inches. It was estimated that the ischiatic diameter was increased from one to one and a half inches; and in extracting no compression was necessary. Careful experiments, said Dr. Savage, had demonstrated that during pregnancy the ends of the pubic bones could be separated three inches, or, if necessary, three and a half inches, without endangering the integrity of the sacro-iliac joint. He concluded, therefore, that in his case the same sized fetus could safely have been brought through a considerably narrower pelvic outlet.

The vagina and bladder projected into the wound after the removal of the gauze, and considerable difficulty was experienced in preventing them from being pinched when the bones were brought together. Silkworm-gut sutures were used to close the wound, and broad bands of rubber adhesive plaster to support the pelvis. Not more than two drachms of blood were lost from the wound during the operation.

Primary union took place, but on account of extensive serous infiltration into the abdominal wall, the upper end of the cicatrix was opened for drainage, and a sinus existed for about four weeks. At the end of four weeks the patient was allowed to get out of bed, and she experienced no difficulty in walking at once, the union at the symphysis being quite firm. At the present time (a little more than three months after the operation) she is able to attend to her household duties as usual. There is slight mobility between the pubic bones, but not enough to cause her any inconvenience.

The child was asphyxiated when born, and it required fully half an hour to satisfactorily establish respiration. This, he said, was quite a common complication of symphyseotomy, the number of cases in which it had been reported being surprisingly large.

Dr. William T. Lusk said that he heartily congratulated Dr. Savage on the good results attained in his case, and that he would like to call attention to the good work in connection with symphyseotomy that has been done of late in Paris, especially by Pinard. In 48 cases at the Hôpital de Bandelecque there were four deaths; but out of 44 cases in which the operation was performed under favorable conditions, there was but a single death. These 44 patients were women in good condition who were in the hospital before confinement. Out of four cases, however, in which the patients were sent into the hospital after being long in labor and already suffering from septic infection, no less than three died.

One formidable source of danger in symphyseotomy had always been loss of blood. Dr. Savage had been very fortunate in this respect in his case; but in a second case he might have the most alarming hemorrhage. Another reason why symphyseotomy had been fatal was too much delay in operating. If we could only be sure of our measurements of the pelvis and

of the child's head, there was no good reason why it should not be done early in labor. If these measurements could be accurately ascertained we could tell at once whether the operation was called for or not. At present, however, our measurements were very imperfectly made, and if we found that the pelvis was not extremely contracted we were apt to go on trying to get the head through. In this way valuable time was lost, and both mother and child were exposed to imminent risk. He was happy to state, however, that Farabourg had devised two instruments which, when perfected, it was hoped would enable us to make the pelvic and cephalic measurements with considerable precision.

If we wished to avoid hemorrhage, we should follow the directions laid down by Pinard. With the index finger and thumb the clitoris should be seized, and the suspensary ligament of the latter put upon the stretch and divided with the knife. Through the opening thus made the vessels could be pushed back with the finger placed behind the symphysis. Dr. Lusk then exhibited a metallic guard which was used for retracting the vessels and holding them out of harm's way.

In regard to common position of the joint to the left of the median line, as stated by Dr. Savage, he thought the latter must be mistaken. In hundreds of dissections made in Paris the articulation was found in all in the median line. The reason why asphyxia of the child was so common after symphyseotomy he believed to be because in this country and in Germany no attempt was made by the operator to separate the ends of the pubic bones, which were left to be forced apart by the head of the fetus. It was no wonder, therefore, that asphyxia resulted from the great pressure thus caused. In Paris it was the practice to separate the bones at once by means of an instrument furnished with a graduated arc. The separation should be made precisely equal on both sides, for if one of the bones yielded and the other did not irretrievable injury might be done to the joint. In case one of the bones should not yield the process could be facilitated by abduction of the limb on that side. He thought that Dr. Savage was mistaken in claiming that a separation of three inches, or even three and a half inches, could be safely accomplished. In France and Italy the separation was carried to two and a half inches, but never more.

If, in delivering the child the forceps were applied, it was of the greatest importance to have the cervix fully dilated. As there was no anterior support, it required great care to avoid making a rent in the soft parts. After the birth of the child the strong fibrous tissues should be united by means of silk ligatures. In this way the most perfect union could be secured. At the Hôpital de Bandelocque all the patients could hop on one foot a month after the operation, this exercise being used as a test. In this country, however, there was almost always imperfect union of the symphysis, and it was highly desirable that the method of holding the parts together should be improved.

Dr. George T. Harrison thought we should be over-hasty in assigning a definite place to symphyseotomy. It was true that it came before us with many promises; but the accumulation of a large number of cases was requisite in order for us to decide positively upon the position which it should hold. One difficulty was that a considerable number of cases had been unsuccessfully operated on in which such an operation as symphyseotomy was not indicated. In one instance that he knew of, the patient had been a long time in labor and had a pulse of 150 and other signs of exhaustion. The question of whether the subcutaneous or open method of procedure should be adopted was one of interest. Dr. Grandin in his work objected to the open method on the ground that it subjected the patient to the greater danger of infection and of hemorrhage. But so far as the latter was concerned the method described by Dr. Lusk seemed to accomplish all that could be desired. At present Dr. Harrison was inclined to believe that the operation of symphyseotomy should, as a rule, be confined to maternities, for the reason that so few had the skill and experience required for its proper performance. In case the patient were to suffer from permanent disability from the lack of union in the joint the physician would be liable to a suit for malpractice.

Dr. C. A. von Ramdohr said in regard to the status of symphyseotomy that as at the present time it is impossible to make accurate measurements of the pelvis and of the fetal head, so that only the most skilful and experienced can make a fair estimate of these diameters, and as the procedure is accompanied with the danger of hemorrhage, injury to the bladder, etc., it should, as a rule, be performed only in maternities, as Dr. Harrison had remarked. It was also an operation for multiparæ, since in women who had never borne children, unless the pelvis was known to be greatly deformed, there was always a chance of delivery by simpler methods.

Dr. E. E. Tull said that there was clearly a selection between symphyseotomy and Cæsarean section. The mortality from symphyseotomy appeared to be steadily diminishing, and in Paris 39 successive cases had been reported without a death. Still, it was an operation which required a much more accurate diagnosis than Cæsarean section, and the latter, in selected cases, was only a little more fatal. In symphyseotomy there was always the possibility of non-union, of serious injury to the bladder, etc., and on the whole, it seemed to be an operation which has a very limited field.

Dr. Edward van den Hoff said that he could not understand just why we should be so carefully warned against hemorrhage in the performance of symphyseotomy. It was, of course, an operation which should not be attempted except by a competent surgeon well prepared for any emergency that might arise, but in the anatomy of the parts concerned there was nothing which could not with ordinary care be avoided. As to the position of the symphysis, he had very frequently observed that it was not just in the median line, and that it was most often met with a little to the left.

---

Fifty Years in the Same Office.— D. Colvin, M.D., writes to the *Journal of the American Medical Association* from Clyde, N. Y., that he has been fifty-one years in practice, and has lived for fifty years in the same house. He has also just completed his fiftieth year of married life. His inquiry as to whether any other member of the Association can boast of an equal number of semi-centennial anniversaries of like character, will, we opine, be answered only in the negative.

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

## A HISTORY OF THE PENNSYLVANIA HOSPITAL.

THE Pennsylvania Hospital, incorporated in 1751 and opened in 1752, was the first permanent, public provision made in this country for the care of persons "distemper'd in Mind and depriv'd of the irrational Faculties," or for the relief of sick and injured inhabitants. This fact alone would lend great interest to its history. But when there is added to that, the association with the foundation and development of this institution of many of Philadelphia's best citizens, and of many of the country's best physicians and surgeons, both in pre- and post-revolutionary days; and when still again we remember the contributions made by the former to the hospital and by the latter through the hospital to the advancement of medical science and medical practice — the interest in the history of such an institution is greatly enhanced to all students of sociology and of medicine. The very handsome volume[1] prepared by Drs. Thomas G. Morton and Frank Woodbury, the publication of which was authorized by the contributors at their annual meeting, May, 1893, and directed by the Board of Managers, does justice to the subject, and lays under obligation those to whom it is sent.

About ten years ago Dr. Morton discovered in an abandoned closet in an out-building of the hospital a large collection of letters, accounts and memoranda, which thirty years previously had been temporarily placed there during repairs to the library, and forgotten. That the valuable historical material therein contained might be rescued from further risk of loss and permanently preserved, it was determined to incorporate it in a publication; with the present result.

The idea of the hospital originated with Dr. Thomas Bond, who, however, found it necessary to secure the co-operation of Benjamin Franklin, the latter thus becoming almost the earliest and certainly one of the most efficient promoters of the undertaking. Franklin practised with the happiest result the provisional subscription method — a method which continues to work successfully under similar circumstances in our time. The Provincial Assembly, unwilling to appropriate £2,000, was finally induced to do so on condition that the inhabitants of Philadelphia subscribed a similar sum — a result regarded by the objectors as unlikely of realization. In a short time £2,750 was subscribed, and the Assembly made good its pledge. In regard to this consummation Franklin subsequently wrote: "A convenient and handsome building was soon erected, the institution has by constant experience been found useful, and flourishes to this day, and I do not remember any of my political manœuvres, the success of which at the time gave me more pleasure; or, wherein, after thinking of it, I more easily excused myself for having made some use of cunning." A legacy of debts due to and from Dr. Franklin, accruing prior to his prolonged absence from the country on government affairs, the draft of which appears in his will dated July 17, 1788, and showing signs of his wonted shrewd benevolence, did not turn out so well, for it was not thought safe by the Contributors after due consideration to accept it and thus expose themselves to uncertain loss as well as uncertain profit.

One of the objections entertained by members of the the Assembly to appropriating funds for the hospital was that the expense of paying physicians and surgeons would eat up the whole of any fund that could be reasonably expected to be raised. This apprehension was allayed by Drs. Lloyd Zachary, Thomas Bond and Phineas Bond "generously offering to attend the hospital gratis for three years!"

The hospital in its earlier days benefited by various miscellaneous sources of revenue. The Assembly at different times granted to the hospital a proportion of various fines and penalties, and on one occasion a handsome award of unclaimed prize money; it also granted to the hospital the fines imposed upon its own members. The Penn family were generous benefactors.

One of the most interesting episodes in the financial history of the hospital is associated with Benjamin West's painting of "Christ Healing the Sick in the Temple." In 1800 the managers wrote to Mr. West asking him for a contribution. In the following year Mr. West sent a favorable answer, and suggested the subject for the painting. In August, 1810, notice was received that the painting might soon be looked for. The exhibition of the picture in England, however, aroused a determined effort among its many admirers to retain it in that country. As a result it was purchased for £3,000 and retained in England as a commencement of a National Gallery. Mr. West immediately began making a copy, which he resolved should excel the original. This painting did not actually reach Philadelphia until October, 1817. It was placed on exhibition in the building erected for it by the hospital. The money received from the opening of the

[1] The History of the Pennsylvania Hospital, 1751–1895. Philadelphia: Times Printing House. 1895.

exhibition to its close in 1843 amounted to something more than $25,000 and netted the hospital as much as was paid in England for the original. This painting is now in the clinical amphitheatre of the Pine Street Hospital.

This history of the Pennsylvania Hospital suggests to a Bostonian the similar subject of the Massachusetts General Hospital. At the beginning of the present century Massachusetts still had no hospital or insane asylum. In 1810, the year of the completion of Mr. West's first picture, a circular letter was issued; in 1811 a charter was obtained, and on July 4, 1818, the corner-stone of the Massachusetts Hospital was laid. The first patient was admitted September 3, 1821. Chronologically, Boston was a follower, *sed longo intervallo*. In other details there was imitation. We note that a mummy from Thebes was presented to the hospital May 4, 1823, it was placed on exhibition, and $1,500 were netted to the hospital. Here, also, miscellaneous sources of revenue were very acceptable. April 9, 1824, the thanks of the trustees were given to Gorham Parsons, Esq., "for the present of a sow of uncommonly fine breed," the weight of which was stated in the visiting committee's records at 273 pounds.

At the end of the year 1825 there were 28 males and 18 females in the hospital. Those were the days of small things; but our predecessors both in Philadelphia and here built well, and left us, moreover, good examples. Philadelphia led Boston in her hospital, but Boston led Philadelphia in the history of her hospital, Mr. Bowditch's history of the Massachusetts Hospital being privately printed in 1851, and a second edition, prepared by Dr. Geo. E. Ellis with a continuation, published in 1872. An interval of twenty-three years, and this handsome history of the Pennsylvania Hospital may suggest to the trustees the desirability of a miscellaneous source of income, and a preparation of a third edition.

## TEMPERANCE TEACHING IN THE PUBLIC SCHOOLS.

A LAW was enacted in Massachusetts in 1885 containing the following provisions:

ACTS OF 1885, CHAPTER 332.

Physiology and hygiene, which, in both divisions of the subject, shall include special instruction as to the effects of alcoholic drinks, stimulants and narcotics on the human system, shall be taught as a regular branch of study to all pupils in all schools supported wholly or in part by public money, except special schools maintained solely for instruction in particular branches, such as drawing, mechanics, art, and like studies. All acts or parts of acts relating to the qualifications of teachers in the public schools shall apply to the branch of study prescribed in this act.

Similar statutes were enacted in other States. Various methods were devised for the purpose of training the youthful mind in this branch of knowledge. Numerous text-books at once came into use, in which the abuse of alcohol formed a prominent feature, and old text-books were remodelled to conform to the provisions of this new law. Many of these books contained radical defects, and some of them were unfavorably criticised in the pages of the JOURNAL. It is needless to say that a marked improvement has followed the first attempt in this direction, and that methods of illustration, and forms of instruction which were first employed are now deemed to be useless. The present executive of the Massachusetts Board of Education has treated the question in an intelligent and progressive manner in the following statement:[1]

"It is the misfortune sometimes of a noble movement to be indiscreetly pushed. Such advocacy leads to reaction, and the cause suffers. In this way temperance is sometimes wounded in the house of its friends. The very commonness, too, of its presentation tends to take off the edge of that presentation, to permit the introduction of an element of cant, and to make of that which should be vital and effective something mechanical and inoperative. Thus temperance, either in its narrower sense of abjuring that which intoxicates, or in its broader sense of high self-control and self-respect, loses something of caste where it should be one of the royal themes. It is a common experience for genuine believers in temperance and workers for temperance to have moods in which they prefer not to hear the subject discussed, — at least, if the discussion promises to follow certain stereotyped ways.

"And yet the conviction is strong and deep, and among no class of people is it stronger and deeper than among teachers, that the young should be trained to temperance as well as to the other virtues. How shall it be done? The earlier laws say, "By moral measures." The later laws say, "By a scientific presentation of the effects of alcoholic drinks, stimulants and narcotics." Both of these classes of laws still stand; both methods are, therefore, obligatory, and it is the duty of school boards and of teachers to respect them. But when we inquire as to what precise methods shall be employed for the moral or scientific enforcement of temperance, the laws are silent. It is safe to say that, whatever those methods may be, they should be in harmony with such pedagogical principles as command general acceptance. In teaching spelling, for instance, it is not regarded as sound principle to put bad spelling before children to correct. There is great danger that the wrong thing a child is cautioned against may make the deeper impression upon him, and sway him more than the right thing. Of course, since the child goes frequently astray, it becomes the duty of the teacher to look sharply after his blunders, and in this way attention is necessarily focussed for a time on departures from good standards. But this does not affect the main principle that, in the initiative of all instruction, the sound thing, the wholesome thing, the right thing, should be presented first; that the minds of children should be directed upward and not downward; that love of higher things is a stronger motive than fear of baser things, — or if, unfortunately, not

[1] Fifty-eighth report of the Massachusetts Board of Education, 1893-1894, p. 137.

a stronger motive, a better motive for first presentation; that, in short, the true way to keep bad things out of the mind is to put good things into the mind.

"Applying this principle to instruction in temperance, it seems to be psychologically a bad method to make the woes of intemperance the main reliance in an endeavor to save people from them. The sad fact, indeed, remains that innocent children are frequently exposed to the repulsive pictures of intemperance, and that, in certain cases, effective lessons for good can be drawn from such experiences; but, as a general principle, there is more virtue in setting before children the joy of right living, with the scientific basis therefor, than the sorrow of wrong living. It is difficult to draw a satisfactory line between the two policies, but the principle is sufficiently conveyed if we say that, whatever attention it may be necessary to give the diseased, the criminal and the awful in intemperance, these are pictures upon which the curtain, if raised at all, should be quickly let fall. The main policy should still be the higher one of filling the soul with good ideals, and of inspiring the pupil, through the exercise of his will, to strive for their attainment.

"Instruction in temperance should be scientific, it is true; but science for little children must be exceedingly simple, — very much like the science involved in that nature study which is now growing in favor with so many of our schools.

"It must not be overlooked that lessons have a deeper meaning and weight for children if they are given and enforced by teachers whom the children respect and love; so that we finally get back in temperance instruction, as in every other kind of instruction, to the living teacher as the most potent influence for good."

This is very well put. There is, however, one point which would bear a little more emphasis: that only "in a narrow and limited sense does the word temperance stand for abjuring that which intoxicates, that in its broader and truer sense the word stands for high self-control and self-respect." It would be a pity that the youthful mind should not be made to understand that even an advocate of "temperance," in the narrow sense, who abjures alcoholic stimulants may still be a very intemperate person. Let the young learn that temperance means moderation, and above all self-control. The methods suggested by the Massachusetts Board of Education for teaching this are excellent.

## THE VITAL STATISTICS OF ENGLAND FOR 1894.

"THE General Abstract of the Marriages, Births and Deaths in England, for 1894," has been received. This document consists of a brief summary which is made up and presented to Parliament early in the year, to be followed several months later by the registrar-general's annual report, which contains full details for each registration district. The annual report contains the corrected figures which are usually a little larger than those of the general abstract. The difference, however, is usually so slight as not to change the decimal figure more than one-tenth. We may, therefore, consider these advance figures of the general summary as sufficiently correct for ordinary comparisons.

The following are the numbers of marriages, births and deaths in England, for 1894, together with the ratio per 1,000 of the estimated population. The registrar-general's estimate of the total population of England and Wales for the middle of 1894 was 30,060,763.

| | England | Ratio per 1,000 living. | | | | |
|---|---|---|---|---|---|---|
| | 1894 | 1894 | 1893 | 1892 | 1891 | 1890 |
| Persons married | 452,218 | 15.0 | 14.7 | 15.4 | 15.6 | 15.5 |
| Births | 889,242 | 29.6 | 30.8 | 30.5 | 31.4 | 30.2 |
| Deaths | 498,515 | 16.6 | 19.2 | 19.0 | 20.2 | 19.5 |
| Excess births over deaths | 390,727 | 13.0 | 11.6 | 11.5 | 11.2 | 10.7 |

In London, similar statistics for the year 1894, are as follows:

| | | Ratio per 1,000 living. |
|---|---|---|
| Persons married | 73,801 | 16.07 |
| Births | 130,853 | 30.02 |
| Deaths | 75,262 | 17.31 |
| Excess of births over deaths | 55,291 | 12.71 |

The following are the quarterly percentages for 1894, for England:

| | Marriages. | Births. | Deaths. |
|---|---|---|---|
| First quarter | 21.1 | 25.7 | 29.7 |
| Second quarter | 23.6 | 24.9 | 23.8 |
| Third quarter | 26.5 | 24.2 | 21.5 |
| Fourth quarter | 28.8 | 25.2 | 25.0 |
| | 100.0 | 100.0 | 100.0 |

The births of males were in the ratio of 1,037 males to each 1,000 females. Of the deaths, 51.3 per cent. were males and 48.7 were females. The great diminution in the death-rate from 19.2 in 1893 to 16.7 in 1894, is quite remarkable considering the comparatively uniform rate of the previous years.

## MEDICAL NOTES.

YELLOW FEVER AT SANTOS.— Yellow fever in its severest form has again broken out at Santos, the daily mortality being six.

CHOLERA IN CHINA — Cholera is reported to be very prevalent in Hong Kong, and in Macao, near Canton. The disease is also said to exist in the northern part of the empire, and to have been brought into Japan by the returning troops.

THE ILLINOIS COLLEGE OF PHARMACY. — The Illinois College of Pharmacy at Chicago has added to its faculty two new professors, Mr. Henry Kraemer, and Mr. Jan B. Nagelvoort.

MEDICINE. — A new monthly medical journal has appeared under this title. It is published by George S. Davis at Detroit, Mich., and takes the place of the *American Lancet*, which lately went out of existence. The first number contains several interesting and well illustrated articles.

DR. RUSH AND GENERAL WASHINGTON. — The article on Dr. Rush and General Washington in the May *Atlantic*, which contains several letters from Dr. Rush to John Adams, is an interesting contribution, and deserves the attention of students of history and of the profession to which Dr. Rush belonged. The writer, Mr. Paul Leicester Ford, states that there exists to-day in Philadelphia an autobiography of Dr. Rush in which frequent comparisons are drawn between himself and Washington to the latter's disadvantage. Unfortunately the publication or sight of it is prohibited, or further light might be thrown on the subject of the paper.

RESULTS OF ANTITOXIN TREATMENT. — Schröder (*Münchener med. Woch.*, April 4, 1895), gives the results of the treatment of diphtheria with antitoxin at the Altona Hospital from September 1, 1894 to March 1, 1895. Sixty-three cases were treated with Behring's serum, in all but seven of which the diphtheria bacillus was found. Of the 63 cases, only eight, or 12.69 per cent., died. In order to show that it was not only in the mild cases that the serum had its effects, he is able to report that 31 of the cases required tracheotomy, and that of these only three died, or 9.67 per cent. This is certainly the most successful series of cases ever reported of operations for stenosis of the larynx. The lowest mortality from diphtheria in the Altona Hospital during the last seven years was 29.23 per cent. in 1891; the highest, 37.27 per cent. in 1888.

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, May 8, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 37, scarlet fever 36, measles 114, typhoid fever 15.

A FREE HOSPITAL NOT LIABLE. — The Supreme Court of Connecticut has recently decided in a suit brought against the Waterbury Hospital, for alleged maltreatment, that the hospital was not liable, as no fees were paid to the attending physicians, and no charge was made for treatment.

THE FIRST ANNUAL REPORT OF THE MASSACHUSETTS BOARD OF REGISTRATION IN MEDICINE. — This report, a summary of which was given in the JOURNAL of January 24th of the present year, has just been received. The four medical schools mentioned in the report as now conferring degrees in medicine are, the Medical Department of Harvard University, the Boston University School of Medicine, the College of Physicians and Surgeons, and the Tufts College Medical School. Two schools, graduates of which were exempted from examination under the Medical Registration Act, have become extinct, namely, the Berkshire Medical College, which was at one time the medical department of Williams College, and the New England Female Medical College, which was incorporated in 1850, and in 1874 by act of the Legislature was united with the Boston University School of Medicine. The Worcester Medical College is dormant, no instruction having been given since 1859, but its corporate existence is still maintained. The graduates of this college between 1852 and 1859, the period of its activity, were 72 in number. The Medical Department of Clark University does not confer the degree of M.D., but is intended for the study of the purely scientific branches of medicine.

THE OUTBREAK OF TYPHOID FEVER AT STAMFORD. — In the recent severe outbreak of typhoid fever at Stamford, Conn., all the cases have been traced to a foul well in the stabling shed of H. R. Blackham, a retail milk dealer on Greenwich Avenue, in that part of the city known as Waterside, and it is stated that not a single instance of the disease has occurred in a family which was not supplied with milk by this dealer. Blackham is accused by the citizens of having watered his milk, and it is said to be a fact that he sold his milk at a lower rate than other milkmen; but he claims that he merely washed his pails and cans in the water from the well. At all events, Health Officer Hexamer has made a complaint to the Public Prosecutor against him, and he will have to defend himself in the courts on the charge of violating the city ordinance regarding the selling of unwholesome food. Dr. T. Mitchell Prudden, of New York, who made the analysis of the water of the well for the Stamford authorities, says, in his report on it: "The number of living bacteria of various kinds in one cubic centimetre is 69,660. This number of living germs would be reasonable in sewer water or a cesspool, but indicates in a well which is being used a gross contamination. It may be interesting, as a matter of comparison, to know that the Croton water of New York contains 156 germs to one cubic centimetre. This is a fair average number for good surface water; which, as a rule, is liable to contain more bacteria than that of properly constructed wells." The Common Council has ordered this well and a number of others in the immediate neighborhood closed. It is easy to understand how its water could contain typhoid fever germs, in addition to other bacteria, as it has been found to receive the direct drainage of the privies of several small dwellings which stand on rising ground within twenty-five feet of it. Dr. W. P. Northrup, of New York, who was called in consultation to see the infant of Dr. E. J. Mechs, who was one of the sufferers, states that the number of children under two years of age who had well developed cases of typhoid was remarkable. He had the opportunity of personally examining quite a number of them, and he ascertained that they had all been fed upon the Blackham milk.

### NEW YORK.

IN MEMORY OF DR. ALFRED L. LOOMIS. — At the semi-monthly meeting of the New York Academy of Medicine held May 2d, the session was devoted to

special memorial exercises in honor of the late Dr. Alfred L. Loomis, who was President of the Academy at the time its handsome and commodious new building was erected, and to whose persevering and energetic personal efforts the successful accomplishment of the great enterprise was largely due. On this occasion the eulogies were pronounced by Dr. Lewis A. Stimson, Professor of Surgery in the University of the City of New York, by the Rev. Dr. Henry M. McCracken, Chancellor of the University, and by Ex-Mayor Abram S. Hewett.

Superintendent of the New Aquarium. — Dr. Tarleton H. Bean, of Washington, who is the author, in collaboration with Dr. Goode, of a work on Deep Sea Piscatology, has been appointed superintendent of the new city aquarium at Castle Garden, at a salary of $3,000 a year. Dr. Bean, who for twenty-one years has been connected with the Fish Commission and the Smithsonian Institution at Washington, is an expert on aquariums, and recently passed the Civil Service examination requisite for his appointment with a very high percentage.

## Miscellany.

### STATE ROADS IN MASSACHUSETTS.

In a letter on the subject of State roads in Massachusetts, Col. Albert A. Pope gives a summary of the work done by the Highway Commission under the Act of 1894, authorizing the appropriation of $300,000 to be expended by the Commission in building State Highways. The question of the improvement of our roads is so important to the welfare, and, so far as they facilitate bicycle and equestrian exercise, to the health of the community, that we give a brief summary of the work already done, in the hope that medical men will lend their influence and assistance in furthering legislation to carry on and complete the work already accomplished.

The $300,000 has been pretty evenly divided among fourteen counties. Before deciding which of the many petitions should be granted, an official visit was paid to each locality, and full information as to the value of the proposed improvement collected. While this method has distributed the work in small sections of roads, thus increasing the expense per mile, the advantage to the people at large will be greater, for the reason that each portion of the State highway constructed is intended to be an object-lesson to those living near by. County commissioners and other officials will watch the work as it progresses, and follow out the same lines in building county and other roads which are not intended for State highways.

Wherever the traffic was of sufficient proportions to warrant it the roads have been broadened. The advantage to owners derived from the construction of the way is, as a rule, so much greater than the injury to them by widening the road that, in a large majority of cases, the town officials have been able to procure releases without any cost.

Thirty-eight sections have been contracted for, and only eight of them are to have a width of eighteen feet of hardened surface, all others being fifteen feet wide. As the primary object is to get length of way, the Commissioners are considering the advisability of building single-track roads in the thinly-settled districts. These would not be over nine feet wide, with here and there portions of double width as convenient passing points for carriages. A mile and a half of such roads can be built for less than the cost of a mile of fifteen feet width, and the advantage in getting produce to market is not lessened, provided such construction is confined to localities where the average traffic is from six to eight vehicles an hour.

There is need of legislation to regulate the care of, and responsibility for, sidewalks on State highways. These being of purely local advantage should be under the supervision of the town, the wheelways alone being constructed and kept in order by the State.

Progress has been made in the laboratory work on the road-building stones of the State. Experiments of this kind are carried on at Harvard University in the Lawrence Scientific School, whose dean, Prof. N. S. Shaler, is a member of the Highway Commission. The chief aim of these inquiries has been to determine the qualities which constitute fitness for road making. This will be of value to the Commission in enabling them to utilize the road material near at hand, and thus lessen the cost of construction. As this phase of the work progresses maps are made showing the location of all deposits suitable for road building.

A number of towns have already appropriated money to build their streets in the same careful manner as those constructed by the State, and others have purchased road machinery with the intention of extending the work on roads other than State highways.

Careful consideration has been given to the plan of planting shade trees along the highways. With this end in view, experts have been consulted concerning the best varieties for the purpose, and the wayside trees have been examined, so as to determine the species well adapted to the climate and soil of Massachusetts.

### THE CAUSE OF PREMATURE BALDNESS.

Leslie Phillips, M.D., in the April number of the *Birmingham Medical Review*, after showing the fallacy of the argument that the greater frequency of baldness in men than in women is due to lack of ventilation in the head covering, the pressure of the hard head gear interfering with the circulation, etc., offers a more obvious and to all appearances reasonable explanation. He says:

"This marked difference in the two sexes coincides with very marked differences in the conventional treatment of the hair. The association and relation of these two circumstances obviously agree with and are an example of the well-known pathological proposition that disuse leads to atrophy. In men the hair is habitually cut short from childhood, while in women the converse is almost universally true. In boyhood and manhood by clipping or cutting the hair we remove the gentle traction on the bulb and follicle which the natural weight of the hair exercises, and which constitutes the essential and natural stimulus necessary to secure due innervation and vascular supply to the hair-producing structures. Loss of vigor, and finally more or less pronounced atrophy, is the inexorable result, modified or delayed, it may be, by collateral circumstances, predispositions or conditions. In the light of the same consideration, the rationale of the beneficial influence of regular, gentle, and prolonged dressing and brushing of the hair is to be sought for in the stimulating influence of traction upon the circulation within the hair bulb and follicle."

He further calls attention to the fact that the treatment of loss of hair in women is much more successful than in men, and the prognosis is also much better in women. He refers to the tendency of the "eman-

cipated woman" to cut her hair short in terms of condemnation, and points out that in assuming this mannish convention they are taking a retrograde, and not a forward step, and calls attention to the fact that Jeremiah puts cutting off the hair in the same class as circumcision, which, like other mutilations, has been shown to be of the nature of a representative sacrifice.

"In the case of men and emancipated hair-cropped women, we contravene Nature's law; and Nature's revenge is — slowly, perhaps, but none the less surely — atrophy." If the emancipated women can be made to believe that wearing the hair short brings with it the danger of baldness, she will have to be very thoroughly emancipated, or she will give up this method of emphasizing her masculinity.

## THERAPEUTIC NOTE.

THE STERILIZATION OF CATGUT. — Johnston[1] recommends a method for sterilization of catgut devised by Krönig, one of the assistants of Zweifel of Leipzig, and used with success by him in the hospitals with which he is connected at Grand Rapids, Mich. It is intended to do away with the necessity of boiling under pressure which obtains when alcohol is used as a medium, owing to its low boiling point. The method, as described by Johnston, is as follows:

"Krönig therefore uses cumol, which is obtained by the distillation of coal tar, and whose boiling point is about 170° C. In this the gut can be boiled one hour without the least injury, providing it is first thoroughly dried by being subjected to dry heat at 70° C. for about two hours. Care must be taken that the temperature of the incubator or drying oven be *slowly* raised to the desired point, else the gut will be rendered brittle; also, that the temperature be not allowed to exceed 100° C., else the integrity of the gut will be injured. When dry, the gut, which has previously been cut into proper lengths and wound into coils of any desired size, is transferred to a glass jar filled with cumol, which is then placed in a sand bath. Care should be taken that the sand surrounds the jar to about two-thirds of the height of the cumol, in order that the latter may become heated as evenly and rapidly as possible. The jar is then covered with a piece of glass or wire netting to prevent the cumol from accidentally catching fire, and a couple of Bunsen burners are placed under the sand bath. When the boiling point of the cumol is approached one of the burners is removed, the other being sufficient to keep the cumol at or near its boiling point. If it boils no harm is done, as the gut when properly dried bears a temperature of 170° C. in cumol without injury, but the consumption of cumol is then unnecessarily great. At the end of one hour the second burner is removed, and when the cumol has cooled the catgut is removed with sterile forceps and placed in a sterile jar filled with petroleum benzine in order to remove the cumol, which is an oily fluid. The gut can remain in the benzine permanently; or be transferred to sterile Petri dishes at the end of three or four hours, and kept dry; or be preserved in absolute alcohol, as is done in the hospitals with which I am connected. Catgut prepared carefully in this manner retains its original qualities and is absorbed in from seven to fourteen days, according to size."

[1] American Journal of Obstetrics, April, 1895.

## METEOROLOGICAL RECORD,

For the week ending April 27th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer. Daily mean. | Thermometer. Daily mean. | Thermometer. Maximum. | Thermometer. Minimum. | Relative humidity. 8.00 A. M. | Relative humidity. 8.00 P. M. | Relative humidity. Daily mean. | Direction of wind. 8.00 A. M. | Direction of wind. 8.00 P. M. | Velocity of wind. 8.00 A. M. | Velocity of wind. 8.00 P. M. | We'th'r.* 8.00 A. M. | We'th'r.* 8.00 P. M. | Rainfall in inches. |

Deaths reported 2,975; under five years of age 1,025; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 327, acute lung diseases 569, consumption 351, diphtheria and croup 122, diarrheal diseases 44, measles 38, scarlet fever 36, whooping-cough 27, typhoid fever 23, erysipelas 17, cerebro-spinal meningitis 11, malarial fever 9.

From scarlet fever New York 12, Providence 5, Boston and Cleveland 3 each. Philadelphia and Brooklyn 2 each. Washington, Fittsburg, Nashville, Lynn, Somerville, Lawrence, Brockton, Malden and Chelsea 1 each. From whooping-cough New York 17, Philadelphia 4, Brooklyn 3, Cincinnati, Lynn, and Haverhill 1 each. From typhoid fever Philadelphia 10, New York 3, Boston, Pittsburg and Lawrence 2 each; Washington, Nashville, Charleston and Fall River 1 each. From erysipelas Brooklyn 6, Boston 5, New York 3, Philadelphia 2, Wor-

cester 1. From cerebro-spinal meningitis New York 4, Washington, Worcester, Lynn, Somerville, Lawrence, New Bedford and Woburn 1 each. From malarial fever New York 9.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM APRIL 27, 1895, TO MAY 3, 1895.

Leave of absence for two months to take effect upon the conclusion of his examination to determine his fitness for promotion, is granted FIRST-LIEUT. HENRY D. SNYDER, Assistant Surgeon United States Army.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 4, 1895.

E. R. STILT, passed assistant surgeon, detached from U. S. S. "Chicago," and to Nicaragua Canal Board inspection of work on the Isthmus.

H. G. BEYER, surgeon, detached from Naval Academy and to the "Monongahela."

L. W. ATLER, passed assistant surgeon, from the New York Hospital and to the "Richmond."

J. M. EDGAR, passed assistant surgeon, from the "Richmond" and to the school ship "Saratoga."

V. C. B. MEANS, passed assistant surgeon, from the "Saratoga" and to the New York Hospital.

ROBERT BOYD, assistant surgeon, from Philadelphia Hospital and to the "Monongahela."

LEWIS MORRIS, assistant surgeon, ordered to the Philadelphia Naval Hospital.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING APRIL 30, 1895.

C. S. FESSENDEN, deputy surgeon, detailed for duty on Board for examination of officers Revenue Cutter Service, April 17, 1895.

J. B. HAMILTON, surgeon, granted leave of absence for twelve days, April 20, 1895.

G. W. STONER, surgeon, detailed to represent service at meeting American Medical Association, April 25, 1895.

F. W. MEAD, surgeon, detailed as Chairman, Board for physical examination officers Revenue Cutter Service, April 17, 1895.

C. E. BANKS, passed assistant surgeon, when relieved to report at Bureau for duty as Chief of Purveying Division, April 24, 1895. Granted leave of absence for fourteen days, April 29, 1895.

L. L. WILLIAMS, passed assistant surgeon, detailed for duty on Board for examination of officers Revenue Cutter Service, April 17, 1895.

W. C. MCINTOSH, passed assistant surgeon, detailed for duty on Board for examination of officers Revenue Cutter Service, April 17, 1895.

J. J. KINYOUN, passed assistant surgeon, detailed to represent service at meeting American Medical Association, April 25, 1895.

R. M. WOODWARD, passed assistant surgeon, to proceed to Ashtabula, Ohio, as inspector, April 19, 1895.

C. P. WERTENBAKER, passed assistant surgeon, granted leave of absence for ten days, April 16, 1895.

B. W. BROWN, passed assistant surgeon, detailed as Recorder, Board for physical examination officers Revenue Cutter Service, April 17, 1895. Granted leave of absence for twenty days, April 23, 1895.

W. J. S. STEWART, assistant surgeon, to rejoin Station at Washington, D. C., April 20, 1895.

EMIL PROCHAZKA, assistant surgeon, to proceed to Evansville, Ind., for temporary duty, April 29, 1895.

A. R. THOMAS, assistant surgeon, granted leave of absence for thirty days, April 19, 1895.

## SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.— The last regular meeting of the Society, for the season, will be held at the Medical Library, 19 Boylston Place, on Monday evening, May 13, at 8 o'clock.

Dr. Clarence J. Blake will present a paper entitled, "An Infirmary for Harvard College."

Dr. G. W. Fitz: "A College Infirmary from the Standpoint of Official Medical Visitation."

Mr. C. H. Walker: "Hospital Construction."

The following gentlemen have been asked to discuss the topics of the evening: Dr. H. P. Walcott, Dr. J. L. Hildreth, Dr. Walter Ela, Mr. Edmund M. Wheelwright and Mr. A. G. Everett.

JAMES G. MUMFORD, M.D., *Secretary*.

NORFOLK DISTRICT MEDICAL SOCIETY.— The Annual Meeting will be held at the Old Dorchester Club House, Tuesday, May 14th, at 12 M.

The Board of Censors will meet at the same place, at 12.30 P. M.

The Examination of Candidates will take place one week later, on Tuesday, May 21st, at 7 P. M., at the office of the Secretary, 130 Warren Street, Roxbury. The written Examination will begin at 7 P. M., the oral at 8 P. M.

Order of Business: (1) Reading of Records, (2) Reports of Committees, (3) Report of Treasurer, (4) Election of Officers, (5) Incidental Business.

The Annual Address will be delivered by C. E. Stedman, M.D.

The Secretary particularly requests that all who expect to attend the Annual Meeting, will notify him, so that he may be able to make suitable provision for the dinner.

JAMES C. D. PIGEON, M.D., *Secretary*.

130 Warren Street, Roxbury.

AMERICAN NEUROLOGICAL ASSOCIATION.— The Association will hold its twenty-first annual meeting in Boston on the 5th, 6th and 7th of June, in the rooms of the Society of Natural History, on the corner of Berkeley and Boylston Streets. The programme of the meeting will be published later.

AMERICAN PEDIATRIC SOCIETY.—The Society will hold its Seventh Annual Meeting at the Virginia Hot Springs, May 27, 28, and 29, 1895. The Society will be the guests of the Virginia Hot Springs Company.

SAMUEL S. ADAMS, M.D., *Secretary*.

## APPOINTMENT.

FRANKLIN GREENE BALCH, M.D., has been appointed surgeon to out-patients at the Carney Hospital.

## RECENT DEATH.

PATRICK HENRY CAMPBELL, M.D., M.M.S.S., died in Dorchester, May 3, 1895, aged thirty years.

## BOOKS AND PAMPHLETS RECEIVED.

The Therapeutical Employment of Ferropyrin. By Dr. W. Cubasch, Stansstad. Reprint. 1895.

A Unique Form of Motor Paralysis Due to Cold. By Ezra Clark Rich, M.D., of Ogden City, Utah. Reprint. 1894.

Progress in the Care and Treatment of the Insane during the Half-Century. By Edward Cowles, M.D. Reprint. 1894.

On Rheumatic and Allied Affections of the Pharynx, Larynx and Nose. By W. Frendenthal, M.D., New York. Reprint. 1895.

Malposition of the Testicle; Phimosis; Acute Insanity; Operation; Cure. By Howard Crutcher, M.D., Chicago, Ill. Reprint. 1895.

The Advertiser's Handy Guide for 1895. Compiled and published by the Lyman D. Morse Advertising Agency, 38 Park Row, New York.

Free Hydrochloric Acid; Is its Absence from the Stomach a Sign of Cancer? By Richard B. Faulkner, M.D., Alleghany, Pa. Reprint. 1895.

Subvolution; A New Pterygium Operation. Ripening of Immature Cataract by Direct Trituration. By Boerne Bettman, M.D., of Chicago. Reprints. 1894-95.

The Relative Age-Occurrence of Colles' Fracture; A Table of Nine Hundred and Eighty-eight Cases. By Charles A. Powers, M.D., of Denver, Col. Reprint. 1895.

Ainhum. The Treatment of Syphilis with Intravenous Injection of Mercuric Chlorid. By Walter Lytle Pyle, A.M., M.D., of Washington, D. C. Reprints. 1895.

The Practical Examination of Railway Employés as to Color-Blindness, Acuteness of Vision and Hearing. A New Wool-Test for the Detection of Color-Blindness. By William Thomson, M.D., Philadelphia. Reprints. 1882-1894.

Ophthalmia Neonatorum. The Importance of Active Treatment of the Naso-Pharynx in the Treatment of Obstructive Disease of the Lachrymal Passages. A Case of Albuminuric Retinitis. By C. A. Veasey, M.D., Philadelphia, Pa. Reprints. 1895.

## Original Articles.

### CASES ILLUSTRATING THE PLASTIC SURGERY OF THE NOSE AND PALATE: AN OPERATION FOR CLEFT PALATE.[1]

BY H. L. SMITH, M.D.,
*Assistant Visiting Surgeon of the Boston City Hospital.*

THE operations here described were performed during the past year at the Oral Hospital connected with the Boston Dental College. They are seven in number, four having been done for various defects of the nose, and three for cleft palate. The nasal cases will be reported quite briefly, that special attention may be called to the method employed for the restoration of the palate.

PROMINENCE OF NASAL BONES FOLLOWING FRACTURE; SKIN FLAP RAISED TO ROOT OF NOSE; PROJECTING BONE CHISELLED OFF; LOOSE CARTILAGE SUTURED; SEPTUM STRAIGHTENED; IMPERCEPTIBLE SCAR; SUGGESTED METHOD OF REMOVING INTRA-NASAL GROWTHS.

The deformity resulting from fracture of the nose may be one of two kinds. Probably the more common form is associated with the well-known sunken bridge, the depression beginning near the root of the

nose, and extending nearly to its tip. With it are associated some of the well-recognized displacements of the bony and cartilaginous septum. Correction of this deformity consists in "setting up" the nasal bones, and in correcting the position of the septum. In the second variety to which the following cases belong, the nasal bones themselves are either not depressed at all, or the depression is upon one side only, or, in addition, during the process of repair, a distinct thickening occurs at the lower end of one or both bones. Generally this apparent projection of the bone is due in large measure to the separation and downward displacement of the lateral cartilages, the lower ends of the bones projecting sharply beneath the skin. The deformity thus produced is often very noticeable, and is exaggerated by all motion of the facial muscles, such as eating or talking. The changes in the septum are similar to those in the first variety.

Two operations, at least, have been used for the relief of this condition. The simplest plan is to cut directly down on the prominent bone, generally by a vertical incision running along the ridge of the nose, then to turn a skin flap to each side, remove the offending tissue and suture the flaps. Roe[2] has operated by passing a suitably curved knife into the nasal cavity, perforating the mucous membrane, and then shaving off the required amount of tissue subcutaneously. The only and obvious objection to the first operation is the resulting scar. The second method was not used in the cases reported, because it was thought impracticable to remove in this way the very dense bone which caused the deformity. As the result showed, it would have been very difficult, to say the least, for even with the open incision it was a matter of very great difficulty. Moreover, another advantage offered by the open method was the opportunity which it afforded of correcting the lateral deformity at the same operation.

CASE I. A male nurse, forty years old, received a fracture of the nose when a child. At the present time the lower extremity of the right nasal bone projects strongly against the skin, and is evidently increased in size by the process of repair. All the cartilages of the nose, down to the tip, are abnormally movable, giving very slight support to the organ. The nose, as a whole, is turned toward the right side, and the tip droops. The septal cartilage is dislocated from its ridge into the left nostril, and at the same time its centre bulges in the same direction, so that the left nasal passage is nearly occluded. The operation proposed was explained to the gentleman; and he requested that it be done, although it could not be foreseen just how far the incisions would have to be carried. The plan was to cut across the septum at its middle and to make a second incision in each alar groove, the two skin incisions to be

joined by a third, passing along the mucous membrane just inside the nostril. By this means it was hoped that the skin might be lifted from the entire nose, without extending the lateral cuts beyond the natural crease beside the ala. If this could be done, the resulting scar would be inconspicuous. The plan proved even more feasible than was expected, and the whole nose was thus laid bare. With chisel and cutting-forceps the bone was trimmed down to the level desired. The left lateral cartilage, which was more loosely attached than its fellow, was brought up toward the nasal bone by a suture passed through the fibrous tissue overlying each, and in this manner the lateral deflection of the nose was diminished. Although correction of the septal deflection had not been intended, the incision gave so good access to the nasal cavity that the cartilage was loosened from its new base and pressed toward the median line. No instruments were at hand for carrying out any one of the recognized operations for deviated septum, and permanent relief was not hoped for, yet the nostril was so well opened by the simple procedure, that no further interference has been required; and at the present time, nearly a year later, there appears to be no tendency toward further closure. The skin flap was then replaced, and fine silk sutures applied at the alæ and septum. They were removed on the third day, and the line of incision was hardly visible at the end of two weeks. The nose became slightly discolored, and was somewhat swollen for several weeks. The patient had an attack of tonsillitis during the process of repair, but suffered very little discomfort that could be referred to the operation.

CASE II. This case was almost identical with that just reported. The deformity was upon the opposite side, the

[1] Read before the Boston Society for Medical Improvement, March 4, 1895.

[2] Roe: Medical Record, New York, vol. xl, 1891, p. 57.

septum being deflected into the right nasal cavity, where it was adherent to the right inferior turbinate over a considerable area. It was separated, and replaced in the median line at the time of the operation, and has given no more trouble. Access to the nose was found quite as complete as in the previous case, and the resulting contour of the nasal bridge was perfectly satisfactory. Here, too, the lateral cartilage was drawn up by a suture.

It need hardly be said that the method here described is applicable only in those cases where the nasal bones are prominent rather than depressed, and where it is evident that the contour will be satisfactory if the redundant and projecting tissue is removed. Apparently it could be quite well applied to those cases where the natural shape of the organ, due chiefly to the prominence of the nasal bridge, amounts to a deformity.

The procedure of freeing the alæ in order to obtain a better access to the nasal cavity is an old expedient; but the writer has seen no statement of its use in combination with an incision across the septum, with the complete flaying of the nose, for the purpose of gaining access to the nasal bridge.

The size of the opening into the nostrils which was disclosed in these operations leads to the suggestion that the same incision might be employed for the purpose of gaining access to the nasal space, in the case of large intra-nasal growths. The operations devised for attacking this space from in front, such as Cheever's, Ollier's, Langenbeck's, Dieffenbach's, v. Brun's, etc., require incision through the skin of the nose or cheek, which necessarily leave scars. In most of the operations, and Ollier's notably, the needed room is gained by pressing the cartilaginous and bony septum to one side. In Cheever's operation, as I understand it, this is not necessary, and the latter seems to have the advantage of giving greater entrance space than any other. After lifting up the skin flap in the way here suggested, it is an easy matter to cut through the lateral cartilages, or separate them in the median line, and then it remains only to press to one side the flexible septum in order to gain a passage into the nasal space as large as that given by most of the operations named. If necessary temporary resection of the nasal bones could be employed without lengthening the skin incision.

"PUG NOSE"; INCISION THROUGH SEPTUM; SKIN RAISED FROM TIP OF NOSE; WEDGE OF CARTILAGE REMOVED.

A prominent nasal tip is sometimes repugnant enough to its owner to call for surgical relief. The protuberance has been removed by various methods, and is commonly believed to be made up of fat tissue. In the following case there was no increase of tissue, but an abnormal shape of the cartilage.

CASE III. The patient, a lad of sixteen, had a prominent tip to the nose, the organ projecting forward rather than upward, and the tip feeling rather dense. An incision was made through the middle of the septum and continued through the mucous membrane out to the ala, on each side, but without involving the skin of the ala. This incision was found sufficient to allow the skin to be turned up over the tip of the nose. The prominence was now found to be due entirely to a crumpling of the cartilages, which had been curved upon themselves in some such way as is natural in the cartilages of the ear. There was no extra amount of fatty tissue. The two upward-projecting pieces of cartilage were removed by including them in a wedge-shaped piece which was excised, the edges being then sutured with fine silk. In this way the somewhat broad tip of the nose was narrowed, and its prominence distinctly diminished. On returning the skin to its place it was found too large for the shrunken organ, and a portion of the septum was removed. A moderate amount of swelling supervened, and it was several weeks before the permanent shape was attained. It was then found that still more tissue might have been sacrificed, although the result is now quite satisfactory to the patient.

FORMATION OF A SEPTUM NASI FROM THE UPPER LIP.

CASE IV. The patient was a girl of thirteen, who at the age of eighteen months had had an ulceration of the septum lasting nearly a year, and resulting in the destruction of the septum and a portion of the tip of the nose, the nostrils thus being thrown into a single cavity for a distance of about two centimetres. The operation was undertaken at the earnest request of a lady who was desirous of adopting the child, in case the deformity could be lessened. I remembered to have seen Prof. C. B. Porter make a nasal bridge for a man, and recalled his remark that the mucous membrane would gradually take on the character of the skin, and the hair of the lip cease to grow. Such an operation was suggested for this case, and was requested. Owing to the undermining of the upper lip it was feared that the blood-supply would not prove sufficient, and in fact for some days there was a doubt whether the flap would survive. No sloughing occurred, however, although on account of this fear it was impossible to cut up as far on the lip as was desired, or to push the new flap deep into the nose. As a consequence several operations have been necessary. The new septum is rapidly losing its reddish color, and is fairly satisfactory. The scar in the lip has a tendency to keloid formation, which thus accentuates the cicatrix, and the latter is not absolutely in the median line, although when the incisions were made great care was taken to have them central. While the friends express themselves as satisfied with the change, I am not entirely pleased with the result, and in another case would prefer before resorting to the knife to try the effect of an artificial contrivance, which could be fastened to some support passed into the nostril.

CLEFT PALATE.

In discussing this subject I shall omit all controversial matters, such as the comparative value of the operation and the appliance, at what age we should interfere, etc., and deal briefly with the following points:

(*a*) What function impaired by this deformity are we attempting to restore, and what is the cause of its impairment or loss?

(*b*) What is the surgical problem presented in attempting to restore such function?

(*c*) How, if at all, do the operations now in use fail to solve this problem?

(*a*) To the first of these questions there can be but one answer — the restoration of normal voice. In the infant, to be sure, the question of ability to swallow may for a time be uppermost, but that problem, if it is capable of solution, is solved by the nimble tongue, long before operation is thought of. We are led at once to the second part of the inquiry, namely, in what way does the cleft palate prevent natural speech. I do not know that this problem has been worked out with the care it deserves. Without being dogmatic, perhaps the following will be accepted as reasonably accurate: For vocal resonance there should be a roomy oral vault, without obstruction anywhere. For the production of all the open vowels and of all the consonants save the nasals, there must be perfect closure of the post-nasal space. In effect-

ing this closure the velum palati does not simply swing backward and upward, as if hinged at the posterior edge of the palate bones. The process is a modified sphincter action, the chief muscles taking part being on each side the levator palati and the superior constrictor of the pharynx. When the vault of the pharynx is shut off, the velum is so raised that it extends for a little space directly backward on a level with the palate bones, and then curves gradually downward and backward, its posterior surface striking the posterior wall of the pharynx, at some distance from the free edge. In this act the anterior fold of the edge of the velum, made of the palato glossus muscles, does not come in contact with the pharyngeal wall at all, this being left for the part represented by the palatopharyngeus, the uvula projecting between these folds in much the same way as the tonsil projects between the two faucial pillars.

It must be remembered that at the same time that the velum is being lifted upward and backward the pharyngeal space is narrowed, laterally, by this action of the superior constrictor, which muscle also, at least in some cases that I have observed,[3] raises the whole pharyngeal wall directly upward, even at the posterior surface, where it is least movable on account of the closeness of the vertebral bodies. Another rather curious feature of this closure is the behavior of the uvula. When the contact of the velum with the posterior wall is light, it stands pointing downward and forward at an angle of about 45°; but when the closure is very firm, instead of being carried bodily back against the wall of the pharynx, as might seem its natural action, the whole uvula disappears from view, being literally telescoped into itself, by the contraction of the azygous uvulæ. Precisely what effect such a movement has we can only conjecture, but it may be conceived that the velum is thus thickened in the median line, at a point where, on account of the presence of the vertebræ, the sphincter action is at a certain disadvantage, and the perfect closure of this space is thus assured.

(*b*) What, then, is the problem? Obviously it is to restore the continuity of the sphincter, and to replace at the posterior edge of the palate bones a muscular velum voluminous enough to bridge the chasm and form a flexible veil to be lifted by its own muscles up against the posterior pharyngeal well in the required vaulted shape. Any operation which falls short of this cannot, if our reasoning be true, prove satisfactory. The chief difficulty of the problem lies in the fact that there is a loss of tissue. It would be a small thing to bring together the edges of a sphincter which had been merely separated; but with the loss of even a small portion of the normal velum, the still further decrease resulting from freshening the edges, and the contraction which occurs during the healing process must evidently leave a valve considerably less voluminous and less supple than normal.

(*c*) The facts just stated explain fully why there has been such a large proportion of failures, so far as restoration of function is concerned, after surgical operations. Primarily the surgeon has directed his attention toward getting union of the edges, and to accomplish this he soon found it necessary to devise methods of relieving tension. Simple lateral incisions were tried, but were not enough. Dieffenbach,[4] who devised this lateral incision, afterward proposed chiselling through the palatal process and displaced it inward on each side, an operation which Furgusson[5] revived many years after and is generally known by the latter's name. The latter gentleman also made incisions through the velum and performed tenotomies of the levators to relieve tension. Langenbeck[6] in 1861 made public his use of the muco-periosteal flap, and his work has served as the basis for all operations since. Drs. John C. Warren[7] and Mason Warren[8] developed the operation in this country in about the same lines as the German workers, though independently. The latter seems to have been the first one to close the cleft with flaps of mucous membrane. Billroth chiselled off and displaced inward the internal pterygoid process, recognizing, more clearly than any one before, the sphincter-like action of the velum, and the necessity for relieving the tenseness which is sure to follow the ordinary operation. Passavant[9] tried to displace the velum backward, by a lateral incision, but apparently with but partial success, although the idea seems to be more promising than any other for the relief of the nasal speech. Probably it failed in not relieving the tenseness of the velum, so that, although the latter reached farther back toward the posterior wall than before, it could not be arched and approximated closely enough to close the posterior passage.

Other operators have attempted to increase the length of the velum either by plastic operations in the region of the uvula, or by attaching to it behind a flap of mucous membrane dissected from the posterior pharyngeal wall or from other parts in the vicinity. These very ingenious procedures failed of their object from the fact that the new tissue was devoid of muscle, and therefore acted merely as a foreign body, in one case tacked on to the velum, and serving rather as a hindrance to its action. Passavant even sutured the posterior edge of the velum at its centre to the pharyngeal wall, leaving a space on each side. He hoped thus to prevent nasal speech and at the same time to permit the passage of air through the nasal passages. The result was only moderately satisfactory.

None of these many attempts to secure a good voice have proved constantly successful, because none of them secures the formation of a voluminous flexible velum composed of muscular tissue. For the ten years following Langenbeck's work the operation was done very frequently, but during the 70's it fell into well nigh complete disuse, partly owing to the unsatisfactory results of the operation and partly due to the improvements made in the artificial appliances. In the early 80's, largely through the advocacy of J. Wolff, the operation was taken up again, and since then there has been a more or less vigorous competi-

[3] This was especially well seen in the case of a woman of about fifty years who had a cleft running forward to the incisor teeth, but which involved the right nostril only. The posterior wall of the pharynx could easily be studied through the cleft, and during all attempts to shut the nasal passage off from the mouth the mucous membrane in the centre of the pharynx was seen to be thrown into folds as it was raised, the amount of this elevation being at times fully a centimetre. No doubt this represents an unnatural degree of motion, due to the changed conditions, although a smaller movement is sometimes present in normal throats.

tion between the operators and the makers of the appliances. Wolff's [10] first successes were reached by a combination of operation and artificial velum. His patients were made to use at once an apparatus which could be worn back of the repaired velum, and served to lengthen it and thus insure contact with the posterior wall. With confidence in his ability to make clear sounds thus established, the patient who would otherwise soon become discouraged would continue his efforts and after a time would be able to dispense with the artificial aid. Later Wolff discarded the appliance in most cases having developed his method of instruction so that it became unnecessary.

This fact, that the successes of the last named surgeon, who probably has a better record than any other operator in this line of work, were accomplished by means of such particular attention to methods of training the speech, seems to strike at the root of the whole matter. The operation alone is but one factor in the result. Quite as much depends on the intelligence, patience and willingness of the individual, and the knowledge, on the part of the teacher, of the instruction required. The work done by Herr Gutzmann, the deaf and dumb teacher in Germany, in the instruction of these afflicted with the cleft palate, bears out the above statement. Much can be done, even with no operation, to make an utterly unintelligible speech fairly clear. An operation which succeeds in closing the cleft, but leaves a short, tense, thick velum, which is almost immovable, is of no use whatever, and no one will honestly deny the superiority of the artificial velum to such a condition. On the other hand, I believe there is no one who would not express a preference for the operation if it could accomplish the same ends. There can be no doubt that the whole velum changes its shape in the production of each sound, its surface being thrown into varying curves, as finely drawn as those of the sensitive and expressive face by the muscles and nothing can take the place, in the production of pleasing sounds, of this active and delicate organ of speech.[11] Some hint of this constant use of the velum in the production of sounds can be obtained by examining the throat during the pronounciation of some of the open vowels. Although there are few that permit the palate to be seen, since they require the closure of the mouth for their correct production, yet it can easily be proven that the velum is extremely mobile, changing its position and shape with every change in tone, and even with the character of the inspiration and expiration, and that the other muscles of the throat and base of the tongue, especially the superior constrictor, take part in the process. To reproduce this power then in the case of a cleft, no appliance could accomplish as much as a muscular velum, provided only the latter reaches far enough back and is sufficiently under control.

The operation performed by the writer in the cases reported has for its main object the formation of such a velum as is described above. Assuming that the separation is of moderate width, and extends about half way through the bony palate, the operation is done as follows: From the anterior end of the cleft an incision is made running outward and a little backward toward the alveolus, about one-third the distance to the teeth, when the direction of the incision is changed so that it is carried in a straight line nearly to the posterior extremity of the alveolar process. The point at which this incision ends depends somewhat upon the case, care being taken that there is left sufficient tissue for the blood-supply of the flap. A corresponding incision having been made upon the opposite side, the two flaps thus outlined are dissected up from the bone, the periosteum being included, and are freed completely from the posterior edge of the palate bones behind. This last act is very important, as only thus can the velum be really carried backward and so lengthened. An incision is now made on each side, beginning at the point, near the last molar, where the preceding incisions terminated, and running along in a curve, close to the roots of the teeth as far forward as is necessary or as is deemed safe, sufficient space being left in front for the nourishment of the flaps. This cut will usually terminate near the lateral incisors. There are thus formed two triangular flaps, composed of mucous membrane and periosteum, which are carried into the median line and sutured together. The freshened edges of the velum are now sutured, and the posterior edges of the anterior flaps are sewn to the middle of the newly-formed velum. If deemed best tension can still further be guarded against by extra sutures placed in the velum, at some distance from the edge. In case there seems danger that the palate may be carried too far forward during the process of repair, through contraction of the flaps, it has seemed to the writer quite feasible to pass a suture through the periosteum at the posterior edge of the palate bones, and thus anchor the velum at the desired point. In three cases that have been done by the above method there has been no difficulty whatever in obtaining union throughout by first intention, this satisfactory result being due in large measure, apparently, to the entire lack of tension.

The three cases are, in brief, as follows:

CASE V. E. C., a boy of twelve years, who had a congenital cleft involving the soft palate and about half of the hard palate, was operated upon about four years ago, by the Langenbeck method. The velum is united, but there remains a cleft in the hard palate, about two centimetres long and one centimetre wide. The soft palate is thick, hard and very tense, and can be moved but little during efforts at correct speech, so that the voice is thick and nasal, although many of the defects are clearly due to faulty habits of articulation, and not at all to the condition of the palate. In considering the possibility of remedying the condition the question was asked: What would be done for this condition if it were elsewhere in the body. Obviously the greatest chance for relief lay in making lateral incisions, and bringing in flaps from each side. This was done in the manner described above and as soon as the sutures were in place it could be seen that much had been gained, as the velum instead of being tense was now perfectly lax, and was lying, of its own weight, back against the posterior pharyngeal wall. There has been some forward contraction during the process of healing, but the condition is far better than before, and with the aid of the measures that are now being employed to correct the defective habits of speech it is hoped that he may be given a good enunciation. Among other measures massage of the soft palate is being used to give it flexibility.

The result in this case leads the writer to think that in those cases where union has occurred after suture, but speech has remained unsatisfactory on account of the tenseness and shortness of the velum, much relief might be gained by a second operation of the kind just described. It is in this class of cases that the dentists

[10] J. Wolff: Archiv f. klin. Chir., 1886, xxxiii, s. 150.
[11] J. Wolff: Op. cit., s. 170.

have felt obliged, at times, to undo the work of the surgeon, by deliberately cutting open the palate again, in order that an appliance may be fitted. The depressing effects of such a procedure must be very great; and if such palates could be lengthened and rendered more flexible, this experience might be avoided and possibly the speech be rendered satisfactory.

Case VI. The patient was a girl of six, whose cleft included the soft palate and about one-third of the hard palate. The success of the lateral flap in the first case led to its use here also. The result was entirely satisfactory, the velum being carried well back into the pharynx, and the resulting slit in the palate being closed thoroughly by the flaps. About a week after the operation the suture nearest the bone was found to have cut out on one side. The patient was at once etherized and a second suture put in, a little deeper in the flaps. The patient was allowed to go to her home in the country at the expiration of three weeks, still wearing the sutures, and they were not removed until her return, ten weeks after the operation.

The retention of sutures for so long a time would have been looked upon as impossible in the early days of the operation; and one is led to wonder that union was ever obtained, when the first suture was removed on the third or even on the second day, none being left longer than a week. In the first of these three cases the sutures, which were, in all cases, of copper wire, silvered, were not removed until eight weeks after the operation, and in the third case the time was about five weeks. In no case was there the least disturbance that could be attributed to their presence. Probably the time allowed to elapse in these cases is unnecessarily long, and may result in more thickening than is needed, and in the future I shall remove them in from two to three weeks, in case union is assured.

Case VII. F. R., a boy, sixteen years old, had a cleft running from the uvula half-way through the bony palate. Some years ago he applied at a hospital to have the operation done, but was dissuaded, on the ground that the results were not satisfactory. The operation was identical with the last mentioned, and without incident. He remained in bed but a day or two, and soon left for his home in a suburb, coming into the city once or twice weekly, to report progress. His speech improved from the beginning, but more rapidly after the removal of the sutures, which sometimes slipped around and impeded the action of the tongue.

All the operations were performed in the semi-upright position, and with ether narcosis. No great amount of hemorrhage was met with when the incisions were made, slight pressure easily controlling it. An ordinary mouth-gag was used, the tongue-depressor being sometimes necessary. The wire sutures were pulled through the flaps by means of loops of silk thread attached to long-handled curved needles. Hot salt-solution was used as a mouth-wash, and the patients were encouraged to drink milk and to take as much as possible of other liquid and semi-liquid foods.

The bone left bare by the turning of the flaps became covered with swollen tissue and granulations within a few days, and gave no trouble whatever. A considerable fold of tissue is left in the middle of the roof of the mouth, and just how far this will be flattened down time alone can tell. I do not think it will be of any disadvantage, unless possibly in fitting an artificial denture.

Much might be written about the exercises, vocal and other, which should be employed after the operation. All those acts which require the closing off of the nasal space from the mouth are the most important. Among these are the blowing out of a candle by a strong puff of the breath; the blowing of a lead pencil or similar object forcibly from the lips, etc. In order to follow the improvement made by these patients, and with the idea that the defects in speech may be made known to the patient himself, and thus corrected more intelligently, I have taken phonographic records of the speech of each one before the operation, and at different times after. The value of this procedure will be determined only after a wider experience.

DISCUSSION.

Dr. H. A. Baker: It is not my purpose to come here to criticise a surgical operation on the palate, as perhaps most practitioners would who make appliances for the same effect. Of course, any one would say if an operation is a success in improving speech there would be no argument on the side of appliance; of course, it would be preferable to any appliance that could be inserted for that purpose. I know that this operation was done many years ago by eminent surgeons, and, of course, the cases that I have seen have been cases that have not been a success, because if they had been they would not have come to me; but I do not propose to discuss the merits or demerits of an operation, because many of you here are eminent surgeons, and operations may have come up that I am not familiar with. I saw three patients Dr. Smith operated on, and in one of them it seemed that there was a chance of a great deal of improvement. I do not know but that everything was done that could be done in that case. It was a child six years old. The child had habits to overcome aside from the deformity, and most of those cases do have habits in their speech, that is, hitching in speech. The idea is, that in imitating speech they imitate as well as they can, and in doing so they do not use their muscles correctly, because they have not the organs to use correctly; and in putting in an appliance or performing an operation, they have a great deal to learn and overcome to correct that speech. Whether that can be done is a question. As I said before, many cases have come to me for correction that have been operated on. Some of them have been a surgical success, that is, there would be an entire closure of the palate. In those cases we have to cut them open, and put in a certain appliance. Of course, if a surgeon operates and has not made a success of it, the patient is worse off than if no operation had been done. They must go through almost as severe an operation to undo the former operation as to have had it done in the first place.

As far as appliances being a success, there is no further question about that. That has been demonstrated time and time again; but, of course, an appliance is an objection. They have always got to wear an appliance if they once have one; and at the same time I find they are pretty willing to if they get any benefit from it.

## SOME OF THE SIMPLER TESTS FOR DETECTING ERRORS OF REFRACTION AND INSUFFICIENCIES OF THE OCULAR MUSCLES.[1]

BY FRANK INGERSOLL PROCTOR, A.M., M.D.,
*Assistant Ophthalmic Surgeon, Massachusetts Charitable Eye and Ear Infirmary; Instructor in Ophthalmology, Harvard School of Veterinary Medicine.*

The importance of correcting ocular errors for the relief of headache and various other functional neuroses has been emphasized by many writers. In the last ten years numerous articles have been published, the titles of a few of which illustrate the direction in which the subject has been investigated.[2]

These articles treat of the relation of ocular defects

[1] Read before the Warren Club, Boston, February 5, 1895.
[2] See list at end of the article.

to headache, and the numerous cases reported prove conclusively that in many instances headache, vertigo, neuralgia and other nervous symptoms are due to some defect of the eyes.

As regards the percentage of headaches due to this cause, it is difficult to make even an approximate estimate; some of the writers referred to consider that eye strain produces more headaches than all other causes combined, and even the most conservative agree that it produces more than any other one cause.

In view of all that has been said and written on this subject, it might be expected that one of the first steps taken by a physician when meeting with these symptoms would be to examine the eyes, to determine whether there were any error of refraction or lack of balance of the ocular muscles. That such a course is the exception, and that an examination of the ocular condition, if undertaken at all, is often the last resort, may be due to the following reasons:

(1) There may be nothing to direct the physician's attention to the eyes. In many of these cases the sight is normal, or nearly so; the patient sees clearly, the eyes themselves may occasion him no discomfort; and he usually attributes his symptoms to some other cause, as to indigestion or overwork, for example.

The following case is an illustration. Dr. R. B., a dentist, thirty-eight years old, consulted me November 1, 1894, with this history: He has practised dentistry fifteen years, and has always been able to work and use his eyes with perfect comfort. On Sundays and holidays, however, when he does no work, he almost invariably suffers with headache, which becomes more severe as the day advances, and is often accompanied by nausea and vomiting. Otherwise, he has always been in good health. Recently he was examined by his brother, a physician, who found nothing to account for these attacks. The eyes were tested, and hypermetropia of 1.25 D. was discovered, for which correcting glasses were prescribed, to be worn constantly. Two months later he returned and reported that since wearing the glasses he had been entirely free from the headache and nausea with which he formerly suffered nearly every week.

(2) Should the physician suspect the existence of some ocular defect, in most cases he possesses neither the apparatus, nor sufficient familiarity with the methods employed, for making a positive diagnosis. The exhaustive articles on refraction in the text-books are more or less confusing, and to carry out their suggestions would necessitate procuring an equipment wholly incommensurate with the needs of the general practitioner.

Dr. Valk, one of the writers referred to at the outset, has appreciated the need of a ready test, adapted to the use of physicians in examining the eyes for purposes of diagnosis. He describes at length a method which, he claims, will meet every requirement. "Retinoscopy," he says, "is the name of this simple test." Referring to this, Dr. Swan Burnett, of Washington, remarks: "It (retinoscopy) has been called a simple test, and so it is; but, simple as it is, it cannot be mastered without painstaking care as to the smaller details, and considerable experience is necessary before it can be executed with the rapidity and certainty of which it is capable . . . and which are among its recommendations to the practitioner."

A few quotations from a recent article[3] by Dr. Edward Jackson, of Philadelphia, which furnishes an excellent description of retinoscopy, give an idea of some of the difficulties encountered in applying this test. "Retinoscopy . . . is a method of determining the refraction of the eye by observing the direction in which the light appears to move across the pupil, when the mirror by which light is thrown upon the eye in the dark room is rotated." After considering its use in myopia, hypermetropia and emmetropia, he describes its application in regular astigmatism: "The principles involved and the methods to be employed are essentially the same as in myopia or hypermetropia; but the refraction has to be determined in the principal meridians, instead of in any meridian indifferently, as it can be where all meridians are alike. . . . The direction of either of these principal meridians is revealed by the area of light in the pupil assuming the form of a more or less distinct band of light, extending across the pupil in the direction of this meridian, when its point of reversal is approached. When the band-like appearance is most noticeable, it is easy to cause its apparent movement from side to side; but it is more difficult to distinguish the movement in the direction of the length of the band. Still, this latter movement is the one especially to be watched and its reversal point to be determined."

The chief objections to retinoscopy as a test to be used by physicians generally for detecting ocular errors are —

(1) Its successful employment requires considerable experience.

(2) In the majority of cases the amount of error is small; and it is in these cases that retinoscopy is least reliable, even in the hands of an expert.

As retinoscopy presents these difficulties, and inasmuch as no simpler method is suggested in the article referred to, I will attempt to describe briefly some tests, which, without previous experience on the part of the physician, may be applied in practice for determining the existence of such ocular errors as may give rise to the nervous symptoms before mentioned.

The errors of refraction are, (*a*) astigmatism, (*b*) hypermetropia, (*c*) myopia.

The muscular insufficiencies are, (*d*) exophoria,[4] (*e*) esophoria, (*f*) hyperphoria.

The necessary apparatus[5] consists of test letters and an "astigmatic chart," two convex trial lenses (.50 D. and .75 D.), a candle, and a glass rod about the size of a pencil.

The test letters are placed twenty feet from the patient, and on a level with his eyes. The eyes should be examined *separately*, one being covered while the other is tested. If the card is in a good light and the eye is normal, the patient will see each letter distinctly. Ability to do this, however, does not exclude hypermetropia.

*Test for Hypermetropia.* — With the test card arranged as before, the eye to be examined is directed at the letters, and the trial lens .50 D. is held before it. If the patient sees the letters as distinctly with the lens as without it, there is hypermetropia of at

[3] De Schweinitz: Diseases of the Eye, Philadelphia, 1893.

[4] This classification of muscular insufficiencies is of comparatively recent date. The terms are defined by their originator, Dr. G. T. Stevens, as follows: "Esophoria, a tending of the visual lines inward; Exophoria, a tending of the visual lines outward; Hyperphoria, a tendency of the right or left visual line above its fellow." Funct. Nerv. Dis., p. 192, New York, 1887, G. T. Stevens, M.D., Ph.D.

[5] This apparatus may be obtained from any optician. At my suggestion, Messrs Miller and Welch, 39 West Street, have prepared some pocket cases containing the trial lenses and a suitable glass rod.

least .50 D. The .75 D. lens is then substituted for the .50 D. If the letters are still seen distinctly, the hypermetropia is at least .75 D.

These tests simply demonstrate the existence of hypermetropia. There may be latent hypermetropia which is not shown by these tests; but if the patient can read the letters through either trial lens, he is hypermetropic to that extent, at least.

*Test for Astigmatism.* — The astigmatic chart is substituted for the test letters and the eyes are examined *separately*, as before. The patient is directed to observe carefully the radiating lines on the chart. If the eye is normal, the lines all appear equally clear and distinct, and of a uniform shade. But if some appear black and distinct, while others are more or less blurred and indistinct, the eye is astigmatic. The other eye is then tested in the same manner.

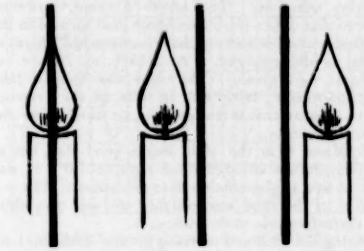

Fig. 1. Fig. 2. Fig. 3.

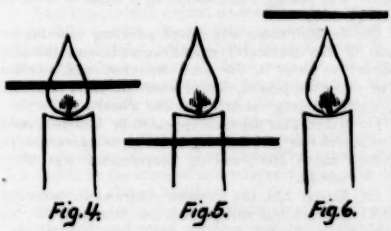

Fig. 4. Fig. 5. Fig. 6.

It may happen that none of the lines are seen distinctly at the given distance, twenty feet. In this case the card is gradually brought nearer to the patient until some of the lines are seen distinctly. If now some of the lines appear to be more distinct than others, the eye is astigmatic; but in this case there is either some additional error, or possibly some disease of the eye.

(Tests for myopia have been omitted for the following reasons: In this country simple myopia is much less prevalent than hypermetropia and astigmatism; patients who are myopic are usually aware that their eyesight is defective; and finally, myopia is far less productive of nervous symptoms than are hypermetropia and astigmatism.)

*Tests for Muscular Insufficiencies* (Maddox). — In these tests better results will be obtained if the room is partially darkened.

To test first the balance of the lateral muscles. A lighted candle is placed twenty feet from the patient, and on a level with his eyes. The patient's left eye being covered, he looks at the candle with his right eye. The glass rod is now held horizontally before this eye, whereupon a vertical line of light is seen in place of the candle flame. While the rod is held in this position before the right eye, the left eye is uncovered. The left eye now sees the candle flame, the right eye sees the line of light. If the line of light passes directly through the flame (Fig. 1), the lateral muscles balance. If the line is to the right of the flame, there is esophoria (Fig. 2). If the line is to the left of the flame, there is exophoria (Fig. 3).

To test for vertical deviation. The left eye is covered, and the rod is held vertically before the right eye. A horizontal line of light is now seen in place of the candle flame. The left eye is now uncovered and sees the flame, while the right eye sees the line of light. If there is no vertical deviation, the line of light will pass directly across the flame (Fig. 4). If the line is below the flame, there is right hyperphoria (Fig. 5). If the line is above the flame, there is left hyperphoria (Fig. 6).

In these tests of the muscular equilibrium, the degree of error is measured by the distance between the line of light and the candle flame. In any case it should be borne in mind, as Dr. DeSchweinitz remarks, that "an absolute balance of the external eye muscles is quite as rare as emmetropia, and hence small errors of the lateral muscles are often unimportant."

## Clinical Department.

### A CASE OF LARYNGEAL DIPHTHERIA TREATED BY ANTITOXIN.[1]

BY F. B. LUND, M.D.,
*Surgeon to Out-Patients, Boston City Hospital.*

THE following case is of interest for three reasons, namely: the extent to which disease had progressed before the antitoxin treatment was begun, the large amount of antitoxin which was required before the symptoms began to subside, and the severity of the after-effects. To these may be added the fourth, the unfavorable nature of the patient's surroundings.

On March 13th I was requested by Dr. F. R. Tower to operate upon a case of laryngeal stenosis occurring in his practice as dispensary physician. The child had been first seen by Dr. Tower on March 7th, the parents informing him that he had had a cough for two or three days. There was no sore throat, and the child was thought to be suffering from a tracheitis or bronchitis of the larger bronchi. About March 11th, a membranous deposit had formed upon the tonsils, and a diagnosis of membranous croup was made. On March 12th, the child was restless and the respiration somewhat obstructed, retraction of the suprasternal notch being marked. On March 13th the nurse found the child sitting up in bed, with marked cyanosis, and obstruction to respiration. At 11.30 A. M., I found a boy three years old, well developed and nourished, in a critical condition from obstruction of the respiration. Intubation was performed with marked relief of dyspnea. The tonsils were found to be covered with discrete patches of a not very thick white membrane. On the right side of the neck were enlarged and softened glands, evidently tubercular, a sinus discharging a small amount of pus, and several scars.

At 3.50 P. M. 15 c. c. of Gibier's antitoxin (marked 1–80,000) was injected under the skin of the thigh. The temperature at that time was 102.4°, and the pulse 130. At 4 A. M. of March 14th, 10 c. c. of antitoxin were given. At 10 A. M. a culture was taken from the pharynx, which showed the presence of the bacilli of diphtheria. There was now but little obstruction to the respiration, but as the child had been able to take but little nourishment and stimulant during the night, rectal alimentation was begun. As the temperature at 4 P. M. was still high (102°) and there was no apparent change in the general or local condition, 25 c. c. of antitoxin were administered. During the night the temperature fell to 99.2°, but rose rapidly during the following morning till 10 A. M., when it was 103.4°. The child's general condition, however, was good. Considerable milk and whiskey was taken by mouth during the early morning; and on the 15th the child slept nearly all day, breathing quietly. The tube was coughed up at 3.45 P. M., and it was not necessary to replace it. During the night, however, the respiration gradually became obstructed, and the next morning, the 16th, it became necessary to replace the tube, as the child was becoming exhausted by its efforts to breathe. The tonsils and palate were swollen and red, but the membrane had nearly disappeared, only a few small shreds still remaining adherent. The severe dyspnea, however, showed that either fresh membrane had formed in the trachea, or that it had not become detached there, as it had in the pharynx. At 3.45 P. M., 25 c. c. of antitoxin were given. The child was able to take milk and whiskey fairly well in spite of the presence of the tube, so that it was possible to discontinue the nutrient enemata.

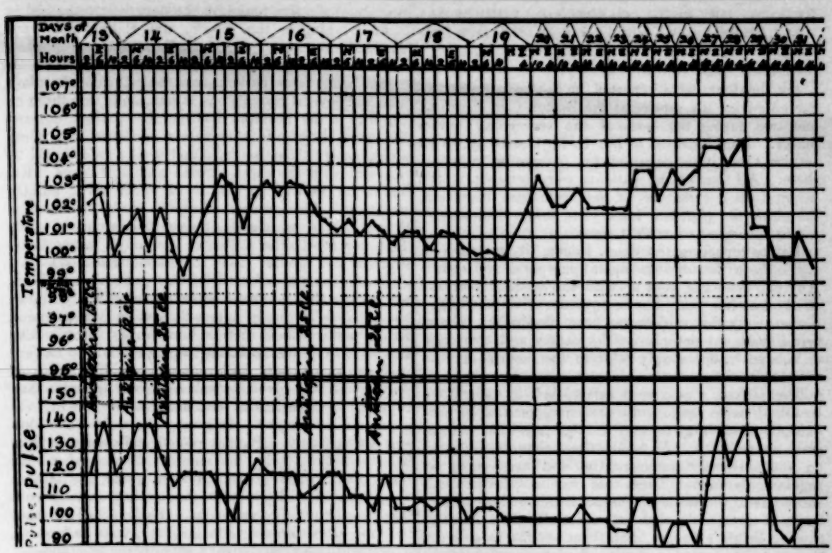
On March 17th the child had a good day, but as the temperature still remained high (101.5°), it was thought best to give another dose of antitoxin (25 c. c.). At 6 P. M. the tube was coughed up, and the child was thereafter able to do without it.

During the 18th and morning of the 19th the temperature gradually fell; but on the forenoon of the 19th an eruption resembling measles appeared on the face, neck and arms, with intense itching. The child refused to taste nourishment, and was very restless. The itching was relieved by a wash of carbolic acid (1–100).

On the 20th there was noted swelling and tenderness of the cervical lymphatic glands, and the skin about the sinus in the neck was red and swollen. The rash disappeared, except where the child scratched himself, bringing out urticaria-like wheals.

On March 21st the rash appeared in blotches, most marked on the face and legs. The temperature remained above 102°, and no nourishment was taken by the mouth.

On March 22d, the appetite returned in some degree; the rash was still present on this and the following day.



On March 24th the rash had nearly disappeared, but the child's temperature was still higher (over 103°); very little nourishment was taken, and the nutrient enemata were not retained.

On the 26th, the other conditions remaining about the same, the child was noticed to be passing very little urine. Examination of a specimen by Dr. Greene showed it to be free from albumin. Sweet spirits of nitre were given one-half drachm every four hours.

On March 27th the morning and evening temperatures were 104.8°, but the child took a little more milk.

On the 27th the evening temperature reached 105°, and the patient was covered all over with a rash, confluent over the body, and looking like scarlet fever. On the arms and face, however, the eruption was macular. Very little milk was taken, and the child was very weak, restless and uncomfortable.

[1] Read before the Clinical Section of the Suffolk District Medical Society, April 17, 1895.

On the following day the temperature had fallen to 101.2°. On the 30th and 31st the temperature continued to fall, and the child became fairly convalescent, taking plenty of milk and improving in every respect. A culture taken on the 26th showed that bacilli of diphtheria were still present in the throat.

This case, which cannot be considered to have been a hopeful one for the antitoxin treatment, which was begun on the eighth day of the disease, shows in the first place the necessity of continuing the administration of antitoxin until definite improvement is shown. After the child had received fifty grammes of the remedy and shown some temporary improvement, it became necessary to reinsert the tube and continue the administration of antitoxin. The appearance of the child at the time of this relapse was so bad as to seem to me almost hopeless.

The severity of the after-effects also deserves notice. In the reported cases where a rash has followed the antitoxin treatment three forms have been noted: (1) an urticarial form, which may be recurrent, and which was so in this case; (2) an erythematous rash resembling measles; (3) a confluent erythema, resembling scarlet fever. I have been able to find no reported instances in which all three forms occurred in the same case. In this case, however, all these forms certainly occurred at different periods. The child was so sick during these secondary symptoms, that if it had not been for the fact that no deaths had been reported from this cause, I should have almost despaired of his recovery.

The distinct period of incubation from five to seventeen days, which has always been noted between the administration of the serum and the appearance of these secondary symptoms, has led to the deduction as stated by Dr. Cyrus Edson,[3] "that the eruption is not due primarily and directly to anything contained in the serum, but to the action of the serum on the system of the patient, or perhaps to the development in the blood of the patient of some pathogenic substance through this action." Whether normal horse-serum, or serum from certain particular horses will produce these symptoms remains to be determined.

The recovery of this child, aside from the purely medical side of the treatment, is certainly due in a large measure to the untiring and enthusiastic devotion of the district nurse, Miss King, who was indefatigable in her attention to the case, and whose careful records form a larger part of the material for this report. We may form an estimate of the work required when we consider the length of time during which the child had to be supported by three-hourly nutrient enematas. The Instructive District Nursing Association also furnished a night nurse during the period in which the intubation tube was required; as they have done for me in previous cases where it was necessary to operate for laryngeal obstruction in district work. The faithful work done by the nurses of this association, and their readiness, in cases requiring special care, to undertake special work in addition to their already heavy duties, cannot be too highly praised.

---

THE late David S. Ingalls, of Springville, New York, left an estate valued at over $600,000, most of which was bequeathed to charitable institutions. The will was hotly contested by two surviving sisters and a niece. One of the sisters was alleged to be of unsound mind. The contest has been "on" since early in 1893. The hospitals and other charitable legatees will receive about two-thirds of the estate, the contesting relations and counsel will get one-third, nearly. — *Journal of the American Medical Association.*

## REPORT OF FOUR CASES OF PUERPERAL ECLAMPSIA OCCURRING IN THE BOSTON CITY HOSPITAL.[1]

BY S. E. COURTNEY, M.D.

OF the four cases reported in this paper, two occurred during my service at the Boston City Hospital, and two during the term of the succeeding house-officer. I am indebted to Dr. C. M. Green, in whose service these cases occurred, for permission to report them. All four of the patients were brought to the hospital in a comatose or semi-comatose condition, therefore the previous history in some instances is not as accurate as I wish it were.

Before reporting the cases, I deem it necessary to say only a few words upon puerperal eclampsia. Any one who has kept up with the medical journals of the last few years knows how extensively and comprehensively this subject has been discussed. Therefore I shall not enter upon the causes and treatment of eclampsia, but simply refer to the theories and to some of its signs.

The phrase, "puerperal eclampsia" is understood by all of us to mean a disease characterized by convulsions which may or may not be followed by complete insensibility. As a rule, these convulsions come on suddenly and unexpectedly, and may recur at regular intervals. There are various theories advanced as to the cause of puerperal convulsions at any stage of gestation; such as acute Bright's disease, chronic Bright's disease, disturbance of the vaso-motor system, and more recently, toxines produced by special microbes acting upon the nervous system already prepared by the gravid state.

We know there are many instances in which eclampsia has occurred when there was no trace of albumin in the urine, either before or after convulsions; and in many cases it has been found *after*, but not before convulsions. Such cases are usually classed under nervous symptoms. In the chronic Bright's disease existing before pregnancy, it is not necessary to give an unfavorable prognosis, as many or, in fact, most all of these patients pass through the confinement without convulsions.

Almost all authorities consider albuminuria a grave condition and significant of danger, especially should this condition be accompanied by edema, nausea, vomiting, headache or nervous symptoms, and a knowledge of these signs is absolutely necessary in the care of patients during the pregnant state.

The chief interest in the cases I report, lies in the fact that upon the two who died, we were able to have an autopsy, and in the case of one of the two patients who recovered, a pathological examination of the placenta. In one of the cases the urine was examined for urea each day. This examination proved a most interesting record of the return of the urine to its normal state.

CASE I. M., primipara, single, about twenty-two years of age, was sent to the hospital October 31, 1893, with the following history:

"Three days ago patient began to complain of general pains, severe headache, followed by nausea and vomiting; but she kept up and about the house. The night before entrance, patient went to bed early, complaining of feeling sick. At 3 A. M., friends heard groans in patient's room. The door was broken open, and she was found on the floor beside the bed in a fit, frothing at the mouth, and rolling her eyes. Medical aid was summoned, diagnosis made of epilepsy, for which some pills were ordered."

Six hours later patient was sent to the hospital. She had several convulsions at her room, and three on the way to the hospital. When the patient entered the ward she was in a comatose condition, breathing stertorously; the pulse rapid and weak; râles could be heard all over the chest. Some edema of limbs. Examination showed patient to be about seven months pregnant. Two ounces of thick, smoky urine were drawn, which contained albumin .25 per cent., urea 1.21 per cent.; the sediment contained many fatty, granular and hyaline casts, some abnormal blood.

Dr. Green was informed of the patient's condition, and in less than an hour after entering the hospital, she was delivered by internal podalic version of a living child, which died a few hours later. The bowels moved freely during the operation. Patient was put in a hot-air bath; one-eighth of a grain of pilocarpine was given by subcutaneous injection and repeated in three hours; two drops of croton oil was given on the tongue. In a very short time the skin was acting freely. Patient rallied sufficiently to take brandy and milk by the mouth. Cream of tartar, water and acetate of potash were given *ad libitum*. Two hours after delivery the hot-air bath was discontinued, patient being conscious. Patient had six convulsions after entering the hospital; four before delivery, and two after delivery, ether being administered each time. Twelve hours after delivery the patient had a severe convulsion, out of which she never rallied.

The autopsy by Dr. Councilman showed fatty degeneration of the kidneys and liver, and edema of the lungs.

CASE II. R., married, twenty-two years of age, primipara entered the hospital at 7.40 P. M., December 31, 1893. Friends said patient had ten convulsions before she came to the hospital. Patient in a semi-comatose condition. Examination showed she was about seven and one-half months pregnant. There was some edema of the feet and face. Urine was scanty, smoky, and contained one-fourth per cent. of albumin. She was at once put in hot packs. Thirty grains each of chloral and bromide were given by the mouth, one-eighth of a grain of pilocarpine was given subcutaneously. An enema of suds and glycerine was given. At 9.15, labor pains having set in, Dr. Green completed dilatation, and delivered the patient by internal podalic version, of a still-born child. Patient was put in hot packs, given one-eighth of a grain of pilocarpine subcutaneously, and thirty grains each of chloral and bromide per rectum. Under the above treatment the skin and bowels acted freely. Patient had three convulsions before delivery and six after delivery, the last one at five in the morning. I remained with her all night, repeating the hot packs and administering ether when there were signs of convulsions. Patient was discharged well January 8th.

Examination of placenta by Dr. Councilman: The placenta is small; the surface covered with whitish, elevated nodules; many of these composed of necrotic tissue with a cavity containing more or less gelatinous-looking bloody fluid. Other areas present the appearance of hemorrhagic infarction.

[1] Read before the Obstetrical Section of the Suffolk District Medical Society, February 27, 1895.

Diagnosis: Anemic and hemorrhagic infarction of the placenta.

It is interesting to notice in this case, the amount of urea which was estimated each day.

At entrance the urine was:

| | | | | | | |
|---|---|---|---|---|---|---|
| 1. | Smoky, specific gravity | 1.030, | albumin | ½, | urea | 1.39 |
| 2. | .... | " | 1.030, | " | ½, | " | 1.71 |
| 3. | .... | " | 1.025, | " | trace, | " | 2.02 |
| 4. | .... | " | 1.023, | " | trace, | " | 1.51 |
| 5. | .... | " | 1.023, | " | trace, | " | 2.30 |
| 8. | .... | " | 1.028, | " | trace, | " | 2.50 |
| Day of discharge | | | | | | " | 2.80 |

Case III. C., seventh pregnancy, thirty-eight years of age, married, eight months pregnant, entered the hospital July 31, 1894. The following history was obtained:

Fifteen days ago noticed feet, hands and face were swelling. The day before entrance she began to vomit, and had headache with pain in epigastrium. She said she vomited, off and on, for two hours. At 5 A. M. on the morning of entrance the first convulsion occurred. From that time until the time of entrance to hospital (11.30), she had had eleven convulsions. While being carried from the ambulance to the ward two others occurred.

The house-officer made a hurried examination, and at once put patient into hot packs, administering chloral and bromide, thirty grains each, per rectum. She was also given one-sixth of a grain of pilocarpine subcutaneously, a drop of croton oil on the tongue. Ether was administered during each convulsion, or at the signs of an approach of a convulsion. Patient not wholly unconscious at any time. After six convulsions she was found to be in labor, with the os fully dilated. The house-officer delivered the patient by internal podalic version of a dead child. The woman was replaced in the hot packs, and one-eighth of a grain of pilocarpine given subcutaneously. The bowels moved freely before the operation. Cream of tartar water and acetate of potash were given *ad libitum*. There was no convulsion after delivery, though it was found necessary to administer ether for the patient's restlessness.

Discharged well on December 25th. The urine on entrance showed one per cent. albumin, .76 urea, hyaline and granular casts, but no fat or blood.

Case IV. She entered hospital December 9, 1893, in a comatose condition; and no previous history could be obtained from friends. Examination showed edema of feet and some edema of face. The urine was small in amount and smoky; albumin, two and one-half per cent., urea 1.45; specific gravity 1.033; hyaline, granular and fatty casts, with abnormal blood. She had one convulsion after entering the hospital.

Dr. Green at once delivered the patient by manual dilatation and internal podalic version. She bled very freely from a marginal placenta previa. The child was dead. The woman was at once placed in hot packs. Stimulants were administered subcutaneously; two drops of croton oil placed upon the tongue, chloral and bromide administered per rectum; but in spite of all efforts the patient died seven hours later.

Autopsy showed severe laceration of the cervix with hemorrhage into broad ligament, splenic tumor, edema of lungs, double pleural effusion, pericardial effusion, edema of glottis, and fatty degeneration of liver and kidneys.

Bacteriological examination showed in the spleen, kidneys and lungs colonies of pneumococci.

Microscopic examination of a section of frozen kidney showed very little fat in the epithelium. Hyaline thrombi in the vessels of the glomeruli.

## A CASE OF ECLAMPSIA; DEATH.[1]

BY C. H. HARE, M.D.

Believing that bad results are fully as instructive to study as are successes, this case is presented for your judgment. With the fatal result to look back upon I can only wish that I had induced labor. Your severest criticism and instruction are invited.

Mrs. A., forty-three years old, came from a neurotic family. She had been, together with two sisters, a nervous sufferer all her life. Her own statement was that she was never well, and was rather worse after marriage. Twenty months after her first child, she was operated upon for lacerated cervix, and after that time wore a support for retroversion almost continuously. In February, 1893, she was curetted for an hyperplastic endometritis. She was married when twenty-one years old. There were no abortions.

The first child was born four years after marriage, and a second three years later. During the latter part of both these pregnancies there was marked swelling of all the extremities and of the face. Both pregnancies went to full term. Convulsions occurred in both soon after labor pains began, and both were terminated with forceps under chloroform anesthesia. No satisfactory opinion of the number of convulsions could be obtained but they were stated as "many." The patient was unconscious for one or two days after each delivery, and not expected to live at either time. The history of the first was rather more severe than that of the second, both before and during labor. The first child was a boy weighing seven and one-half pounds; the second a girl, weight not known. Both children lived.

The menstrual periods had never been regular, being inclined to be a week or two late, and the amount of flow was rather less than in the average woman. Menstruation continued up to the last pregnancy without change. Coitus had not occurred for five or six months until unfortunately it did occur on June 25th or 26th, about five or six days after cessation of the last flow. Pregnancy was recognized by the usual symptoms in the latter part of August, and the undesired condition was thereafter an added nervous burden.

I first saw her, in my turn amongst the series of her medical attendants, on November 16th. She had been in her room for two months, and in bed constantly for one month. There had been very troublesome vomiting. For two or three weeks liquids by the stomach had been retained about half the time, and no solids taken. Rectal alimentation had been given daily. She had lost considerable flesh. The bowels had not moved for weeks, except after enema. Vaginal examination showed a red and easily bleeding area about the os uteri. The urine was abundant, and showed nothing abnormal chemically or microscopically. There was no edema. She was ordered

[1] Read before the Section for Obstetrics and Diseases of Women of the Suffolk District Medical Society, February 27, 1895.

liquid food by mouth every three hours. Three drops each of dilute hydrochloric acid and tincture of nux vomica four times daily, after taking nourishment; podophyllin, one twentieth of a grain, four or five times daily. The cervix uteri was painted with tincture of iodine, but this was not repeated, as she complained of tasting it; but fluid extract of hydrastis was substituted, and applied three times a week up to ten or twelve times. She never vomited again, though nausea was troublesome and a sour stomach very annoying up to the time of her death. Enemata to move the bowels were used twice.

In a week or ten days the stomach bore carefully selected solid foods. She sat up, and soon began exercising a little in a large, airy, sunny room. I do not assume that this selection of drugs caused the improvement, but attribute it to chance and it was my good fortune to take charge of the case just at the time change and improvement began. Edema appeared in the early part of January in the feet and ankles, and later in the hands and face in the morning. The urine was examined every week; the quantity was large, being about four pints daily until about the middle of January, when the amount dropped to about two and a half pints, and albumin appeared. She was then given tincture of chloride of iron and infusion of digitalis; and the daily amount remained above three pints. The albumin gradually increased until it was one-fourth per cent. two days before death. A very few hyaline and granular casts were found in the urine about two weeks before her death, but their number did not seem to increase. Her danger was explained to the husband, and a consultation advised; but it was not desired, as she had been much better than in preceding pregnancies.

I was called early on February 4th, as she had been having pain sufficient to prevent sleep. Uterine contractions could be distinctly felt at short intervals, but only lasting a few seconds. The pain decreased in frequency during the day, ceased at night, and she had a good night's sleep. She was then seen daily; but her condition gave no increased anxiety until the morning of her death. Fetal movements were vigorous up to that morning. About two A. M. during her last night, there was an attack of pain in the abdomen, which she attributed to something eaten; and a physician a few doors from her was called and gave morphia subcutaneously with entire relief. I saw her soon after nine A. M. on the following day (February 9th). Her voice was thick and her mind confused. I went to a telephone about seven or eight minutes away, and Dr. C. M. Green kindly agreed to see her in about two hours. On my return to her she was unconscious. A messenger tried in vain by telephone to get any member of the Lying-in staff, but no one could be gotten. Before I had finished scrubbing my hands the first convulsion came. Chloroform was immediately given. I dilated, did version, and extracted a dead child after about half an hour of the hardest work I ever did. A second convulsion occurred just before delivery, and the woman died about ten minutes later. Large doses of tincture of digitalis, strychnia and brandy hypodermically, and heat externally, all failed to give the slightest benefit.

---

Twenty-five per cent. of the Johns Hopkins Medical School students are now women.

# Medical Progress.

## RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.,

### INOCULABILITY OF CANCER.

Gratia and Lienaux[1] have attempted to produce carcinoma experimentally in dogs by inoculating the animals sometimes with small pieces of carcinomatous tissue, sometimes with the expressed fluid or scrapings. The result was wholly negative, whether connective-tissue, serous cavities, mammary-glands, lymph-glands, testes or veins. The experimenters concluded that the parasitic character of cancer is not shown conclusively; that direct or indirect contagion is also not shown, except perhaps where especial predisposition exists, for example, a person already affected with cancer; and that the etiology or pathogenesis is not known.

### AN ADDITION TO PRESENT METHODS OF CLOSING LARGE CONGENITAL FISSURES OF THE HARD PALATE.

Milton[2] reports a case of severe double hare-lip and cleft palate, in which he supports the theory of insufficient approximation as the chief factor in the production of the deformity by the following points: (1) the separation between the two halves of the bifid uvula largely exceeded the width of any possible undivided organ; (2) the upper teeth overlapped the under teeth laterally to the extent of three lines on either side; (3) the upper canines coincided when the jaws were closed with the first lower premolars; (4) the expansion of the alæ nasi was one and three-quarters times as great as in the normal child of the same stature; and (5) the alveolar process of the intermaxillary bone projected four lines beyond that of the lower jaw and lay two lines higher than those of the superior maxilla. Convinced that the deformity was due to insufficient approximation, the author grasped the two superior maxillæ with a strong pair of forceps shaped somewhat like lion forceps, and with very considerable pressure, exerted with great care, at once brought together the two maxillæ along the greater portion of the fissure, the only obstacle being the interposed septum nasi. The snout was then forced down to take up its position between the two maxillæ. The sides were held in their approximated position by a wire passed in the groove between the teeth and the gums and across from behind the last premolar on one side to the last on the other, and then tightened by twisting in front. The patient had no reaction after this operation, and wore the wire comfortably for thirty-eight days. The bones retained their new position after its removal, and a plastic operation of the soft parts easily completed the restoration.

The author feels justified only in expressing the following opinions on the strength of this one case:

(1) That in some cases of fissure of the hard palate, especially, perhaps, in those in which the fissure is complete, the non-approximation of the two maxillæ may be an important factor in the production of the gap.

(2) That in such cases the approximation of the

[1] Bull. de l'Acad. roy. de Med. Belgique, 1894, No. 8.
[2] Lancet, July 14, 1894; American Journal of Medical Sciences, December 1894, p. 718.

separated portions by forcible pressure may be possible. Such approximation is very simple in performance, is not likely to be harmful in its results, and may greatly facilitate the subsequent operation for complete union of the soft parts.

(3) It remains to be seen whether the forcible manipulation of the jaw is disadvantageous to its future development; and it may be that in some cases the approximation may entail so much deformity in the jaws as to greatly discount its advantages.

### LARYNGECTOMY BY A NEW METHOD.

Swain[3] referring to recently recorded cases in which, after removal of the larynx, the open end of the trachea was stitched to the skin, and the communication between the air passage and the mouth thus shut off, states that the results of such procedure have been better than those of the older method of laryngectomy. The danger to life from inspiration-pneumonia is much reduced by the shutting off of the mouth. The patients can swallow with the greatest ease. In three at least of the cases a voice useful, and fully as satisfactory as any produced by an artificial larynx, was obtained, and the patients were able to speak without incurring the trouble and risk of the constant presence of a foreign body in the neck. A recent case is reported in this paper, in which Carmatt, after total removal of the larynx for epithelioma, closed the large wound by continuous suture, except at one part of the middle line of the neck, to which the trachea, which two weeks before the operation had been opened for the relief of extreme dyspnea, was carefully stitched. The patient, a man aged forty-two, made a good recovery; and, when the last observation was made by the author, he was perfectly well and the wound was quite healed. Although words were not then clearly spoken, the author was able to understand short sentences, and single words very satisfactorily with his back turned, and at a distance of several feet from the patient. No clear explanation is given of the manner in which the capacity for speech has been preserved in this and other cases in which the communication between the lungs and the mouth was completely closed by this new method of laryngectomy.

### TREATMENT OF PULMONARY STAB-WOUND BY SUTURE.

Feliciani[4] reports a case where a wound of the lung was successfully sutured. The operation was performed on account of hemorrhage. The patient, a laborer, forty-three years old, was stabbed in the back with a knife. There were four penetrating wounds on the right side. The seventh rib was fractured. There was pneumothorax, with marked hemorrhage into the pleural cavity. The seventh rib was resected, and a wound of the lung three centimetres deep exposed. This was closed by three silk sutures which checked at once the profuse bleeding. The pleura was then washed out, and the wound in its parietal surface closed by suture, as was also the external wound in the skin. The patient left the operation-table in a pulseless condition, but was discharged well at the end of four weeks. The pulmonary suture apparently was effectual in controlling the hemorrhage and in shortening the period of treatment.

[4] Riforma med., 1894, x, 9.

### TUBERCULOSIS OF THE BREAST.

Charles A. Powers,[5] reports two examples of this affection, and speaks of the pathology, symptoms and course, diagnosis, treatment and prognosis of this rare affection. He summarizes as follows: The relative frequency of tuberculosis of the breast cannot be approximately estimated from present data. It may in general be considered of infrequent occurrence. Diagnosis must rest upon microscopic examination. Adequate treatment calls for the removal of the gland and the axillary contents. The prognosis, as regards local recurrence, is good. Where possible, local operative treatment should be supplemented by placing the patients under climatic and other conditions suited to the prevention and cure of tuberculosis in general.

### THE THOROUGH EXTIRPATION OF MAMMARY CANCER.

Halstead[6] is an advocate of a very thorough removal of parts adjacent to a cancerous breast when it is amputated. He lays down the following rule: The pectoralis major muscle, entire, or all except its clavicular portion, should be excised in every case of cancer of the breast, because the operator is enabled thereby to remove in one piece all the suspected tissues. The suspected tissues should be removed in one piece: first, lest the wound become infected by the division of tissues invaded by the disease or of lymphatic vessels containing cancer cells; and, secondly, because shreds or pieces of cancerous tissue might readily be overlooked in a piecemeal extirpation. Halstead claims excellent results. Seventy-six operations (complete and incomplete) for breast cancer have been performed in the Johns Hopkins Hospital, and not one death resulted from the operation. Twenty-six of the operations were incomplete. Of the fifty which were complete, local recurrence occurred only in three, or in six per cent, the lowest known record. The disability produced by the operation was, as a rule, slight.

### PYLOROPLASTY.

R. Shalders Miller[7] reports three pyloroplasties performed in England with a successful result. He states that the first was that of Mr. F. Page and Dr. Limont, done early in 1892, and the second that of Mr. Pearce Gould in December, 1892; and it is satisfactory to note that all three patients have not only survived the operation but have been completely relieved of their previous disability and suffering.

In the third instance the abdominal section was considerably longer than was needed for pyloroplasty, which, as the subjects for it must usually be thin, might be done with an incision of three inches and a half. It seemed needful to explore the abdomen extensively, as no disease about the pylorus could be found before making the visceral incision. The case appears to have been of a spasmodic nature, but the pyloric sphincter was certainly sharper and more prominent internally than normal, and its closure on the finger was notably sudden. Probably the same thing occurred when food approached it. The outer row of sutures in the gastro-duodenal wound were not according to Lembert, but were passed through the peritoneum and muscle about a quarter (or rather

[5] Annals of Surgery, August, 1894, p. 159.
[6] Johns Hopkins Hospital Reports, vol. iv, No. 6, 1894; British Medical Journal, December 29, 1894.
[7] Lancet, December 1, 1894, p. 1270.

less) of an inch from the cut edge, and were brought out on the one side and commenced on the other side of the cut just under the edge of the peritoneal coat. This was done so as not to interrupt the continuity of the longitudinal muscular fibres, which are pretty thick and close together at the pylorus; it was hoped thereby to secure the best possible peristalsis at the critical spot. Possibly the spastic condition found in this instance may explain some cases of actual hypertrophy of fibroid stricture, the constant irritability of the muscle leading to the hyperplasia as well as hypertrophy, especially if any inflammatory process supervened. In this patient the disease had not lasted long enough to cause more than slight overgrowth of the circular fibres of the pylorus.

### THE OPERATIVE TREATMENT OF DIAPHRAGMATIC HERNIÆ.

A Neumann, Berlin,[8] describes a fatal case of this variety of hernia. The patient was twenty-nine years old. The hernia was reduced on the ninth day by abdominal operation. In discussing the operative treatment of this rare lesion Neuber recommends that large hernia should be approached through the pleural rather than the abdominal cavity. He claims that no extra injury is done by this method, since the lung is already compressed, and that the diaphragmatic defect is more accessible in a majority of cases.

The writer divides these cases into three classes: (1) Those large herniæ with a large diaphragmatic defect, which allow entrance of abdominal viscera into the pleural cavity, with injury to the patient, and which are only discovered by chance. Here no operation is indicated. (2) Where the abdominal viscera encroach so much on the pleural space that both their functions are interfered with as well as those of the thoracic organs. (3) A small defect in which the hernia is strangulated or incarcerated.

### INTESTINAL SUTURE.

Ullmann[9] has adopted, in place of the Murphy button (which he considers sacrifices security for rapidity in operating), the Maunsell method for intestinal suture. He has concluded after experimental work on cadavers and living animals, that this method is rapid and efficient. The objections advanced against the method, namely, that there is only a single row of sutures, and that the mucous membrane is involved, are not actual objections. If the operator feels that the single row of sutures is insecure it can be easily and rapidly reinforced by a few serous sutures. That the mucous membrane is included in the suture has been proved unessential. Ullmann has modified the technique somewhat, in that previous to the invagination of the distal into the proximal end of the resected intestine four sutures are introduced, one at the mesenteric attachment, the other three ninety degrees apart. The ends of these are tied so that the knots are inside the intestines, and they hold the ends loosely together. After the longitudinal incision is made in the proximal end, a pair of forceps introduced through it seizes these sutures, and as they are withdrawn drags after them the sutures and intestinal edges which the sutures transfix. These sutures, Ullmann claims, are an assistance in forming the temporary intussusception which permits the suture to be placed. They can be afterwards used for permanent sutures. He reports one case where a resection operation in a woman was quite successful and satisfactory.

### COMPLETE CLOSURE OF ISOLATED PORTIONS OF THE INTESTINE.

P. Reichel[10] objects to Obalinski's recommendation to close completely portions of intestine isolated by intestinal resection or anastomotic operations.[11] The article is an interesting one, but too long to report more than its essential points. The results of animal experiments are unsatisfactory, namely, death from peritonitis; or, if this danger is survived, death later from the distention of the occluded portion, and ulceration of the mucous membrane. Only a few animals ultimately survived. The danger is from retained secretions in the occluded portion of the intestine. Reichel discusses the seven cases of this operation in the human subject on record, and states that such complete isolation in the large intestine is safer than in the small since its function is absorption rather than secretion of intestinal fluids. In the small intestine, especially in its upper part, the secretions are abundant, and would soon dangerously distend an isolated loop of gut. The writer recommends that both ends of an isolated portion of small intestine should be sewn in the abdominal wound so as to allow an opportunity for fluid to escape, according to the Hochenegg and Frank method. If these fluids are small in amount, the fistulæ cause no especial inconvenience.

## Reports of Societies.

### SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

JAMES M. JACKSON, M.D., SECRETARY.

REGULAR Meeting, Wednesday, February 27, 1895, DR. GEO. H. WASHBURN in the chair.

DR. C. G. CUMSTON reported

A CASE OF OSTEOMALACIA: OPERATION, RECOVERY.

DR. S. E. COURTNEY presented a report of

FOUR CASES OF ECLAMPSIA OCCURRING AT BOSTON CITY HOSPITAL.[1]

DR. C. H. HARE also reported

A CASE OF ECLAMPSIA AND DEATH.[2]

DR. A. D. SINCLAIR: I have very little to say on this subject. We have no more formidable state of things to meet than a case of eclampsia in a pregnant woman. It was my misfortune to meet with more of them at one time than seem to occur nowadays, I think attributable to the care taken by the rising generation of physicians, who know better about these things, seeing to the general condition of the patient, especially her kidneys. At one time in this city it seemed to me that puerperal convulsions were more common than now, perhaps seemingly so; at any rate I know they were more fatal than now, because the means for treat-

[1] See page 486 of the Journal.
[2] See page 487 of the Journal.

ment were limited, and consisted largely in bleeding and opiates — not bad treatment by any means, certainly not very successful, although persisted in I think to-day by a great many who believe in bleeding as being one of the most powerful agents in reducing arterial pressure in many cases dependent on uremic trouble. We did not know much about the pathology of these cases. I do not know as we know much now; at any rate, we knew less then. Resort to delivery in any case unless the mouth of the womb was open and the head or some portion protruding was not had, because it was contrary to all teachings — was meddlesome midwifery. There was a certain autocracy that prevailed over the young men, especially by the older, and nothing was done that would not be approved in higher quarters. We do not hear much of that to-day.

I was house-officer in the Lying-in Hospital at Edinburgh in 1857–58; and there was brought in a woman in convulsions in the eighth month of her pregnancy. She was given chloroform, but she died undelivered. There was no thought of delivering that woman, although after her death it was with difficulty that the child could be kept in the womb; and I thought, why should not that woman be delivered, at least, the womb be emptied and give the woman a chance to recover. It was thought that it was meddlesome midwifery. But the thought came to me that, if a similar case presented itself to me, I should empty the womb. A case did occur. I delivered by manual dilatation, and continued to do so when a case of the kind came up, I think saving my patient in one or two cases, and in one or two losing the child. I did this privately ten or twelve years, until twenty-five years ago I delivered a woman who had been in convulsions for several hours, with little or no secretion from the kidneys, in one and a quarter hours by manual dilatation without a convulsion during the manipulation; under ether, the woman was delivered without leaving a single trace of tear, the child born alive and still living, and the woman had several children afterwards. That case was detailed before the Boston Society for Medical Improvement, January 18, 1870. The Medical Improvement Society was perhaps the most conservative body of medical men in this land, and I cannot say that my plan of delivery was received with the utmost warmth or welcome. But I did not care very much about that. I felt that it was a plan that was useful, and a thing come to stay. It has saved some lives in this community.

In regard to bringing about labor in one or two cases of convulsions in early pregnancy, say the fifth month, I had such a case where blindness came on, and evidently a bad state of things was threatening; there I delivered at the fifth month with perfect recovery. I think that we are very apt to delay in those cases, rather than to go to work at once; and I have seen cases where that thing was impressed upon me very strongly. I was called to Dedham a good many years ago to the case of a young woman in the eighth month of her first pregnancy, in convulsions. I said to the physician in charge that I did not think any temporizing would be of service, and I would advise immediate delivery. Said he, "If the woman should die, we should be accused of killing her." Twenty-four hours later I was again sent for and delivered her. She had had twenty-seven fits meanwhile; and she died nine hours later, as also the child.

I will say this to the younger men here, that manual dilatation is a very simple thing. It is too simple; and I believe that Dr. Lusk, when asked why he did not put it in his book, said he did not dare to, it was so easy and men would be doing it recklessly. It must be done with deliberation and care. I have seen very good men in Boston tear the uterus. It can be done with a great deal of safety. It is called forced delivery, and so it is in a way — but not a bit more force than natural pains would give, however.

Dr. Call: I do not know that I can say anything new. My experience at the New England Hospital at the maternity department has given me some cases. We do not have as many cases now as when the hospital was in the city. I remember when I was a student there, it was not very infrequent to have a woman brought in comatose, having had convulsions outside. Now that the hospital is quite a distance from the centre of the city, we seldom get those cases, and for three years there has been no case. I think the treatment is almost exactly like that detailed by the gentlemen to-night, — hot packs, bromide and chloral per rectum, and ether during the symptoms of convulsion. I think that we have not lost a case there with convulsions now for six years, but, as I did not look up the records, I cannot tell how many cases we have had in that time. A point that I would like to ask about, is the length of time after delivery that we must fear convulsions provided we get a patient who has albuminuria safely delivered without an attack. My attention was drawn to that by a private case, because I have heard it said by physicians of experience that if twenty-four hours elapse after delivery without convulsions, you may feel that the patient is safe from convulsions. I was called to see this patient about three weeks before the normal time of her delivery, and found her with extensive edema of the face and extremities; and as she was a woman among the working classes who could not command skilled nursing, I advised removal to the hospital, but they were not willing to act at once, and within forty-eight hours I was called, and found she had been delivered with one pain. She appeared to be doing very well. I congratulated myself that she had gotten through. For twenty-four hours she did very well, but about the end of that time she complained of pain in the back of the neck and shoulders. She thought she took cold from lying on the floor after labor, and had no symptoms such as we usually look for in cases with convulsions; but twenty-four hours later, forty-eight hours after delivery, she was found unconscious; for twenty-four hours had convulsions at intervals; and for several days was partially comatose, although she eventually recovered and had a child afterwards without any trouble.

Dr. Sinclair: In answer to the question about the lateness at which convulsions may come on, I have only a single case. A woman was confined, and I was called to her I think two or three days afterward, when she went into convulsions; and the convulsions kept recurring; and, finally, I kept the woman under ether continuously, did not let her wake up for something like nine hours. I gave her also a large dose of calomel and jalap, had an excellent evacuation of the bowels; she recovered after a long time, to have, I believe, some pelvic peritonitis which kept her in bed for weeks.

Dr. Cushing: I would like to ask the reader in regard to the use of morphine. I do not think I

heard it mentioned whether it is entirely out of fashion in the hospitals here. It is quite largely used in different parts of the country. By those who use it it is thought to be very efficacious, used in conjunction with chloral. At the time when I was in Bellevue Hospital it was found out quite accidentally that morphine used hypodermically was a very satisfactory treatment of uremic coma — the last thing one would expect. It was found out by one of the house staff, who gave it for some reason; and it set the patient in a very profuse perspiration, and quieted spasmodic symptoms. After that it was used a great deal. I have known that it is used by a good many and with a good deal of success, not, however, to the exclusion of chloral or ether.

DR. CUMSTON: Dr. Sinclair, in speaking of the dilatation of the cervix, I believe referred to manual dilatation. In speaking of the instrumental dilatation there has been recently invented by Tarnier a very good instrument, which he has been using for the last three years at the Maternity in Paris, and which I think now is quite largely used in France and has been used in New York. It is described in many of the new French treatises on obstetrics. It consists of three blades about as long as forceps; and the end of the blade that is introduced into the uterus is bent at right-angles. You push it beyond the internal os, and you introduce each blade separately; they all join together like forceps and over the ends which are outside you pass a very large strong piece of elastic band. Little by little the elastic contracts and dilates the cervix without laceration. You can obtain full dilatation in about an hour or an hour and a half. It is a very safe method.

DR. HOGNER: One speaker asked how long after delivery convulsions may come on. We must remember that eclampsia or cramps depend on many different causes. One of these is infection by the tetanus bacillus, and such an infection can be established in every suppurating wound. We must also remember the possibility of such an infection during convalescence.

DR. TWOMBLY: The cases to-night have been instructive. There are never too many cases of this kind reported. I remember when I was in Karl Braun's clinic I waited nearly a year before I was summoned to one and then did not see the convulsion at all. In my own practice since then, I have met with it several times. Each case must be considered by itself. The consensus of opinion in these days is for immediate delivery. The risk to the woman by letting her have convulsion after convulsion is very great, and we do not diminish the chances of risk to the child. In fact, the child is of secondary importance to us; the mother's life is of the first and greatest. At nearly full term I think we all would consider immediate delivery the best method of procedure. Where the child is just at the viable stage it is a serious question whether to wait and hope that the best will come without immediate delivery; or to proceed with forced delivery with the chances of losing the child. Even in that case I believe it is better to deliver immediately rather than to run the risk of losing the mother. We cannot tell how many convulsions or how few will terminate her life.

There are many different symptoms of eclampsia, and the principal ones we know very well. In a case of mine there were a few I would like to mention, as perhaps not always seen. A young woman of twenty-six in her second pregnancy two months before delivery had what was supposed to be a partial paralytic stroke. The sister described her to me as a woman in perfect health who fell suddenly on the floor but had no fit. After recovering consciousness she spoke thickly, with the tongue protruding to the right and that side of the face partially paralyzed. She could mumble words, but could not formulate ideas. This passed off in two or three days. Two days before full term I was sent for in great haste, as she had been vomiting all night and had intense headache. I found every symptom of eclampsia present except the convulsion, and that we could expect at any minute. There was one noticeable thing beside intense blinding light before the eyes; it was twitching of the abdomen from the navel crosswise nearly twenty times a minute; the navel would go to the left with a twitch, and this continued until the convulsion occurred and then stopped. I immediately sent for an assistant, and without waiting any time at all performed internal podalic version and delivered the child, and she made a complete recovery. I think Dr. Hare will agree with me that it is the best plan in these cases not to delay, but immediately proceed, even if we have ignorant people call down unkind things upon our head. The question came up at the time I delivered this woman whether it would not have been better to put on forceps and deliver the child rather than to perform internal version. I remember Dr. Worcester had a case in which he put on forceps and delivered the woman all right, and the woman died in a few hours, and no apparent reason could be found. It seems to me the head being high up the risk of lacerating the soft parts and further complicating the case would be a sufficient cause for not using the high forceps. I have no doubt it is done successfully in some cases, but version is preferable I think.

DR. WHITE: My experience in puerperal eclampsia has not been great. I have seen in the past two or three years three or four cases. One was an Italian, a primipara. I was called to see her three or four days before delivery. There was considerable edema about the feet and ankles. I found a slight trace of albumin in the urine, and treated her in the usual way with milk diet, bromides, etc., and in a few days I was called to deliver her. I staid some three or four hours, and labor seemed to be going on in a normal way, and when the head was engaged a convulsion came on. I gave ether, and delivered rapidly with forceps. She came out of the ether very well, had convulsions continuously for three days, and finally recovered after quite a long illness; but the child died on the third day in convulsions. Whether the tetanus bacillus was there I do not know. Another case I saw in consultation in Winthrop. She had had a number of convulsions, feet considerably swollen, labia very much swollen. She had been in labor some hours. I could find no signs of life of the child. I applied forceps, and to my surprise delivered the head without the rest of the fetus. After working for some hours I got the arm down. The contractions were firm, and I could not turn the child. I delivered the arm. After working some time I got the other arm and delivered that, and finally I got a traction hook, put it into the anus of the fetus and delivered the remaining portion, and then had to scrape the placenta off with my hands. Soon after coming out of the ether the woman had a

convulsion; and three or four convulsions followed in rapid succession; and the patient died. Another case, a primipara, had considerable edema about the face and feet; labor went on normally; convulsions rather severe; administered ether; delivered; and she recovered and the child lived.

DR. J. B. BLAKE: I etherized a patient in the practice of an older physician, about a year ago. The case presented two points of interest: (1) no premonitory symptoms except extreme pain referred to the epigastrium; (2) marked difficulty in dilating the cervix. The woman was a healthy primipara, seven months pregnant. Morphia, subcutaneously, did not affect the pain. Under ether it was found impossible to dilate the cervix by the fingers, and a uterine dilator was resorted to. The internal os was like India-rubber, and the fetus was delivered in much the same way described by Dr. White — first a leg, then an arm, etc. Finally, after seven hours' work, the entire fetus and placenta were removed. The woman did not fully recover consciousness, in spite of free stimulation, had two or more post-partem convulsions, and died in about twenty-four hours.

DR. CUMSTON: There is one symptom which is a prodrome of albuminuria, namely, what the French call the "doigt mort," numbness of the index finger when the patient wakes up, which may remain an hour or two.

DR. SINCLAIR: I think pain in the epigastrium is a remarkable symptom and it has occurred in many instances.

## AMERICAN MEDICAL ASSOCIATION.

FORTY-SIXTH ANNUAL MEETING, BALTIMORE, MD., MAY 7–10, 1895.

### GENERAL SESSION. — FIRST DAY.

The Forty-Sixth Annual Meeting of the American Medical Association held at Baltimore, Md., was called to order at 10 A. M. on Tuesday, May 7, 1895, by the President of the Association, DONALD MACLEAN, M.D., of Michigan.

The meeting was opened with a brief but impressive prayer by the Rt. Rev. William Paret, D.D., Bishop of Maryland.

### ADDRESS OF WELCOME.

Owing to the absence of Governor Frank Brown, of Maryland, the opening address was delivered by F. C. LATROBE, Mayor of Baltimore, who thanked the members for the compliment they had paid Baltimore in selecting that city for the place of their present meeting, and called attention to the fact that although physicians and lawyers are often slandered and called necessary evils, yet among the men who have won honor and national fame there is no class more numerous than from medicine and law.

The address was closed by extending a hearty and sincere invitation to the members to visit the City Hall of Baltimore.

As chairman of the Reception Committee, DR. SAMUEL C. CHEW welcomed the members present, and stated that great changes had taken place in the Association and in medical science since their last meeting held at Baltimore twenty-eight years ago. At that time Baltimore was a city of two hundred and fifty thousand inhabitants, while to-day it contains over half a million. A far more important change than increase in population is found in the fact that this city has become one of the chief centres of medical education, and attracts about one thousand students here every year. Since our last meeting in this city one of the greatest advances made in medicine is the elevation of the standard of medical education which has been effected in late years, and which is being raised higher and higher. Many are now entering our ranks equipped by a science which not long ago was in a great degree unknown, making them better qualified for our profession.

DR. WILLIAM OSLER, Vice-Chairman, in making announcements from the Committee of Arrangements, called attention to the objectionable advertisements inserted in the Guide-book presented to each member at the registration office, stating that had this book been first submitted to the majority of the committee a most vigorous protest would have been made against said advertisements.

### PRESIDENT'S ADDRESS.

At the opening of his address DONALD MACLEAN, M.D., of Michigan, stated that it was his earnest wish that the present meeting might be greater and productive of more good than any of its predecessors.

Regarding the present tendency of many of our medical colleges to raise the standard of medical education, he spoke as follows:

I should be untrue to my oft-reiterated convictions if I hesitated to mention here one cause of complaint still justly chargeable to a considerable number of our American medical colleges. It is summed up briefly but truthfully as follows: Some of these institutions claim to supply to their alumni complete courses and means of instruction. The fact is, that one-half of them are shamefully deficient in clinical resources and facilities, while the other half are no less devoid of the men and the means necessary to do anything approaching to justice in teaching fundamental branches, without which a reliable and intelligent knowledge of surgery and the practice of medicine is an impossibility.

In the rapid evolution and growth noted in medical education it has seemed to those most closely concerned that the time has arrived when a united and determined effort might be made to establish a well-defined plan which would secure uniform co-operation in remodelling the whole system of medical graduation, thus securing for the various designations of "doctor," "surgeon," "physician," etc., an intelligible and definite signification. This, in my opinion, is "a consummation devoutly to be wished."

Upon the importance of a National Bureau of Health, he said that such a bureau superintended by a competent medical authority, who shall be a member of the Cabinet, could not fail to secure for the nation benefits beyond the language of dollars and cents to express. A united and dignified effort on the part of this Association and its allies ought to secure this enactment. The vast importance of such an act is obvious to the members of this Association; and our imperative duty, as it seems to me, is to impress the active and public-spirited statesmen who guide and control the affairs of the nation with the essential truth and value of our views. The very respectable problems of foreign policy which have in recent times engaged the attention and elicited the energies of our

law-makers seem to sink into insignificance in comparison with the great and benign proposition here presented.

It is my deliberate opinion that the establishment of a bureau of health, as an integral part of the nation's executive, will prove an effective instrument in promoting public welfare. It will be the means of unifying efforts in the suppression of dangerous diseases. It will afford opportunity for restraining the effete despotisms of the old world from adulterating our population with the vicious and degenerate. It will be the means whereby this enlightened and progressive republic may exemplify to the world the true mission of medical science. It will offer another agency for disseminating the truths of scientific discovery; another means of discriminating between that which is transitory and accidental in medical achievement and that which is permanent and immutable, and will furnish another promise that medicine in the future shall in no wise be unworthy of her past traditions.

The party, professional or political, which shall succeed in consummating this wise measure will assuredly earn for itself the gratitude and applause of an appreciative nation.

On motion of Dr. Gihon, of Washington, the portion of the address referring to the establishment of a National Health Bureau was referred to the proper authorities at Washington.

### OBJECTIONABLE ADVERTISEMENTS.

A communication from the judicial committee regarding the advertisements appearing in the Medical Association *Journal* caused a lively but confused discussion.

Dr. Kohn moved that a committee be appointed to confer with the trustees upon this subject. This motion was objected to as reflecting upon the trustees.

Dr. Ingalls, of Chicago, one of the trustees, moved that a committee be appointed to meet the trustees and take part in the preparation of the report to be presented by the trustees; but, on motion of Dr. Cochrane, of Alabama, Dr. Ingalls's motion was laid on the table by a vote of 138 to 108.

### PAY OF NAVAL MEDICAL OFFICERS.

Dr. Millard, of St. Paul, moved that a memorial be presented to the President and Members of the Fifty-fourth Congress requesting the enaction of such legislation as shall confer upon the officers of the navy medical corps the same status, pay and emoluments as are now accorded to the medical officers of the army. This resolution was unanimously carried.

### PRESCRIBING PROPRIETARY MEDICINES.

A motion of Dr. O'Connor, of Detroit, for the appointment of a committee of three authorized to find out how many members of the Association prescribed proprietary medicines, provoked considerable wrangling.

Dr. Ferguson, of Troy, N. Y., said the question of proprietary and secret medicines should be kept clearly divided; and on his motion, that of Dr. O'Connor was laid upon the table.

### GENERAL SESSION. — SECOND DAY.

After the reading of the minutes, Dr. A. L. Gihon read a report as chairman of the Committee on the

### RUSH MONUMENT FUND,

and deplored the fact that it reflected disgrace upon the Association that sufficient funds had not been subscribed years ago.

He was willing to still take the lead in this matter; but if they wished him to do so, they must subscribe sufficient funds at once. He had thought it necessary to raise at least $25,000; but after Dr. Wyeth, of New York, exhibited a photograph of the Sims Monument, erected in that city at a cost of $10,000 for the statue and $3,000 for the pedestal, Dr. Gihon asked for the raising of that sum, and he would see if they could not get a monument similar to that to Dr. Sims. He then appealed to the members present, and asked for one hundred men to subscribe one hundred dollars each or guarantee the collection of that sum. In response to this appeal over $2,000 were subscribed in a very few minutes, and, on motion, a resolution was adopted appointing each delegate a collector for the fund in his particular section.

After the reading of the Secretary's Report, a communication from Hot Springs, Ark., was read inviting the Association to hold its next meeting at that place. The communication was referred to the committee. This was followed by the reading of the Treasurer's Report, which was adopted as read.

A resolution that a Section on Orthopedics is inexpedient at the present time, was read and adopted.

A communication from State Section on Medicine, asking the Association to appoint a committee to go to Washington for the purpose of having a National Bureau formed and that the sum of $1,000 be appropriated to defray expenses, was read. On motion, this was accepted, and the portion referring to the appropriation was referred to the trustees.

A resolution was read protesting against the registration of any member of the Cleveland Medical Society at this meeting owing to that society admitting to membership and retaining others who were known as quacks or assistants to such, and by so doing tending to degrade the entire medical profession. This resolution was referred to the proper committee with a request for a prompt report.

A resolution by Dr. Wilson was read and unanimously adopted requesting the medical colleges of the entire country to make a four-year course compulsory for the obtaining of the degree of M.D.

The Address on Medicine was read by William E. Quine, of Illinois. Its title was

### MALARIAL DISORDERS IN LARGE CITIES, WITH ESPECIAL REFERENCE TO CHICAGO.

In this paper he called attention to the habit of some physicians designating by the term malaria many ailments of which they were unable to make any satisfactory diagnosis, as the easiest way out of the difficulty. Also, where a patient was suffering with malaria, the questions were asked as to whether there was any building going on in their neighborhood or turning over of soil; and, if so, the conclusion was jumped at that this was the source of their disease. Cases where no building was going on, nor soil disturbed were asked if they had been out of the city anywhere, and, if so, even though it was as long ago as two years, then, of course, that was the source of their infection. In case neither of the foregoing sources could be elicited, then the soil in their neigh-

borhood was giving off this poisonous effluvium. Thus malaria was theoretically existing in Chicago during the winter months, when the soil was frozen to a considerable depth, and upon top of this a considerable layer of frozen snow, the temperature below zero for months, and all building operations and excavations necessarily suspended; and during this time they had outbreaks of malaria. Did these same physicians claim that the soil, under these conditions, was able to give off this poison?

As to making the diagnosis, he used to think it a comparatively easy matter, but now he does not think it can be done upon the basis of external phenomena alone. That malaria exists in all large cities he had no doubt; but in cities he thought a reliable diagnosis could only be made by aid of the microscope.

The source of the disease was not always easy to determine; but that it could be conveyed through the medium of drinking water where the source of this water-supply was across marshy districts, he did not doubt. This had been demonstrated in the water-supply of Brooklyn, and in all probability the same applied to Chicago.

As to the type of the disease, many patients were cinchonized for a time and then died with their blood teeming with the germs, which demonstrated to his satisfaction that many varieties of germs had been classified under one head.

As to how long the infection lasted, we do not know. In some the germs will linger indefinitely, while in others they can be found in abundance one day, and within a few days they will disappear entirely.

The length of the incubation period is absolutely unknown at the present time.

### GENERAL SESSION. — THIRD DAY.

The resolution of the preceding day referring to the Cleveland Medical Society was referred to the Ohio State Society, the registration of said members suspended, and the money received from any member of the Cleveland Society who had already registered was ordered refunded.

Charges against a St. Louis physician were not allowed to come before the Association.

The report of the Board of Trustees was now read, showing the Association to be on a sound financial standing. It called for more frequent illustrations in the Association *Journal*.

Regarding the objectionable advertisements inserted in the *Journal*, no advertisement of a secret remedy had been published during the last year unless a formula of the same was sent to the *Journal*. The trustees now instructed the *Journal* to admit no advertisements of secret remedies unless the formula of the same was inserted as part of the advertisement. This report was accepted with great applause.

Dr. Cohen, of Philadelphia, congratulated the trustees upon their decision, and claimed that now every American medical journal would necessarily be obliged to clear its pages of such advertisements, and the profession as a whole was to be congratulated.

### ADDRESS ON SURGERY.

This address was read by C. A. Wheaton, M.D., of Minnesota.

The tendency of the present day is to relegate all surgical operations to the specialist. To be a specialist, however, a physician must have had a long successful career as a general practitioner, such as would raise him above the mediocre; for a surgeon who is not such a physician, is like a bird with one wing. With this prerequisite medical knowledge a patient is spared days and weeks of post-operative sufferings which otherwise would ensue.

Dr. Wheaton deplored the tendency to use the female pelvis as a field of adventure for the rising young surgeon, and believed soon the removal of a cystic ovary, or a Fallopian tube because it contained pus, would be an operation of the past, and that plastic methods would take its place.

At present the pelvis of man appears to be *his* source of danger; the operation of castration is strongly advocated for the relief or cure of enlarged prostate. Why the removal of the testicles should effect a cure in this disease we do not know; that it does cure we have ample proof. However, from time immemorial man has been unwilling to part with this part of anatomy; and for this reason, if for no other, the operation will never become popular. Cold abscesses causing no discomfort should not be opened.

A resolution was offered, increasing the annual dues one dollar, for the purpose of establishing a building fund to erect a permanent home for the Association and a home for old or disabled physicians. The resolution empowered the President to appoint a committee consisting of one prominent member from each State represented in the Association, whose duty it should be to solicit subscriptions for this fund and act as an advisory board to the trustees regarding the investment of the same. One-third of the committee were to be appointed to serve one, two and three years respectively, and their successors appointed for the term of three years. This committee was to report at each annual meeting the amount collected. After considerable discussion, on motion, the resolution was referred to the Business Committee.

A motion to amend the By-laws and Code of Ethics, so far as to allow the patenting of surgical instruments, provoked a very heated discussion, in which ex-President Davis of Chicago took a decided stand against tampering with the Constitution, and claimed no surgeon was faithful to the profession who would not freely give to it any discovery which he might make, and moved that the resolution be postponed indefinitely. As a substitute for Dr. Davis's motion, a resolution was offered and unanimously accepted, that any resolution having for its object the altering or amendment of the Constitution or By-laws, in any shape or manner, should not be acted upon at the meeting at which it was presented, but must be laid over until the next annual meeting. That this resolution acted as a boomerang will be seen further on.

### THE REPORT OF THE COMMITTEE ON ESTABLISHING A NATIONAL DEPARTMENT OF PUBLIC HEALTH

was read. The lack of time and want of funds had retarded the work of the committee. During December, some of the members living in Washington appealed to members of Congress, who promised consideration of the subject when the proper time should arrive; but all agreed that nothing could be done during the continuance of the Fifty-third Congress. Much vigorous work will be required, and it will be absolutely necessary for the Association to place at the disposal of the committee an adequate amount of money to defray current expenses.

A motion was made to accept this report and continue the committee with an appropriation of necessary funds; but a point of order raised by Dr. Scott that a resolution had just been passed laying such matters over until the next meeting, was ruled by the President as correct. On appeal taken from the ruling of the President, the President was sustained.

A resolution offered that the Nominating Committee should make its report on Thursday morning of each meeting; after the reading and adoption of the minutes, raised a point of order that the resolution should be referred to the Business Committee. The President's ruling that it was not necessary to refer it to that committee, resulted in an appeal, when the President was again sustained.

On motion, the Nominating Committee was directed to report immediately; but the secretary of that committee being absent no report could be obtained. The chairman of the Nominating Committee announced that Atlanta, Ga., was selected as the next place of meeting.

GENERAL SESSION. — FOURTH DAY.

DR. H. D. HOLTON, of Vermont, read

THE ADDRESS ON STATE MEDICINE.

This paper commenced with a review of the various attempts on the part of the ancients to establish hygienic measures.

It also called attention to Dr. Rush's efforts in this direction, and deplored the lack of patriotism in the erection of a monument to his memory; but Dr. Holton hoped the subscription started the previous day would result in an immediate consummation of its object.

*State Health Boards.* — While every State in the Union, with the exception of three, had established State Boards, which had accomplished more or less good, he thought they should be composed entirely of men who understand the subject from the scientific point of view, and should not be used for political purposes as unfortunately was now the case in many instances.

*State Appropriations for Military Purposes compared with those for the Protection of the Public Health.* — Money was almost lavishly appropriated by State Legislatures for the support of our military organizations. Compare this with the niggardly appropriations for the protection of the public health. New York State alone appropriated in a single year nearly $800,000 more for the militia than for its health board.

*Deaths caused by War contrasted with those by Disease.* — During our last war the deaths in battle amounted to about 93,000 while for the same length of time we have had 108,000 deaths caused by preventable diseases.

*National Health Board.* — That a National Board should be formed admits of no discussion, but the slow, red-tape manner in which it is necessary to bring about any innovation in national affairs makes constant agitation of this subject necessary. During the Fifty-third Congress, the Health Bill, known as Senate Bill, No. 840, met an untimely death in the hands of the Committee on Epidemic Diseases. Before the new bill is introduced in the Fifty-fourth Congress it should be amended so as to appoint medical officers of the Marine-Hospital, Navy and Army Services as an advisory board to the Health Board. However, before anything can be accomplished it will be necessary through the press to educate the people upon this subject. Unless the bill has behind it responsible parties to watch its progress, it is sure to be smothered in the committee.

*National Quarantine.* — Owing to the various laws in different States regarding quarantine measures, we shall never have an efficient quarantine until a national one is established. Of what avail is a rigid enforcement of appropriate laws at some points, when disease can enter our country unhindered at others?

*Vaccination.* — In nearly all foreign countries the production and distribution of vaccine virus is under the control of the government. Here it is almost wholly in commercial hands, who have more interest in the largest returns from the smallest possible outlay. Its distribution is through the middleman and druggist; and frequently this virus has been lying in the drawer for weeks and even months before being sold. Under these circumstances, is it any wonder that it proves inert? And when it is inert, after repeated trials the patient is told that he is not susceptible to the disease. If fresh lymph is used, it is a rare case that will show insusceptibility.

*Contaminated Vaccine.* — This is a far more serious matter than inert virus. Frequently, through the carelessness or gross ignorance of those employed in its manufacture it is exposed to and becomes contaminated by microbes, its use subjecting the victim to all the dangers of septicemia. An earnest appeal should be made for a National Board to have exclusive control of its manufacture and sale.

*Alcohol* was claimed to be the cause of more disease than it helped to cure, and was as much the cause of insanity, pauperism and crime as all the other causes combined.

*Antitoxin* should also be manufactured exclusively by the National Board. It should be absolutely fresh, and great care taken in its use.

*Tuberculin.* — While Koch's lymph does not cure tuberculosis, it has proved of inestimable value in establishing the diagnosis of tuberculosis in cattle.

*Tuberculosis.* — He thought cattle, fowl and pigs were disseminators of tuberculosis. The cattle of the West showed two per cent. afflicted with the disease; Baltimore, three and one-half per cent.; New York, two per cent.; while in Massachusetts it was seven per cent.

*Infectiousness of Milk.* — Milk is infected whether there are tubercles of the udder or not; and the presence or absence of udder tubercles has no effect upon the spreading of the disease through the milk. Also the muscles where no tubercles could be found it was demonstrated that the juice of these muscles could and did produce the disease. This brings up the question as to whether the bacillus is the cause or only the product of the disease.

*Proprietory Medicines.* — Many of these articles are of an extremely dangerous and, in some instances, fatal character, masked behind a trade-mark. If the government at Washington compelled the printing of the formula of said articles upon their containers, it would do more towards eradicating this evil than the strongest possible words of condemnation.

On motion of DR. HAMILTON, hereafter the Treasurer was to precede the Association a few days at it place of meeting, to make necessary arrangements for facilitating business.

The Report of Committee on Benevolence brought out the remarkable fact that the greatest support towards this object came from the bachelor members of the profession. The report was accepted and the Committee continued.

Dr. Woolsey, of California, calling attention to the spreading of diseases through the medium of our money circulation, offered a resolution calling upon the government to retire paper money and recoin the gold and silver at stated periods. How this was going to stop the spreading of disease through the money medium was not made very clear. The resolution was referred to the Committee on State Medicine.

The Report of the Committee on Nominations was as follows:

President, B. B. Cole, of California. 1st Vice-President, J. J. Chisholm, Maryland. 2d Vice-President, C. Le Grand, Alabama. 3d Vice-President, Augustus B. Clarke, Mass. 4th Vice-President, J. B. Satterwaite, Kentucky. Treasurer, H. P. Newman, Illinois. Secretary, Frank Woodbury, Pennsylvania. Librarian, G. E. Wise, Illinois. Trustees: Alonzo Garcelon, Maine; I. N. Love, Missouri; J. E. Reeves, Pennsylvania. Judicial Committee: N. S. Davis, Illinois; H. D. Dideme, New York; Jno. Morris, Maryland; W. E. B. Davis, Alabama; Geo. W. Browner, Missouri; D. W. Smouse, Iowa; M. B. Ward, Kansas; W. W. Welch, Pennsylvania. Readers of Addresses at next Annual Meeting: Surgery, Dr. Senn, Chicago, Ill.; Medicine, Dr. Osler, Baltimore, Md.; State Medicine, Dr. Rohé, Baltimore, Md.

The place of the next annual meeting is to be Atlanta, Ga., on the first Tuesday in May, 1896.

Upon motion the report of the Nominating Committee was accepted with the exception of the portions relating to the next place of meeting and the election of the Secretary.

A motion was made by Dr. Ferguson that the portion of the Nominating Committee's report referring to the Secretary be not agreed to, and the name of the present Permanent Secretary, W. B. Atkinson, substituted. This motion caused considerable personal discussion; but it was finally carried, and the present officer was continued in office.

A motion to substitute Washington as the place of the next meeting was lost, and Atlanta, Ga., finally adopted as the place.

A resolution was offered, inviting the members of the New York Academy of Medicine, New York State Medical Society, and New York County Society to send delegates to the next meeting of the Association; that the members of said bodies be admitted to membership in the Association upon application and upon presentation of proper credentials; and that all former sections in the By-laws, Constitution or Code of Ethics conflicting with this resolution be repealed. Here, again, the boomerang of the previous day returned; and although the Association wished to do so, no action could be taken on this resolution until next year.

Drs. Gihon and Ferguson being appointed as a committee, escorted the President-elect to the chair. He made a short address thanking the members for the honor conferred, at the same time warning them he should rule with a just but very *firm* hand.

A resolution by Dr. Osler was adopted urging the members to support the *Index Medicus* until such time as it should be self-supporting.

A resolution from the Association of Acting Assistant Surgeons, requesting Congress to place the surgeons who had served during the late war upon the same plane as the commissioned officers of the same grade, was unanimously adopted.

Regarding delegates to foreign countries, a resolution was adopted making any one who wished to visit a foreign meeting, a delegate from this Association, and upon application his credentials would be furnished by the President.

Among other resolutions adopted were the following: recommending all medical schools to adopt the metric system; that the American Medical Association adhere rigidly to the unmodified Code of Ethics; that the programme of the Association be published in the *Journal* at least three weeks prior to the meeting (referred to the Business Committee); appropriating funds necessary for printing and circulating circulars relative to the Rush Monument Fund (referred to the trustees, with power to act).

*(To be continued.)*

## Recent Literature.

*The Jewish Method of Slaughter Compared with Other Methods, from the Humanitarian, Hygienic and Economic Points of View.* By J. A. Dembo, M.D., Physician to the Alexander Hospital, St. Petersburg, etc. Translated. Pp. 111. London: Kegan Paul, Trench, Trübner & Co. 1894.

*Bau, Einrichtung und Betrieb, von öffentlichen Schlachthöfen.* Von Dr. Med. Oscar Schwarz, Sanitäts-Thierarzt, etc. Illustrated. Pp. 238. Berlin: Julius Springer. 1894.

Dr. Dembo's book is the outcome of a study of the methods employed for slaughtering animals in the larger slaughtering establishments of the principal European cities, and especially at St. Petersburg. The *shecheta*, or Jewish method, consists in slaughtering by rapid division of the carotids and other blood-vessels of the head, unconsciousness supervening very quickly in consequence of the sudden loss of blood. Other methods named by the author, with which he contrasts the Jewish method, are stunning, shooting, and the neck-stab. Dr. Dembo claims that unconsciousness supervenes, when the *shecheta* is practised, in three or four seconds, and that the cut is painless. He also claims that the epileptiform convulsions which follow this method render the meat less alkaline and hence diminish its properties as a nutrient medium for bacteria.

The work of Dr. Schwarz is an excellent treatise upon the construction, management and business of public slaughtering establishments. After a brief historical summary, the author presents the existing Russian laws relating to public slaughter-houses, and the arguments for and against their establishment. Descriptions are given of establishments suitable for cities of 10,000 and 30,000 inhabitants. One chapter is devoted to the accessories of a well-equipped slaughter-house — such as the different modern appliances for refrigeration by means of various mechanical processes.

The methods of disposing of the sewage of slaughter-houses are also treated in detail. The supervision of such establishments, the disposal of the meat of diseased animals, and other minor topics receive due attention.

This work deserves a good English translation, and would prove very useful to the health authorities of our large cities.

THE BOSTON

# Medical and Surgical Journal.

THURSDAY, MAY 16, 1895.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

Subscription Terms: $5.00 *per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

DAMRELL & UPHAM,
283 Washington Street, Boston, Mass.

## THE BRITISH ROYAL COMMISSION ON TUBERCULOSIS.

The course pursued by the British Parliament in regard to the important question of Tuberculosis in Cattle is in strong contrast to that which has been adopted by the Legislature of several New England States, including Massachusetts. For while the latter contented themselves with settling the economic questions which had to do with reimbursing the owners of slaughtered cattle, the British Commission instituted an investigation, the object of which was to "inquire and report what is the effect, if any, of food derived from tuberculous animals upon human health, and, if prejudicial, what are the circumstances and conditions with regard to tuberculosis in the animal, which produce that effect upon man."

The British Commission (appointed in November, 1894) consisted of Sir George Buchanan, Professor Browne, Dr. J. F. Payne, and Prof. Burdon Sanderson. The report which was presented on the 22d of April, 1895, received the assent of all the members.

Many distinguished pathologists and physicians were examined; and the Commission, concluding that they had not sufficient evidence, entrusted further inquiries to Professor McFadyean, Dr. Sydney Martin and Dr Sims Woodhead upon the following points:

(1) As to the means of recognizing tuberculosis in animals during life.

(2) As to the influence upon lower animals of food of tuberculous origin.

(3) As to the effects of cooking-processes upon food from tuberculous animals.

And the report is chiefly founded upon the results of these investigations.

In settling the question as to the effect of feeding animals with food of tuberculous origin, the investigation showed, first, that uncooked food derived from tuberculous animals, whether consumed by rabbits, guinea-pigs, cats or pigs, produces tuberculosis in a considerable proportion in each; secondly, that tuberculous matter added, if only on one occasion, to the ordinary food of any one of these animals, causes a still larger proportion to become tuberculous.

As regards man, the Commission believes that "any person who takes tuberculous matter into the body as food, incurs some risk of acquiring tuberculous disease."

The Commission takes the view that no distinction can be drawn in nature between tuberculous diseases originating in food infection, and those originating in other ways. They point, however, to the probability that the greatest effect of food infection is to be found in the tuberculous intestinal lesions of children.

With reference to the recognition or diagnosis of tuberculosis in cattle during life the Commissioners speak quite cautiously. Inquiries upon this point were limited by the fact that systematic meat inspection is not carried out in England with such thoroughness as prevails in most Continental slaughter-houses. The results of Professor McFadyean's inquiry show that tuberculous disease may exist in cattle that appear to all clinical tests to be in perfectly good health.

The Commissioners are not inclined to believe that a completely trustworthy test of tuberculosis has yet been proved to exist in the reaction of tuberculin. Professor McFadyean records, as the outcome of his experiments, that he received wrong indications from tuberculin as to the presence or absence of tubercle in cattle in the case of 24 animals out of 75; nevertheless, he sums up his report by the statement, "I have no hesitation in saying that, taking full account of its imperfections, tuberculin is the most valuable means of diagnosis in tuberculosis that we possess." The Commission adds that since these experiments were made the methods of using tuberculin have been improved and its use is now regarded as more trustworthy.

Dr. Martin's experiments form the basis of a very important portion of the report. He states that tuberculosis is chiefly a disease of organs which are, for the most part, removed in the process of "dressing" the carcass. As a result of his examinations and experiments showing the comparative rarity of tubercle in the meat substance, the Commissioners state their belief, that the power of infection of meat from such carcasses is mainly due, not to tuberculous matter left in the meat *in situ*, but to matter carried from tuberculous organs in the process of dressing by the butchers' knives or cloths, and thus smeared freely over the carcass.

The danger of such a proceeding must increase *pari passu* with the amount and distribution of the tuberculosis in the animal.

The Commissioners conclude, with Dr. Martin, that if sufficient discrimination and care were exercised in taking meat from tuberculous cattle a great deal of

meat from them might, without danger, be consumed by the community: and they point to the practice of public abbatoirs on the Continent as being founded on the same belief.

Dr. Martin would advocate, as a principle, that the operations of slaughter and dressing should be done under skilled supervision, with the object of removing and destroying every part of a carcass that contains any tubercle whatever, and also of destroying the whole carcass in cases where the animal is found to have advanced or general tuberculosis. He sees no objection to the sale of meat substance from carcasses which have shown only localized tuberculosis, and from which every particle of tubercle has been skilfully removed; provided always that, in every subsequent process of preparing the meat for sale, due care is taken to guard the saleable portions from contamination by tuberculous matter.

With reference to the danger from milk of tuberculous cows, the experiments of Dr. Martin present striking evidence that the milk of a tuberculous cow is only infective when it comes from a tuberculous udder. They show that the milk from such source is extremely virulent, and that milk, butter, skimmed milk and buttermilk from a cow with a tuberculous udder are actively infectious. The Commission concludes that "the withdrawal from the dairies of every cow that has any disease whatever of the udder, would form some approach to security against the serious danger incurred by man from the use of tuberculous milk, but it would not be an adequate security. The presence in any dairy of a tuberculous cow is a decided source of danger to the public. He suggests the employment of experts to determine the existence or non-existence of cows with tuberculous udders, in dairies, and says, if the expert finds tubercle bacilli in the milk, the cow has dangerous tuberculosis of the udder."

In order to destroy the infectiveness of tuberculous milk the Commission warmly advocates boiling, and evidently regards with suspicion any advice to the public to attempt to sterilize milk by heating it to a temperature short of the boiling-point. (The tourist who drinks milk as a beverage invariably finds it served raw in England, while upon the Continent it is always served boiled.)

The following recapitulation sums up the conclusions of the Commission:

"We have obtained ample evidence that food derived from tuberculous animals can produce tuberculosis in healthy animals. The proportion of animals contracting tuberculosis after experimental use of such food is different in one and another class of animals; both carnivora and herbivora are susceptible, and the proportion is high in pigs. In the absence of direct experiments upon human subjects we infer that man also can acquire tuberculosis by feeding upon materials derived from tuberculous food animals. The actual amount of tuberculous disease among certain classes of food animals is so large as to afford to man frequent occasions for contracting tuberculous disease through his food. As to the proportion of tuberculosis acquired by man through his food or through other means we can form no definite opinion, but we think it probable that an appreciable part of the tuberculosis that affects man is obtained through his food. The circumstances and conditions with regard to the tuberculosis in the food animals which lead to the production of tuberculosis in man are, ultimately, the presence of active tuberculous matter in the food taken from the animal and consumed by man in a raw or insufficiently cooked state.

Tuberculous disease is observed most frequently in cattle and swine. It is found far more frequently in cattle (full grown) than in calves, and with much greater frequency in cows kept in town cow-houses than in cattle bred for the express purpose of slaughter. Tuberculous matter is but seldom found in the meat substance of the carcass; it is principally found in the organs, membranes and glands. There is reason to believe that tuberculous matter, when present in meat sold to the public, is more commonly due to the contamination of the surface of the meat with material derived from other diseased parts than to disease of the meat itself. The same matter is found in the milk of cows when the udder has become invaded by tuberculous disease, and seldom or never when the udder is not diseased. Tuberculous matter in milk is exceptionally active in its operation upon animals fed either with the milk or with dairy produce derived from it. No doubt the largest part of the tuberculosis which man obtains through his food is by means of milk containing tuberculous matter. The recognition of tuberculous disease during the life of an animal is not wholly unattended with difficulty. Happily, however, it can in most cases be detected with certainty in the udders of milch cows. Provided that every part which is the seat of tuberculous matter be avoided and destroyed, and provided care be taken to save from contamination by such matter the actual meat substance of a tuberculous animal, a great deal of meat from animals affected by tuberculosis may be eaten without risk to the consumer. Ordinary processes of cooking applied to meat which has got contaminated on its surface are probably sufficient to destroy the harmful quality. They would not avail to render wholesome any piece of meat that contained tuberculous matter in its deeper parts. In regard to milk we are aware of the preference by English people for drinking cow's milk raw — a practice attended by danger on account of possible contamination by pathogenic organisms. The boiling of milk, even for a moment, would probably be sufficient to remove the very dangerous quality of tuberculous milk. We note that Your Majesty's gracious commands do not extend to inquiry or report on administrative procedures available for reducing the amount of tuberculous material in the food supplied by animals to man, and we have regarded such questions as being beyond our province."

The foregoing conclusions are worthy of the careful consideration of all American legislators, who are vitally concerned in this important question.

## THE NAVY MEDICAL SERVICE.

The trial of Medical Inspector Kershner of the navy, by court-martial on a charge of having given publicity to matters concerning the service, and then of having denied that he had done so, emphasizes the unsatisfactory position of the navy medical officers, discussed at greater length in our editorial of February 7, 1895.

It is well known that the medical officers of the navy are placed upon an inferior footing to line officers of the same grade. The difficulty of getting self-respecting medical men to serve in the navy is, no doubt, due to this fact, and the feeling engendered by this state of things cannot but produce unfortunate results, as it probably did in this case of Dr. Kershner, who refused when ordered by his captain and later by his admiral (Meade) to render service on board a merchant vessel in the Barbadoes. He complained to the department at Washington of having been ordered to render service outside his sphere of duty, and was upheld in his refusal.

## MEDICAL NOTES.

The American Medical Association. — The forty-sixth annual meeting was held in Baltimore, May 7, 8, 9 and 10, 1895. The General Session of the Association was opened by the Hon. F. C. Latrobe, Mayor of Baltimore, in an address of welcome in behalf of the city. His promise that the members would be pleased with the hospitalities, public and private, of which they would be the recipients during their stay, was more than verified by the experience of the visiting physicians at the hands of their entertainers. Dr. Samuel C. Chew, chairman of the Reception Committee gave the address of welcome on behalf of the medical profession of Baltimore, in which he spoke of Baltimore as a centre of medical education, and of the progress of medical science since the Association last met in that city in 1866.

The report of the Judicial Council, finding that objectionable advertisements had been printed in the *Journal* was presented, and the attention of the trustees and the editor was called to the fact. Motions that the trustees report on Wednesday, and that their report be referred to a committee which should report on the following day, and that a committee be appointed to confer with the trustees, were laid on the table.

It was voted, on motion of Dr. Millard, of St. Paul, that it was the sense of the Association that the officers of the medical corps of the navy should have the same rank, pay and emoluments as those of the army. It was moved and carried that this resolution be printed, and also that a copy of the same be sent to the President of the United States, the Secretary of the Navy, and to every member of the Fifty-fourth Congress.

Tuesday evening, May 7th, receptions were tendered to the members and their wives by Dr. Julian J. Chisholm, Dr. Howard A. Kelly, and Dr. Robert W. Johnson. Dr. George H. Rohé, the superintendent of the Maryland Hospital for the Insane at Catonsville, also entertained a number of the visiting physicians at the hospital at Catonsville.

Wednesday evening a reception was held by Dr. and Mrs. Henry M. Hurd at the Johns Hopkins Hospital.

Thursday the report of the trustees on the advertisements in the *Journal* stated that none of its contemporaries present advertising pages that are as free from objectionable material. The editor with the termination of present contracts is to be instructed "to accept no advertisements of medicinal preparations the proprietors of which do not give a formula containing the officinal or chemic name and quantity of each composing ingredient to be inserted as a part of the advertisement."

Thursday afternoon over four hundred of the members accepted the invitation of the trustees of the Sheppard Asylum to visit and inspect the buildings of that institution. In the evening a reception was tendered the members of the Association at the Music Hall.

Dr. W. S. Westmoreland, of Atlanta, was chosen chairman of committee of arrangements for the meeting of 1896, Dr. J. McFadden Gaston, Jr., was named for assistant secretary.

Atlanta, Ga., was chosen as the place of meeting for 1896.

Tubercle Bacilli in the Nose. — Dr. Strauss has reported in *Archiv de Médicine Experimentale*, that he has verified the occurrence of these bacilli in the nasal cavities of persons, themselves in good health, who have been frequenting localities where phthisical patients were habitually present.

Practician or Practitioner. — The *Medical News* in an interesting editorial on "Questions of Nomenclature," characterizes the term practitioner in the following language: "Medical language has a somewhat fatalistic tendency to philologic barbarism that healthy modern minds should withstand. No science is so given to absurdities of nomenclature. Even a much-used synonym of physicians is philologically more than outlandish. The French have a word *praticien* for one who practices, for example, the law, and we have the same word in medical English, unused but properly formed — *practician*. With megalosaurean wit we devise and use the linguistic outrage, *practitioner*. With just as much reason should we say *academicianer* or *dentistianer*. A practicer is, of course, one who practises; a practitioner, therefore, must be one who practitions!"

Mountain Air for Cities. — Dr. S. E. Hampton writes to the *Journal of the American Medical Association* the details of a plan elaborated by him by which "mountain air" can be obtained by suction pumps acting through large steel-plate pipes, carried to a height of 600 feet into the air and supported by guys. An ideal mountain resort could thus be furnished in the middle of a city, by merely having a glass-covered room supplied with air obtained in this way. This audacious plan for bringing climate to patients instead of sending patients to climate, Dr. Hampton thinks would be of trifling cost compared with the benefits to be derived. Perhaps when the patients thus treated had acquired strength enough to begin horse exercise they could be provided with respirators, attached to long rubber tubes, and allowed to ride about a large arena, thus securing a powerful adjuvant in their "climatic" treatment!

A Fatal Case of Poisoning by Lysol. — A case is reported in the Vienna daily papers in which a mother gave a twenty-four-hour-old baby a teaspoonful of lysol solution, instead of rhubarb, with fatal result. The *Wiener klinische Wochenschrift* calls attention to this fact in connection with the endorsement given by the Austrian public health authorities of lysol as a disinfectant combining the qualities of great effectiveness, and at the same time harmlessness as compared with carbolic-acid and corrosive-sublimate solutions, and therefore peculiarly adapted to midwifery practice. This is the first case which has been re-

ported of poisoning by lysol, while in the early years of the employment of carbolic solutions, the daily papers kept a permanent heading for cases of carbolic-acid poisoning. It cannot be denied that the introduction of lysol solutions have resulted in a marked improvement.

A Slight Mistake. — The following instance where a bad cold caused a startling conversation is reported in the *Sanitarian:* "A modest young newspaper man was invited to a party at a residence where the home had recently been blessed with an addition to the family. Accompanied by his best girl he met his hostess at the door, and after the customary salutations asked after the baby. The lady was suffering from a severe cold, which made her slightly deaf, and she mistakenly supposed that the young man was inquiring about her cold. She replied that though she usually had one every winter, this was the worst she ever had; it kept her awake at night a good deal at first and confined her to her bed. Then noticing that the scribe was becoming pale and nervous, she said that she could see by his looks that he was going to have one just like her's, and asked him if he wished to lie down. The paper came out as usual the next week, but the editor has given up inquiring about babies."

### BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — During the week ending at noon, May 15, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 55, scarlet fever 30, measles 132, typhoid fever 14.

The Norfolk District Medical Society. — At the annual meeting on May 14th, the following officers were elected for the ensuing year: President, Dr. D. D. Gilbert, Dorchester. Vice-President, Dr. W. S. Everett, Hyde Park. Secretary and Librarian, Dr. James C. D. Pigeon, Roxbury. Treasurer, Dr. Edw. G. Morse, Roxbury. Commissioner of Trials, Dr. George K. Sabine, Brookline. Nominating Councillor, Dr. T. Garceau, Roxbury. Censors: Dr. C. F. Withington, Roxbury, supervisor; Dr. B. S. Blanchard, Brookline; Dr. E. F. Dunbar, Roxbury; Drs. D. G. Eldridge and Dr. E. B. Lane, Dorchester; and twenty-nine councillors.

Typhoid Fever and Milk. — An epidemic of typhoid fever is reported at New Milford, Conn. There have been already 23 cases, and the disease is ascertained to have its source in milk obtained from a certain farm. The disease in the case of the Yale junior, B. A. White, who died at the Yale infirmary on May 6th, is said to have been contracted from this source. A farm laborer who had come from another town, and was either suffering from a mild form of typhoid, or was in its early stages, was employed to do the milking on the farm in question, which furnished the milk-supply of a private school, and of all the families in which the disease has so far appeared. A rather forcible argument for the sanitary inspection of dairy farms!

### NEW YORK.

Commencement at the University of the City of New York. — The annual Commencement exercises of the Medical Department of the University of the City of New York were held at Carnegie Music Hall on the evening of May 7th. There were 101 graduates. In presenting them with their diplomas the chancellor of the University, the Rev. Dr. Henry McCracken, said: "Young gentlemen, the diplomas I shall now give you bear the signature of the Governing Faculty, with the exception of our oldest and most esteemed professor, Dr. A. L. Loomis, who, while he is absent from us in the living character, is, I am sure, among us in spirit. We shall remember him reverently, as the last of a long line of illustrious men dating from the time of Valentine Mott." The usual prizes and honors having been announced, including the appointment to Bellevue Hospital, the valedictory was delivered by Henry Lincoln Borland, of the graduating class; after which General Horace made the address to the class.

Death of Dr. Byron. — Dr. John M. Byron, chief of the bacteriological department of the Loomis Laboratory and lecturer on that branch in the University Medical College, died of tuberculosis on May 7th, in the thirty-fourth year of his age. He believed that he contracted the disease by the inhalation of tubercle bacilli in some material with which he was experimenting and which he had allowed to become dry. Dr. Byron was born in Peru in 1861, and was graduated at the University of Naples. He also studied medicine for some time in Paris. He came to New York in 1888 and began to teach bacteriology. He soon became known as an expert in that department of medicine, and during the cholera excitement in 1892 he was selected by Health Officer Jenkins to be the bacteriologist at the Quarantine Station, and to have charge of Hoffman and Swinburne Islands. For some time he had been a member of the bacteriological bureau of the New York Board of Health, and a short time before his death he was appointed by the present Health Officer, Dr. Doty, bacteriologist to the Quarantine Department.

## Miscellany.

### A NEW RHINOPLASTIC OPERATION.

In the *Medical Press and Circular* for April 10th is reported the case of an ex-soldier upon whom Mr. Astley Bloxam performed rhinoplasty by grafting a finger over the space left by the loss of a nose. A flap had been previously turned down over the forehead according to the Indian method, but the partially adherent flap hung down in ungraceful folds, and incompletely covered the defect. An attempt to graft on a newly amputated finger proved unsuccessful.

The patient offering to sacrifice one of his own fingers, Mr. Bloxam trimmed and prepared the finger, and placed it in a wedge-like opening which he made in the forehead flap. It was retained for over a month in this position by means of a plaster-of-Paris bandage, and union was obtained. The finger was then amputated, and then gradually trimmed into shape, when it was found to be somewhat too low to look well. The surgeon then shifted it bodily upward half an inch or so, and after further trimming succeeded in furnishing his patient with a fairly respectable nose, with a bony bridge, in which respect it is probably unique.

The grit and endurance of the patient are fully as much to be commended as the skill and persistence of the surgeon in this case; and it is to be hoped that after the nose has had time to settle into shape, a full report with photographs will be published.

## A SYPHILITIC LESION OBSERVED IN A PRE-COLUMBIAN SKULL.

DR. ALBERT S. ASHMEAD writes to the New York *Medical Journal* as follows:

"In the Baudelier collection, Metropolitan Museum, New York, there is a skull of a mummy, just being classified, from Pacha Camac, on the Peruvian coast, near Lima. It was found twelve feet underground, and no other part of the skeleton was in a condition to be shipped. It is, without doubt, according to Mr. Saville, the director, and Professor Putnam, who examined the specimen with me, pre-Columbian. In this burial place nothing modern, nothing post-Columbian has ever been found.

"In the right supratemporal region of the skull, on the parietofrontal suture, there is a mark of disease, almost eating through the bone; there is no doubt that the scalp had been removed, and what followed we may guess — it was found that the skull itself was affected, and the case was left alone. Evidently the man lived long enough to almost allow time to obliterate the mark of the surgeon's instrument. On the inside of the skull no mark of disease, except the extreme thinness of the tissue, strikes the observer. To my mind, this is an instance of syphilis in a pre-Columbian skull. The location of this lesion and the appearance of the diseased bone throughout are peculiarly syphilitic. I have seen such instances many times in Japan, on the living body, and once in a post-mortem examination in a *yoshiwara* (licensed prostitute)."

## Correspondence.

### DEFLECTION OF BULLETS BY TISSUES.

DENVER, COL., May 6, 1895.

MR. EDITOR: — The discussion of the paper of Dr. Julian A. Mead in your issue of April 25th, calls for comment in certain particulars.

It should be more widely known by physicians that deflection of the ball does depend very largely upon its velocity. To illustrate this, let us take the following extreme examples; prefacing these by stating that we shall attempt to prove that the bullet from any large-calibred sporting rifle would scarcely be deflected by any tissues in the human body:

I have known a ball from a .40 cal. Sharp's rifle, weighing 360 grs., with a powder charge of 90 grs., to pass entirely through a buck deer lengthwise, breaking five ribs, the head of the femur and the adjoining pelvic bones, and afterwards cutting a channel nearly two feet long in the hard clay of the cañon in which the deer stood at the time of shooting, and to pass onward with a scream which could be heard for some seconds, showing that its velocity was still considerable. In another instance, a ball of .44 cal., weighing about 400 grs., with 77 grs. of powder, passed lengthwise through a full-grown grizzly bear, leaving a wound nearly five feet in length. In still another instance, a .40 cal. ball, weighing about 260 grs., and fired with 82 grs. of powder, cut a straight furrow through the buttress of dense bone upon the skull of a grizzly which constitutes the chief skeletal mark characteristic of *Ursus horribilis*. This bear was at a distance of 250 yards, and the ball impinged at an angle of about 10 degrees. It was not sufficiently deflected to prevent the second wound, which it made after emerging from the skull and entering the tip of the nose, from being in an absolutely straight line, so far as I could determine, with the wound in the skull. Of more than one hundred black-tail deer killed by a friend of mine with whom I have done much shooting, with a 44-77 Sharp's mentioned, the ball was found in the body but once. After quoting such examples as these, it is needless to state that no tissues in the human body could ordinarily appreciably deflect such missiles as those spoken of; so that, to my mind, at least, that subject needs no further discussion.

In the cases quoted, heavy missiles, with plenty of good powder, were used, in thoroughly well-made weapons, with great length of barrel as compared with the ordinary revolver, thus securing the full effect of the burning powder. On the other hand, if the cheap, pot-metal type of revolver is used, with a small bullet and a little poor powder, the ball is practically a spent one when it emerges from the muzzle. If the powder is improperly made, much carbon may remain after its deflagration, instead of being burned to make gas and thus assist in the work to be done; if the powder be too coarse-grained, it may be blown out of the barrel like shot, even to such an extent that it may stick in a board many feet away, in one instance, which I saw, with coarse blasting powder, at a distance of more than 20 feet. These grains not only fail to assist in making gas, but must detract from the force moving the bullet, because they require a part of the force for their own movement. Further, the gas developed may leak out and thus be inefficient if the weapon lack in accuracy of finish. Where so many variable factors enter, it is easy to see that the effect may be almost anything.

I have known one pistol-ball to strike the collar-bone and drop to the ground, and another one to strike the thenar eminence of a boy's hand and drop in similar manner, leaving merely a hole in the skin. Both shots were at very short range. These examples will show that a bullet may be stopped by the tissues without doing them any very serious damage.

Now we come to those curious and interesting cases, of which many examples are on record, and of which I have seen quite a number, in which the ball has sufficient momentum to enter the body, but not enough to cause it to continue in a straight path. Most of us have repeatedly seen the pistol-ball deflected up the forearm by the flexor tendons — in my experience the most common example of deflection met with. The skin of the chest and neck has many times carried the ball round the body at least half-way, after it has been deflected from a rib or other firm tissue — even the larynx in one case. In one of my cases, which I have quoted elsewhere, the ball was at the spinous process under the skin at about the first lumbar vertebra, having entered near the sternum.[1] I have known the scalp to carry a ball quarter or half-way around the head in two or three instances. Similar examples are so common as to render further quotation superfluous. The

[1] Gunshot wounds in their Medico-Legal Relations, International Medico-Legal Congress, 1893.

ones given will serve to establish, I think, that no tissues will turn some bullets, while any tissues will turn others.

After these considerations, it would be absurd to suppose that the sternum could not deflect a revolver-bullet, and equally so to expect it to materially deflect a ball from a sporting rifle. And when we take into account other features than those studied — the firmness of the tissues and the momentum of the ball — our position will be still stronger.

A bolt-shaped bullet of very hard metal is less likely to be deflected from its course than a spherical ball of soft metal, of equal weight. The latter form of bullet has been the one which has given rise to the most curious instances of deflection on record, for the reason that all favoring features were present. These were (1) low velocity, for such bullets were formerly fired by a small charge of powder, thus giving, whatever the size of the ball, a relatively small momentum; (2) spherical shape, thus offering the greatest possible surface to the tissues of the body penetrated, and doing away with the penetrative effect of a pointed ball; and (3) soft metal in the composition of the missile, favoring deformation. If the deformation be very great, however, the ball tends to stop from the enormously greater resistance with which it meets.

With reference to the brand, there can be no possible doubt that the reason why it appears above the bullet-hole is that the weapon is "kicked" higher up at the time of the emergence of the powder and the gases than at the time the bullet comes from the muzzle, for the brand is at a higher and higher point as the weapon is withdrawn from the target, because the angle between the line of the bullet and that of the gases remaining the same, a greater and greater arc is necessary to subtend the constant angle. It is not at all necessary to open the question of whether the bullet is "kicked" upward, so long as the gases emerge after it.

The position assumed by Drs. Draper and Mead regarding the shape of the wound in the skin is equally as impregnable as in the matters considered. In a murder-case now pending, I was able, at the autopsy, to indicate the general course of the bullet, by the appearance of the wound of entrance which was distinctly elliptical. The ball had entered the chest at an angle of about 50 or 60 degrees, and left, upon the side of the lesser angle, distinct evidence of its course, in the shape of a wide, blackened, rather inverted border, not present in equal degree on the remaining edges of the wound. I have noted the same conditions repeatedly before, and notably in animals shot at a very acute angle. I saw one wound more than twice as long as broad made at an angle of probably not over five to eight degrees, which facts, taken together, certainly settle the question in my own mind. Very truly yours,

J. N. HALL, M.D.

## DIPHTHERIA ANTITOXIN AND "THE METROPOLITAN DISTRICT."

BOSTON, May 9, 1895.

MR. EDITOR: — I notice in your review of the work of the Boston Board of Health for the year 1894, (JOURNAL, May 2d, p. 445), a statement that the city board has under consideration a proposition for extending the distribution of antitoxin "at cost price to the well-to-do and the health authorities of the smaller communities forming a part of what is known as the Metropolitan District."

I would, therefore, respectfully inquire why the city of Boston should be taxed to supply a district outside its own limits, especially when (as you have stated in the previous issue of April 25th), the State Board of Health has already, for several weeks, been engaged in the distribution of the same useful product in an entirely satisfactory manner. Since this life-saving work appears to be a part of the legitimate function of the general board, we sincerely hope that it may be permitted to continue such a distribution.

Yours respectfully,

WEST-END.

## METEOROLOGICAL RECORD.

For the week ending May 4th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | Weather* | | Rainfall in inches. |

| Amesbury | 10,920 | 2 | 1 | — | — | — | — | — |

Deaths reported 2,746; under five years of age 902; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 317, acute lung diseases 499, consumption 315, diphtheria and croup 119, diarrheal diseases 39, measles 32, scarlet fever 38, whooping-cough 19, typhoid fever 37, erysipelas 10, cerebro-spinal meningitis 12, malarial fever 9, small-pox 2.

From typhoid fever Philadelphia 10, New York 6, Cleveland 7, Boston 4, Cincinnati 3, Providence, Lawrence, Newton and Newburyport 1 each. From measles New York 22, Brooklyn 5, Cincinnati 2, Philadelphia, Boston and Providence 1 each. From whooping-cough New York 9, Cincinnati and Haverhill 2 each. Philadelphia, Brooklyn, Providence, Lowell, Cambridge and Lawrence 1 each. From cerebro-spinal meningitis New York 5, Chelsea 3, Lawrence 2, Somerville and North Adams 1 each. From malarial fever Brooklyn 6, New York 2,

Newburyport 1. From small-pox Philadelphia and Cincinnati 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530 for the week ending April 27th, the death-rate was 18.9. Deaths reported 3,829; acute diseases of the respiratory organs (London) 341, whooping-cough 111, measles 85, diphtheria 50, diarrhœa 39, fever 24, scarlet fever 18.

The death-rates ranged from 10.4 in Croydon to 29.3 in Bolton, Birmingham 17.1, Bradford 16.8, Cardiff 12.7, Gateshead 18.5, Huddersfield 13.6, Leicester 17.2, Liverpool 23.7, London 17.9, Manchester 27.6, Newcastle-on-Tyne 19.9, Nottingham 16.3, Portsmouth 15.5, Sheffield 17.0, Sunderland 19.7.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 4, 1895, TO MAY 10, 1895.

CAPT. RICHARD W. JOHNSON, assistant surgeon, is relieved from duty at Washington Barracks, D. C., and ordered to Fort Huachuca, Arizona, for duty, relieving MAJOR TIMOTHY E. WILCOX, surgeon.

MAJOR WILCOX on being thus relieved is ordered to Fort Schuyler, New York, for duty.

The leave of absence on account of sickness granted MAJOR CLARENCE EWEN, assistant surgeon, is extended three months on account of sickness.

CAPTAIN LOUIS W. CRAMPTON, assistant surgeon, will report in person to the president of the examining board, appointed to meet at Denver, Col., on May 14, 1895, for examination for promotion.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 11, 1895.

S. S. WHITE, passed assistant surgeon, ordered to the U. S. S. "Bancroft," June 8, 1895.

J. W. Baker, passed assistant surgeon, from the "Enterprise" and Recorder Naval Medical Examining Board.

M. W. BARNUM, assistant surgeon, resigned from the Navy, May 7, 1895.

ROBERT BOYD, assistant surgeon, resigned from the Navy, May 8, 1895.

M. C. DREIMAN, surgeon, ordered for examination preliminary to promotion.

H. D. WILSON, assistant surgeon, detached from "Vermont" and to the "Monongahela."

H. D. BEYER, surgeon, ordered to the U. S. S. "Monongahela."

## MASSACHUSETTS MEDICAL SOCIETY.

### ONE HUNDRED AND FOURTEENTH ANNIVERSARY.

The annual meeting will be held at 9 o'clock A. M., Wednesday, June 12, 1895, in the building of the Massachusetts Charitable Mechanic Association, on Huntington Avenue, Boston.

Meetings of Sections will be held in the same building, on the preceding day, Tuesday, June 11th.

### TUESDAY, JUNE 11th.

At 10 A. M., the Fellows of the Society are invited to visit the Massachusetts General Hospital, on Blossom Street; the Boston City Hospital, on Harrison Avenue; the Children's Hospital, on Huntington Avenue, and the Carney Hospital, South Boston.

*The Shattuck Lecture, Cotillion Hall*, 1 P. M.— Dr. Robert T. Edes, of Jamaica Plain. "The New England Invalid."

*Section in Medicine, Banquet Hall*, 2.30 P. M.— Dr. F. W. Chapin, of Springfield, Chairman; Dr. G. G. Sears, of Boston, Secretary. "Modern Views of the Nature and Treatment of Exophthalmic Goitre." By Dr. J. J. Putnam, of Boston. Discussion by Dr. G. B. Shattuck, of Boston. "Home Treatment of Phthisis." By Dr. V. Y. Bowditch of Boston. Discussion by Dr. F. I. Knight, of Boston. "The Diagnosis of Malaria by Means of Examination of the Blood and the Presence of Laveran's Bacillus." By Dr. Philip Kilroy, of Springfield. Discussion by Drs. F. C. Shattuck, W. T. Councilman, of Boston.

*Section in Surgery, Cotillion Hall.*— Dr. J. B. Brewster, of Plymouth, Chairman; Dr. C. L. Scudder, of Boston, Secretary. "Recent Progress in Genito-Urinary Surgery. Treatment of Enlarged Prostate." By Drs. A. T. Cabot and W. S. Watson, of Boston. Discussion by Drs. L. Bolton Bangs, of New York City; Abner Post, Paul Thorndike, G. W. Allen, of Boston, and others.

### WEDNESDAY, JUNE 12th.

*Annual Meeting, Cotillion Hall*, 9 A. M.— Business of the Annual Meeting. "The Etiology of Diphtheria and the Use of Antitoxin." By Dr. H. C. Ernst, of Boston. "The Pathology of Diphtheria." By Dr. W. T. Councilman, of Boston. "The Prophylactic Use of Antitoxin." By Dr. F. G. Morrill, of Boston. "The Preparation of Diphtheria Antitoxin." By Dr. J. L. Goodale, of Cambridge. "The Clinical Use of Antitoxin." By Dr. W. H. Park, of New York City. Discussion by Drs. C. F. Withington, of Roxbury; G. G. Sears, of Boston.

*The Annual Discourse*, 12 M.— By Dr. Alfred Worcester, of Waltham.

*The Annual Dinner*, 1 P. M.— At the close of the discourse, the annual dinner will be served.

### BUREAU OF INFORMATION.

In order to increase the social element of the annual meeting, a Bureau of Information will be established, where members will be given information of any kind which may add to their comfort and pleasure while in Boston.

Due notice of the location, and detailed plans of this bureau, will be furnished later.

### EXHIBIT.

On Tuesday and Wednesday, from 9 A. M. to 5 P. M., there will be an Exhibit, including the usual features.

### COUNCILLORS' MEETINGS.

The Annual Meeting, at 7 o'clock P. M., Tuesday, June 11, 1895; Stated Meetings on Wednesday, October 2, 1895, and on Wednesday, February 5, 1896, at the Medical Library, No. 19 Boylston Place, Boston.

F. W. GOSS, M.D., *Recording Secretary*.
217 Warren Street, Roxbury.

## SOCIETY NOTICES.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.— The Forty-fifth Annual Meeting will be held at Chambersburg, Pa., May 21–24, 1895. WM. B. ATKINSON, M.D., *Secretary*.
1400 Pine Street, Philadelphia.

NEW HAMPSHIRE MEDICAL SOCIETY.— The One Hundred and Fourth Anniversary Meeting will be held Monday and Tuesday, June 3 and 4, 1895, at Concord, G. A. R. Hall, 15 Warren Street. The Anniversary Dinner will be served at the New Eagle Hotel, Tuesday, June 4th, at 1 P. M. Tickets will be on sale at the hall by Dr. C. W. Lovejoy, of the Committee of Arrangements. The Anniversary Chairman, Dr. Robert Burns, of Plymouth, will preside.

GRANVILLE P. CONN, M.D., *Secretary*.

## IN MEMORIAM.
## W. H. FLAGG, M.D., AND S. W. BOWLES, M.D.

At the Annual Meeting of the Hampden District Medical Society held April 16, 1895, the following resolutions were unanimously adopted:

*Whereas*, Drs. W. H. Flagg and S. W. Bowles, both worthy and active members of this Society, have been removed by death,—

*Resolved*, that we highly appreciate the valuable services which they rendered to this Society and the medical profession, and that we hereby express our sympathy for their relatives and families in their severe bereavement.

*Resolved*, that these resolutions be entered upon the records of the Society and that a copy be sent to their families and to the *Springfield Republican* and the BOSTON MEDICAL AND SURGICAL JOURNAL for publication.

MARSHALL CALKINS,
RALPH H. SERLYE,
PHEBE A. SPRAGUE, } *Committee.*

## RECENT DEATH.

EX-SURGEON-GENERAL CHARLES SUTHERLAND died at Washington, on the 11th of May. Dr. Sutherland was born in the city of Philadelphia, May 29, 1829. He entered the army as an assistant surgeon in November, 1852, and served for several years on the plains. He rendered distinguished service during the war, as surgeon with the rank of major. He was medical director of the hospitals at Annapolis in 1864; and from 1864 to the end of the war was purchasing medical purveyor at Washington. In 1876 he attained the colonel's rank, and served at different times as medical director of the military divisions of the Pacific and Atlantic. On December 30, 1890, he was appointed surgeon-general, with the rank of brigadier-general, and served in that capacity until he was retired.

## REMARKS ON THE PSYCHICAL TREATMENT OF NEURASTHENIA.[1]

BY JAMES J. PUTNAM, M.D., BOSTON.

There is hardly a subject in practical medicine which is of wider interest than the study of the nature and treatment of the degenerative neuroses and psychoses which the latitude of the present discussion will allow us to designate as neurasthenia.

For many of these cases to be sure, a simple and wholesome life of active usefulness combined with the steadying influence of encouragement and good advice, and the various means which we possess for improving nutrition and strengthening the circulation — prominent among which is the external use of water — suffices to secure a reasonable degree of health. Of all these methods, valuable as they are, I do not mean to speak. In other cases — and their number is great — the sympathy, the ingenuity, the intelligence and skill of the physician is drawn upon to its full capacity without being able to bring relief to his patient, and then perhaps — to crown his disappointment or increase his puzzle — the patient goes to an irregular practitioner or becomes a disciple of the Christian Science or Mind Cure, and gets better, for a time at least.

In selecting the *psychical treatment* for this discussion, I do not in the least mean to claim for it a place of undue prominence.

The best physician will always be he whose resources are the most extensive and the best mastered. But of these two conditions the latter is the more important, and I think neither the profession at large nor the neurologists have yet learned to master this branch of therapeutics to the extent that it deserves.

Every intelligent physician who deals with cases of this class can show a good list of successful results, the fruit of conscientious and skilful work on his part; but the methods are not yet so systematized but that we can all profitably compare notes and enrich our own resources by a study of the results obtained by those who have been working in special lines.

There are still too many of these cases that we fail to reach, and one still hears too much said about the impossibility of benefiting certain patients without appeals to their superstitiousness, such as a self-respecting physician should be unable and unwilling to make.

In a sense, I grudge the irregulars every case that they win from us, be they few or many, because I believe that with a deeper knowledge of human nature, a better understanding of pyschology, a wider range of methods and greater skill in applying them, we could cure more of these patients ourselves.

Many patients are neurasthenic because there is no interest which sufficiently absorbs their energy. It is noticeable that fanatics and enthusiasts, even if naturally feeble or occasionally prostrated by sickness, are rarely permanent invalids. The strong attraction of their one interest focuses their powers, and steadies the ill-balanced forces of the mind. The brain is a machine for grinding out work, and if it can be made to do this effectively, even if the work is of a simple order, so that it be engrossing, the patient is sure to be the gainer. Certainly all of us have had some patients for whom enforced or chosen labor has been a great blessing, though from time to time it may have seemed to aggravate their sufferings.

Whatever other means of treatment have been chosen, this then, should be the general aim, to teach the brain to maintain a steady outflow of effective work, within the limits of the patient's powers. If I do not dwell on this species of mental influence at such length as its importance would warrant, it is partly because the principle is familiar, and partly because each patient's conditions vary so much that it would be difficult to lay down practical rules. It is, however, important to remember that the great usefulness of systematic gymnastics for neurasthenics is largely to be explained in this way. Children who have a tendency to neurasthenia can profitably carry this form of training to a high point, and for them, also, the training of the kindergarten and the technical instruction in the schools of higher grade may be made of great service, by developing the sense of power in the direction of constructiveness and the overcoming of obstacles.

Every one is familiar with the remarkable benefit occasionally obtained by the use of the so-called Dyer's method in the treatment of asthenopia. The action of the very gradual increase in the use of the eyes must surely be mainly a matter rather of psychical than muscular training. On somewhat similar principles perhaps, the persistent and careful use of gymnastics, directed by a skilled teacher, can often be made of material service in the treatment of neurasthenic patients.

What is meant by mental treatment, and what sorts of symptoms among the many that are met with in neurasthenia may be considered as possibly amenable to it?

A few years ago these two questions would have been answered in a far narrower spirit than now, and it is not probable that our conceptions are even yet as wide as they will eventually become. Inasmuch as the cortex of the brain is a great projection plane, in Meynert's sense, on which all the processes which occur in the body are represented, so that they may and must form part of the raw material of emotions, ideas, and memories, it is theoretically conceivable that all these processes are in some measure liable to be reacted upon by the operations of the mind. But, without taking advantage of so wide a generalization as this, every one will admit that the investigation into hysteria, and the kindred phenomena of experimental hypnotism, and the study of the clinical rôle played by disorders of the mind in the production of such affections as anemia and jaundice, and a host of others, have greatly enlarged our conception of the influence which this unseen agency may exert.

Hysterical edema, hysterical atrophy, hysterical anemia, and the like, are now considered as symptoms of a disturbed action of what may fairly be called the mind; it is probable that more of the symptoms of neurasthenia are of that origin than would generally be admitted, though the ultimate chemical causes of the neural weakness which underlies the disease very likely affect the whole nervous system and not the brain alone. At all events, many of the worst symptoms of neurasthenia, such as the morbid ideas, the causeless exhaustion, the sense of inefficiency and loss of control and of identity, the tendency to depression bordering on melancholia, the asthenopia and kindred

[1] Read before the Boston Society for Medical Improvement, March 4, 1895.

localized weaknesses, the persistent "associative" pains, are in great part, though perhaps not often wholly, of psychical origin. It is such groups of symptoms as these that I shall have in mind in the following remarks.

The consciousness of any individual at a given moment forms but a small fragment of what may be termed his mind. It consists of the small nucleus of bodily sensations and recurrent ideas, the constant persistence of which is necessary to give the sense of personal identity, and of a certain number of other ideas and feelings which cohere less strongly but form a subconscious background for his thought. Outside of the personal consciousness of the moment there are countless clusters of mental processes which are registering or regulating the movements going on in the vast workshop of the body, and waiting their turn to subserve the interests of the next moment's consciousness. Perhaps, indeed, it may be said that in health, and in proportion to the perfection with which the mind is organized, the consciousness of the moment gains a fulness and background of great value even from mental processes which lie for the most part outside of it. The mind as a whole might be compared to a deep and swiftly flowing river, and the personal or habitual consciousness to an eddy beneath the bank, which forever seeks to change its shape and draw in water from without, yet never wholly loses its identity.

In health there is a certain degree of co-ordination and mutual support between all the vast activities of the mind, binding them to the consciousness on the one hand and to the vital functions of the body on the other; and though these various activities are grouped in clusters which are more or less independent, just as in one stream there may be many eddies, yet no antagonism or interference takes place between them. The healthy man feels himself a consistent character, and can predict what he will do, not only as regards those new exigencies which require logical thought, but also as regards those which depend upon the promptings of all the deeper-lying and subconscious processes with which his mind is stocked. His reactions to the various problems which present themselves are as prompt as the conditions of the case permit, and the attention of his consciousness is at liberty to devote itself, unembarrassed, to the interest of each new question as it arises.

In neurasthenia, and still more in hysteria, this harmony of action, tending to the furtherance of single interests of the individual, one after another, is more or less deeply impaired. The patient's consciousness is no longer permitted to focus itself exclusively upon the main object of his attention, but unrelated ideas and emotions intrude themselves, to the detriment of his flow of thought, just as floating opacities in the vitreous humor of the eye drift over and obscure the field of vision.

I will not pursue this theoretical survey further. I only desire to call attention to the fact that these intrusive ideas and sensations lie partly or wholly outside of the patient's ordinary sphere of consciousness and will. Even when they recur so often as to form almost constant elements of his personal consciousness, the fact that they originated in deeper lying strata of the mind or have become secondarily rooted there makes it almost impossible for him *without special training* to make them objective, or to help himself much in ousting them through any logical process of thought. The patient is a puzzle to himself and his struggles often seem to carry him deeper into the mire. It is the physician's function to aid him in ridding himself of these disturbing elements of both his conscious and unconscious mental life, partly by surrounding him with influences which will address themselves directly to the subconscious strata of the mind where these morbid processes are going on; partly by teaching him to use his will, indirectly, in displacing them.

It is this notion of the possibility of an outsider's assuming to exert an influence over regions and processes of the patient's mind which he himself is wholly unable to reach and explore, that seems to many persons so foreign, so obscure, and so unreasonable, and yet it is a notion of fundamental importance for securing to the physician the necessary confidence for dealing with neurasthenic patients.

It is also very desirable that the physician should form an accurate physiological conception of the processes by which thoughts are made useful as therapeutic agents, so far as this is possible. A thought is the outcome of a physiological stimulus and becomes a stimulus in its turn, for good or evil.

If it is conceivable that by words or by other forms of adequate stimulus (for a word may be an adequate stimulus just as well as a blow) we can arouse, *within* the realm of consciousness, thoughts and sentiments — or, in physiological language, nerve currents — favorable to the physical and mental health, it is equally conceivable that, by similar stimuli, we should be able to arouse similar images or currents in the regions of the mind lying *outside* the ordinary realm of consciousness. In certain forms of hysteria, indeed, we sometimes have to deal with two definite personalities for each single patient; and even in the case of neurasthenia this is practically true, for the "moods" of the neurasthenic patient are such as to change his characteristics to a high degree. Though ordinarily critical, distrustful, and suspicious to a degree that he cannot control, yet there are times when these characteristics are laid almost wholly aside.

It is under the latter circumstances, that the most effective work is to be done in the way of introducing ideas or sentiments of hopefulness and self-confidence, or of familiarizing the patient with the image of himself freed from harassing thoughts and feelings, and with his nutritive processes in better train. It is, too, in the hope of eventually influencing these deeper strata of the mental life, which form such an important background for the habitual consciousness, that we should stand ready to repeat our encouragements over and over under the same or new forms, or to exert a thousand influences of indirect kinds, some one of which may be successful in planting these sentiments of hopefulness where they cannot easily be dislodged, and where they may act to counteract the emotions and processes adverse to health. The choice of such influences is apt to be determined by the instinct or experience of the physician. This must perhaps always be so; but I think it will be a gain, especially for those physicians in whom these instincts are not strongly developed, to systematize them, and to study the principles on which they rest.

(A) The principal means which have been used to *help the patient exert his own reasoning and will* in overcoming his disease are the following:

By demonstrating to him, with all the patience and

repetition that is necessary, something of the nature of his disease, the fact that his symptoms — his morbid fears, for example — do not necessarily entail the gloomy outlook which he fears, and that if he can change his point of view, can look on himself as capable of better things, and can learn to look in the right direction for the expected good, it will be seen. It is, of course, only now and then that this attempt succeeds; but the better hope is that, if our demonstration is really well thought out, and is presented again and again under different forms, some argument or word may make a relatively deep impression, and *if it happens to coincide with a wave of improvement*, will come to mind again as one of the re-enforcing associations of this latter state and give it a logical cast. In this way it often happens that the physician's logic gets credit which it does not strictly deserve; but nevertheless it does occasionally seem that an intelligent patient is led by a powerfully presented or thoroughly grounded argument to make a strong and successful effort to get the better of his own delusive reasoning.

Dr. Edward Cowles has exerted himself to develop this method, and has succeeded in several cases, even where a good deal of melancholic depression was already present.[2] It is unquestionably important, if not essential, for success that a definite and sufficiently logical plan of exposition should be followed. Even if this is not clearly understood by the patient in exactly the same sense as by the physician, the presentation can hardly fail to increase confidence in the physician for the thought and study which he has given the case. Usually the anxious patient is keen to detect some flaw in the reasoning, but where the emotional state is not too deep and the symptom is an isolated one, it is well known that success is more common. Abundant instances of this are on record, and a striking example is given by Dr. Prince in his interesting discussion of the "association neuroses" (the use of an artificial rose to cure a fancied imperative tendency to sneeze at the smell of roses).

A great deal is gained if the patient can be taught to really conceive of himself as capable of being a different person; for different he must be, as a rule, in habits of mind, temperament, and often even habits of daily life, if he is to make any material improvement. One reason that this is difficult is that the patient finds for the moment a positive relief in acting out his morbid instincts and indulging his morbid thoughts, just as persons with morbid impulses to repeat words or acts and the like, find for the instant a certain satisfaction in doing so, though it is a satisfaction which entails a new torment. There is a certain temporary relief to many persons in assuming the mental habits of a Mrs. Gummidge, but in the long run it is a drain upon the nervous strength.

It is interesting to note that persons who have been exposed to some powerful influence, such as a deep personal experience or some religious change of sentiment, and have thus had effected rapidly the sort of change in temperament which the physician tries to bring about slowly, are apt instinctively to show their own recognition of their new life by adopting simpler forms of dress or by changing their habits and associates, and, in the reverse sense, it may sometimes be possible to favor the mental change by adopting primarily some outward expression consonant with the desired order of things.

It is a matter of immense importance and often entirely possible, to deliberately adopt and persistently maintain the demeanor of cheerfulness and hopefulness. It is easier to act a new rôle in a new and appropriate dress. Prof. William James has dwelt upon this point in his studies on the nature of emotion.[3] It is for this reason, in part, that frequent changes of surroundings, if only for a short time, are often of such benefit to neurasthenic patients.

It must, however, be remembered that it is infinitely more difficult, and requires infinitely more pains and persistence to effect an alteration in character than an alteration in mood. *Cœlum, non animum, mutant, qui trans mare currunt.* The physician must distinguish between the cases that can really be helped in this way, and those which might even be made worse. The patients of the latter class, if they are really intelligent enough, can often do best by looking their difficulties clearly in the face and striking for a more radical improvement which shall be associated with the growth of character and will, and the founding of the really soundest and best habits of daily life.[4]

It is better, where the facts justify or can be expected to justify the assumption, that a patient should learn not to look on himself as an invalid, but, rather, as a person who is well, but who must have a shorter working day than some of his neighbors, and who realizes that he has his health at the price of certain sacrifices which he is ready to make.

Some neurasthenic patients suffer very much from a sense of disgrace at being ill with a condition of nervous weakness; and I cannot but think that this is partly due to the existence in the community at large of a barbarous sentiment of this sort like that which used to be held with regard to insanity. If the patient can be persuaded that he is no more responsible for an attack of neurasthenia than for an attack of gout, provided he is doing his best to get rid of it, and if in this way he can be led to take a somewhat objective interest in seeing what he can make of himself, an important point will have been gained.

A special cause of distress to many of these patients is the fear of insanity, to which they think their symptoms are tending. Fortunately, it usually lies in the power of the patient and his physician to make this fear a groundless one; and no effort tending to this end should be spared, especially in the early stages of a neurasthenia which is likely to become chronic. In this, as in every part of the treatment, it is essential to form powerful associations in the mind, which have a strong sense of hopefulness and cheerfulness as one of their elements; hopefulness associated with signs of improvement which the patient should be systematically taught to recognize; hopefulness associated with definite logical processes through which the patient has been taught to disprove his own morbid reasoning; and with active and engrossing occupation. Van Eeden says that he has

[3] See also Prof. Josiah Royce's very interesting analysis of the case of John Bunyan, in Philosophical Review, 1894.

[4] "In the Will work and acquire, and thou hast chained the wheel of Chance, and shalt sit hereafter out of fear from her rotations. A political victory, a rise of rents, the recovery of your sick or the return of your absent friend, or some other favorable event raises your spirits, and you think good days are preparing for you. Do not believe it. Nothing can bring you peace but yourself. Nothing can bring you peace but the triumph of principles." — *Emerson, Self-Reliance.*

found it of service to recommend to patients harassed with morbid ideas to study some foreign language and to repeat their lessons to themselves when alone, as a distraction from their thoughts; and the same writer speaks of the fact that the artist, William Blake, got rid of his visions by painting them, thus making them an object of objective interest. Others have similarly helped themselves by studying and describing their morbid fancies.

(B) Methods of influencing the patient's mental state *without the direct intervention of his own will.*

It is needless to point out that the most striking of these methods are those which have been discussed under the name of hypnotism. I should, however, be glad if I could show that the hypnotic methods used in practical therapeutics by the best men have nothing abhorrent in them, and are only a further development of various means of treatment familiar to every one.

These methods may be looked at from two points of view: first, as increasing the personal influence of the physician; second, as increasing the susceptibility of the patient.

Every one who deals with neurasthenic patients knows how much the *personal influence* of the physician counts for in their treatment; and knows, too, that the gain of this personal influence is not without its objectionable side. It furnishes opportunities to the charlatan as well as the conscientious physician; and it is a truism to say that the latter is under obligation to use the influence which he gets, solely for the benefit of the patient and for his best benefit. He should feel it his responsibility to leave the patient not only improved in health but with a stronger character, and so far as practicable free from a sense of dependence upon him. It is the duty of the physician, as Madame de Stäel said of the ideal legislator, to make himself unnecessary.

Besides the many and almost indescribable means at the physician's disposal for increasing his personal influence, there is one of some slight value which is secured to him by the growing habit of the physician's dispensing his own medicines, at least to a certain extent. It is not a good thing for a nervous patient to carry off a prescription which he can mull over and criticise at his leisure and perhaps get refilled or hand to his friends as if he were himself the doctor. The physician's medicine ought, logically, to be, like his advice, a part of his personal armamentarium, and if it brings him a little additional glamour in the eyes of the patient, there is gain for both, provided the doctor is an honest man.

More important than the therapeutic influences already alluded to, if only because more capable of systematization, are the means — to use a conventional phrase — of increasing the patient's *suggestibility* to the beneficial influences of every sort by which the physician seeks to surround him. In general, this is done either by taking advantage of states in which the consciousness is favorable to the particular influence and lends it its support, or else states in which the conscious attention is otherwise absorbed, or temporarily in abeyance. Under the latter circumstances an impression can sometimes be made upon the mind which may be so strong as to become a permanent working force, affecting nutrition on the one hand and modifying the current of thought on the other hand. The new influence gets into the chambers of the mind by the back door, but for that very reason is able to entrench itself the more strongly, because the owner of the house hardly realizes what the intruder is about until his presence has become so familiar that he passes for an assured member of the family. To use another simile which I have found very useful, let us suppose that we wish to drop a marble down through a funnel. So long as the funnel is kept in motion, the marble will roll round and round in the brim; bring it to rest and it will fall through. In the same way, if it be desired to drop an effective idea into the deeper strata of a patient's mind, his critical consciousness must first be shunted out, or the idea will be rolled about and torn to pieces in the cogwheels of his habitual and false logic.

It is well known that many healthy persons may be made, in an abstracted mood, to perform quite complex mental acts almost automatically, also that powerful impressions made on any one, especially in youth, may excite antipathies or prejudices which the reason, even years afterwards, is helpless to dislodge.

It is in this way that "fixed" ideas become such dominant forces in men's lives. Some of these fixed ideas are habitually present to consciousness, though even then they have their roots tenaciously intertwined with mental processes over which consciousness never had or has ceased to have authority.

In other cases, and especially with hysterical patients, the fixed ideas are known to consciousness only through the acts to which they prompt. If, under these circumstances, it be considered a misnomer to speak of these mental processes as "ideas," or as evidences of a "subliminal consciousness" (Myers), or of "unconscious cerebration" (Carpenter), at least it will be admitted that these words denote physiological processes occurring in the brain and leading to such and such results, and that for exciting such physiological processes, words falling on the ear, or any of the more subtle modes of human converse may be an adequate stimulus. In other words, there is nothing unreasonable in the notion that mental processes of which the patient is unconscious should be induced or modified by "verbal suggestion."

The working out of the methods for taking advantage of susceptible or "suggestible" moments for the implantation of ideas or initiating physiological processes favorable to mental and physical health, either with or without the conscious co-operation of the individual, has been carried on by educators, psychologists, irregular practitioners, and by regular physicians; by every one, in fact, with whom it has lain deeply to exert a strong influence over his fellows.

A large part of the study of these methods has been conducted wholly unsystematically, and often for selfish ends, but may still be psychologically of interest.

The physicians who have had the most success in the treatment of neurasthenic cases have gained it by working up special methods, which although dissimilar in detail have been from the very nature of the case similar in principle. Some of them have bent themselves to invent new ways of diverting their patients' morbid energies into channels of active work, or of keeping them under the healthy influence of an intelligent nurse, and prescribing with care the details of their daily life; while for a certain class of patients the plans worked with so much skill by Dr. Weir Mitchell, have been studied and utilized with profit by physicians to whom this method was congenial.

Putting aside the influences directed to the improvement of the nutrition, it may be said that all these methods have one feature in common.

Whether it is sought to make the patient realize that he can after all do some effective work, or learn to be cheerful, or learn to accept, temporarily, the physician's will for his own, it is always found advisable to place him under special and peculiar conditions to get the best effect. Either he is isolated, or he is put to bed, or he is kept under the new and carefully chosen influence of another individual. In other words, to use the terms of the day, it is sought to influence him in "suggestible" or susceptible moments of his life.

All those who have studied the literature of this subject are aware that not only the artificial but the natural sleep, or half-sleep, sometimes brings with it an increased receptivity of verbal suggestion. I do not know to what extent this has been utilized, but I was interested to find, one day, that an intelligent nurse was using this method, either following her own instincts or led by some tradition, for the sake of making a child sleep better.

It is, however, the modern students of hypnotism and hysteria and kindred subjects that have undoubtedly carried on these inquiries the most deeply and systematically. There is no doubt that the methods of the school of Nancy are invaluable for those who have to use them properly, and practically free from danger under the same conditions. The physician's personal influence over the patient is increased, but so far from this in itself tending necessarily to enslave the patient's will, it may be made, as in health, to strengthen his will and character if the physician's efforts are intelligently directed to this end.

There is, however, a strong prejudice in the minds of some of the best and soundest people in the community against the use of anything which goes under the name of hypnotism, as seeming to imply the reign of superstition and mysticism, and a falling off from the sound principles which underlie the best mental health. This prejudice is founded on a misconception, but it must be respected, and yet it must not be allowed to interfere with our giving such persons the full benefit of our skill any further than is necessary. Very often it is possible to secure the first degree of the hypnotic sleep, or enough increase in susceptibility to be useful, without mentioning the word hypnotism. If a patient comes to us already coached in hypnotic doctrines, it is often an excellent plan to talk it over with him further; and there are many cases where it is desirable to do this in any event. In general, however, it seems to me a mistake for the physician to assume that a patient can really understand so complex a subject unless when presented in the simplest way; and I think it is better for him to come down to the patient's level and to explain his intentions briefly and in popular language, than to use terms which may, for all he knows, carry mysterious or terrifying associations. All that is necessary is that the patient should give his full and intelligent co-operation to promoting the induction of quiet or sleep; and if he has confidence in his physician, it can often be made sufficiently clear to him that this is a suitable thing to do.

To illustrate my meaning more fully, I will give briefly the case of a lady who has been suffering for many years from a distressing nervous cough which attacked her on the occasion of every embarrassment, even the slightest. I persuaded myself very soon that no treatment but one of a psychical character would help her, and was ready, if it should prove necessary, to propose to her hypnotism, pure and simple. Before doing this, however, I determined to secure the quiet and suggestibility which often attends, or more strictly speaking, can be made to attend the use of static electricity. I told her that I was going to give her a treatment addressed to quieting the general mental irritability from which she suffered, and that at the same time her cough, which was a sort of nervous trick, would become less troublesome; that I wanted her to relax her muscles and her thoughts, and let herself sink into a state of restfulness, which would then stay with her through the day. The result was eminently satisfactory. She made in all ten visits, and before these were over her cough had become so much better that she considered it practically cured, while her general conditions likewise improved. The word hypnotism was never mentioned, and though I am not sure that she went actually into the stage of not being able to open the eyes, yet all the abstraction that I needed was obtained, and that without the necessity of explanations on my part, or of making her an adherent and perhaps prophet of hypnotism, which she would surely have misunderstood. I have treated many other patients in this same way with excellent effect, sometimes using more, sometimes less, in the way of verbal suggestion. I recall especially two cases of asthenopia of long standing, which were greatly benefited.

It often happens that patients fall actually asleep under the agreeable sensations and monotonous sounds attending the application; and although it may well be that for the best "suggestive" effect the operator must take special pains to keep the patient's mind in touch with his own during this process, yet there would seem to be no reason why this should not be done if necessary. On the other hand, the treatment often carries its own suggestion, and the necessity for the physician to intrude his own personality is largely obviated. I am myself in the habit of asking an assistant nurse to carry out the applications, so far as possible, and consider that if the patient is thus led to take a more matter-of-fact view of this process, it is so much the better, provided the desired end is gained.

In this way I have treated with good though not invariable success a number of cases of neurasthenia, and several cases of the milder forms of melancholia. How much the electricity in itself has contributed to the result, I do not feel able to say; but a little light may perhaps be thrown upon this point by some observations on temperature to which I shall refer in a moment. I do not vaunt this method as making hypnotism unnecessary, for both my experience and judgment would lead me to think that where it is a question of dealing with a serious case, requiring a high degree of personal influence or of suggestibility — suggestibility, that is, with special relation to the physician — more can be accomplished through the methods of Nancy, than in any other way, provided the physician is skilled in their use.

It is often said that neurasthenics are not hypnotizable, but the facts do not bear out this view, although success often implies more time and patience than most physicians can give. These statements are borne out by the elaborate statistics of Schrenck-Notzing based on the analysis of 228 cases treated

by a limited number of the best observers.[5] About 7.3 per cent. were shown to be non-influenceable; about 32 per cent. influenceable only in slight degree; nearly 61 per cent. susceptible of deeper degrees of influence. As regards the result, about 31.6 per cent. received but slight benefit or none; nearly 37 per cent. were considerably relieved; 31.6 per cent. were reported as cured.

The detailed histories illustrating the psychical treatment of the psychoses of this class which are given by Van Renterghem and Van Eeden[6] are full of interest, since they enable us to see the progress of the cases, their exact character, and force us to recognize that in some of them the treatment only reinforced the patient's efforts in his life-long struggle with an incurable malady.

The details of their treatment, which is by no means confined to the use of verbal suggestion, but are those of the broad-minded physician as well, are worthy of special note. To make up for the slight degree of induced suggestibility they sometimes continued the treatment through one or two hours, the patient lying quietly with closed eyes and being talked to from time to time in an appropriate manner. I cannot but refer in this connection to an important suggestion of Bernheim's, to the effect that a hypnotized patient is not a totally changed person, much less changed into a mere lump of clay, and that frequently it is necessary to address him with the same forms of argument that would have been used in his waking state. It is also important to remember Forel's caution, that the hypnotized patient is a keen mind-reader and may readily detect a false note in the physician's treatment. If he does not detect it to resent it, as he might do if appealed to with sentimental terms, or as a child, or an inferior person, and the like, then he may detect it and accept such terms as appropriate, to the injury of, we will say, his subliminal self-respect. It is not to be forgotten that the physician is a dual or complex person as well as the patient, and he owes it to the latter to have a sharp lookout on the workings of his own subconscious personalities, which are to be brought into such close contact with those of his subject It is this sort of thing rather than anything more gross, that seems to me to constitute the true danger of modern hypnotism. The physician's personal influence is heightened, and if it is not sound the patient may detect the fact to his own disadvantage, in spite of the verbal suggestion which is made to him.

The principal good effect to be looked for from the psychical treatment of neurasthenics is, by general acknowledgment, an improvement in hopefulness and the general emotional background of the thought and the relief of certain symptoms. The attempt has sometimes been made to go further than this, and, after patiently unravelling the web of false logic which the patient's fears have woven, and tracing back his fixed and morbid thoughts to their original source, to neutralize this primal mental conception with the aid of the hypnotic sleep.

It is well known to all students of the subject that Janet and Breuer and Freund have published remarkable cases of relief from fixed ideas in *hysteria*, obtained through this method; but I doubt whether we can in strictness admit that the same process is likely to occur with neurasthenic patients, whose mental machinery and its disorders are more complex than those of the hysteric. It is legitimate to make the attempt, and probable enough that the patient would be relieved, but in many cases a close critic might say that the patient had probably only lent himself to the belief that the cause of his unhappiness had been unearthed, with the half-whispered hope that he might thus be cured.

In the course of the treatments with static electricity I have been much interested in studying the changes of temperature which occurred, being led to do so through interest in the extended observations of like character made by Dr. W. J. Morton of New York.

Dr. Morton had found that the temperature of neurasthenic patients was generally subnormal, though sometimes above the normal, and that under an electrical treatment it usually swung, in either case, towards the normal line; and he was inclined to attribute the change to the tonic action of the electricity upon nutrition.[7]

I have observed the temperature in a limited number of cases, during applications of static electricity (breeze, with enjoined rest), and I have also studied the effects of a modified suspension treatment in cases of locomotor ataxia, of massage, and of spurious electrical application, the patient being placed in the chair as usual and enjoined to relax the muscles and close the eyes yet without being connected with the plates of the machine, which, however, were put in motion as usual.

The results were as follows: The temperature in a case of exophthalmic goitre, with nervousness and debility, was either unaffected, or, what was more common, rose from a few tenths of a degree to a degree, but on several occasions when no electricity was actually given the result was the same.

| | Temperature | | Pulse | |
|---|---|---|---|---|
| | Before. | After. | Before. | After. |
| March 11 | 98 | 99 | 150 | 154 (½ hour later, 140) |
| " 13 | 99 | 100 | 128 | 118 |
| " 15 (no elec.) | 99 | 99 | 128 | 128 |
| " 20 (no elec.) | 98 | 98 | 112 | 104 |

| " 12 | 99 | 101 | .. | .. |

In the case of a boy with a slight chronic chorea the figures were as follows:

| | Temperature | | Pulse | |
|---|---|---|---|---|
| | Before. | After. | Before. | After. |
| March 28 | 98.8 | 99.6 | 93 | 80 |
| April 1 (no elec.) | 99 | 99.4 | 78 | 76 |
| " 4 | 98.6 | 99.2 | 78 | 75 |
| " 8 | 99 | 99.2 | 80 | 78 |
| " 11 (no elec.) | 99 | 99 | 78 | 80 |

To judge from these two observations there would seem to be some doubt whether it is the action of the electricity in itself that causes the elevation of temperature, and not rather some more subtle influence on the nervous system, which can be exerted in various ways.

[5] Ein Beitrag zur Psychischen und Suggestiven Behandlung der Neurasthenie, 1894.

[6] Psycho-Therapie, Paris, 1894.

[7] Transactions of the Electro-Therapeutic Association, 1893.

For the sake of control I give a summary of the temperatures taken before and after the treatments by modified suspension in cases of tabes, partly at the Massachusetts General Hospital, partly at my private office. These observations led me to note, incidentally, the interesting fact that, occasionally, in tabetic patients, the temperature is regularly very low. In one case the highest (morning) temperature that I could get, during the period of observation, was 98.2° F., with five minutes' exposure of the thermometer in the mouth. Generally it ranged from 97° to 97.8°, and after one treatment it dropped to 96.5°. In another case the initial temperature (taken at about 10.30 A. M.) was on one occasion 96.4°; and that after treatment, 96.2°.

There was no regularity as to the direction in which the changes occurred, nor could it be said that, as Dr. Morton's observations seemed to indicate, the deviation was regularly towards the normal line. The amount of change varied from nothing to .11° F., but changes of .4° to .6° were common.

This is not the place to discuss the psychical treatment of tabes, and I will merely say in passing that it is to this influence that I have been inclined to attribute the favorable effect of the stretching treatment in several cases.

It is, I think, certain that just as patients with sclerosis and organic degenerations are liable to exhibit more or less tendency to neurasthenia and hysteria, so the same class of patients often have more power to counteract some at least of their symptoms than they are aware of or can voluntarily command.

I have recently had a patient, a young girl, with diffuse sclerosis of the spinal cord (verified by autopsy, after death from an intercurrent disease), whose power of getting about was very materially increased through the mental aid of a skilful treatment by Dr. Hamilton Osgood.

In conclusion, I wish to say a word about the "Mind Cure" and "Christian Science" movement, which seems for some reason to have found a safe anchorage in our community. Although, in general outline, this is only the re-echo of old histories, yet such movements get a special tone from the characteristics of the generation and community in which they occur; and I have been greatly interested in the observations which I have made during the past few years.

It has seemed to me noticeable that patients of a simple and impressionable and at the same time not critical disposition, may become more sober, serious, and independent, and far more likely than before to count as figures instead of ciphers in the world. If they are sincere, they are apt to become fanatical for their new doctrines though not necessarily intolerant of those of others. If their critical instinct is a little stronger they are likely to suspect that they have bartered a part of their mental independence for the sake of their recovery.

Another interesting fact is, that besides the improvement in spirits and hopefulness, and what might be called moral regeneration, there are often certain by-products, as one might say, of this treatment, which are noteworthy, especially because they are liable to appear under any treatment of analogous kind, even when not made the subject of verbal suggestion. Such are the relief of constipation and menstrual pain, and improvement in the general nutrition. It is also noteworthy that in many instances the whole treatment is carried on, not only without specific suggestion, but without even conversation of any kind between the patient and the operator. The two simply sit side by side for a sufficient length of time for the production of the required state of mind on the part of the patient, who then takes his leave without a word. A reasonable theory to account for the good effect of the treatment is, that the patient, whether he starts in a receptive mood or not, finds some day, perhaps through the operation of outside causes, that he is better, and at least suspects that the treatment is having its mysterious effect. The seeds of hopefulness and confidence which are thus implanted so regulate the subconscious forces of the mind that the gain becomes steady and progressive.

## HEAT PROSTRATION. AN ANALYSIS OF ONE HUNDRED CASES OCCURRING IN THIRTEEN CONSECUTIVE YEARS.[1]

BY CHARLES F. WITHINGTON, M.D.

The dangers arising from heat prostration affect most particularly that portion of the community which is obliged to work at all times, irrespective of weather and in exposed situations, — in other words, exactly the class of persons for whom a hospital is especially designed. Hence, probably, a larger proportion of the cases of sunstroke and heatstroke which occur in the city are brought to the City Hospital than of any other accident to which the community is liable. It has seemed, therefore, useful to collect some facts from the hospital records bearing upon insolation. The records of the various medical services have been examined from the year 1882 to 1894 inclusive, and all cases of heat prostration tabulated. These numbered a little over a hundred, but after rejecting a very few in which the evidence was not perfectly satisfactory as to the nature of the illness, or where the records were incomplete, there remained exactly one hundred well-marked cases of insolation upon which the following report is based.

As was, of course, to be expected, the male sex was affected in a vastly preponderating degree. There were 95 males and five females. The oldest patient was 70, and the youngest 19, the average age being about 30, and representing that of the most laborious portion of the community.

The time of day at which the attack occurred was deemed of sufficient interest to be noted, and it appears that most of the cases happened in the afternoon. Fifty-two are recorded as occurring after noon, as against 15 in the forenoon, three at noon, and one in the night. Two to three P. M. represents the most frequent hour of the day, as would be natural, after several hours of heat have overcome the resisting capacity of the organism.

The great variation in a number of cases of insolation in consecutive years is illustrated by the following table:

Cases by Years.

| | | | |
|---|---|---|---|
| 1882 | 4 | 1890 | 2 |
| 1883 | 8 | 1891 | 5 |
| 1884 | 8 | 1892 | 16 |
| 1885 | 3 | 1893 | 9 |
| 1886 | 2 | 1894 | 14 |
| 1887 | 19 | | 100 |
| 1888 | 9 | | |
| 1889 | 1 | | |

[1] This paper will appear in the Boston City Hospital Reports, Sixth Series.

The distribution of the cases as regards the date of their occurrence is shown by the following table, in which is incorporated also the meteorological facts of maximum and minimum thermometer, and the mean humidity. These data are furnished through the kindness of Mr. J. W. Smith, Local Forecast Officer at Boston, from the official records of the United States Weather Bureau:

| Date. | No. of Cases. | Maximum temperature. | Minimum temperature. | Mean relative humidity. |
|---|---|---|---|---|

From the foregoing table it is seen that the earliest date of any sun-stroke was May 10th, and the latest August 25th.

The following extracts from the Daily Journal kept at the Boston office of the Weather Bureau, are also contributed by Mr. Smith, and refer to dates which were particularly prolific in heat strokes:

September 5, 1884, "weather generally clear, and very hot; wind from west or south-west." July 2, 1887, "very hot and clear; wind west all day." June 13, 1892, "continued high temperature, very warm, but owing to the low humidity, between forty and fifty per cent. not so oppressive as otherwise would be." June 14, 1892, "slightly higher temperature and very hot. The extreme heat caused many cases of prostration and sun-strokes." July 25, 1892, "partly cloudy day, with very humid atmosphere and high temperature." July 26, 1892, "highest temperature recorded thus far this summer; much lower percentage of moisture in the air (forty-four per cent. at 3 P. M.)." July 27, 1892, "continued high temperature, less moisture in atmosphere than for several days past." June 6, 1893, "high temperature; numerous prostrations from heat."

The relative humidity, it should be said, is taken regularly but twice a day, so that a true mean is difficult to get at. Still, for our purposes the average answers very well.

In only 73 of the cases does the history show whether the heat-stroke was due to direct exposure to the sun or not. Of these, about two-thirds, or 51 cases, were direct, and 22 were indirect. In the former category were, naturally, many laborers upon the streets and in ditches and sewers. There were half-a-dozen teamsters, some of whom were stricken while on their wagons. One, it is worth noting, drove an ice cart. Hod-carriers, coal-heavers, peddlers, masons, carpenters, quarrymen, farmers, etc., made up most of the remainder. Of course, a number of the direct cases occurred in persons not working, but walking on the streets.

Among the indirect cases were three out of the five women. These were employed respectively as cook, worker in a steam laundry, and dish-washer in a saloon. Among the men no indoor occupation proved so liable to heat-strokes as work in sugar refineries, there being five cases among this class of workmen. Iron-foundry men, bakers, stokers, stablemen, and plasterers were also overcome by heat without direct exposure to the sun's rays. A night watchman was found unconscious in the morning in his factory, having had to make the rounds of the boiler and engine room, dry-house, etc., in some of which the temperature was known to have been on the night in question 93°.

The following table shows the maximum temperatures recorded while the patient was in the hospital, with the results as regards recovery for each degree of temperature:

| Temperature | | | | |
|---|---|---|---|---|
| 111 or above | 3 | deaths, | 0 | recoveries. |
| 110—111 | 4 | " | 0 | " |
| 109—110 | 6 | " | 6 | " |
| 108—109 | 6 | " | 5 | " |
| 107—108 | 3 | " | 5 | " |
| 106—107 | 1 | " | 4 | " |
| 105—106 | 1 | " | 3 | " |
| 104—105 | 0 | " | 5 | " |
| 103—104 | 2 | " | 3 | " |
| 102—103 | 0 | " | 3 | " |
| 101—102 | 0 | " | 1 | " |
| 100—101 | 0 | " | 6 | " |
| below 100 | 0 | " | 27 | " |

The highest temperature recorded in any patient was 111.5° by rectum. The highest temperature in any patient who survived was 109.5°. Both the patients who died having had a temperature of 103°–104°, probably had uremia, though there was undoubted evidence of insolation being the immediate cause of death. Probably some of the patients who are re-

corded as having a low temperature (100° or less) had had a considerably higher temperature which had begun to fall prior to their reception into the hospital.

As to the mortality in general, of the 100 cases, 28 died and 72 recovered. All of the deaths except the two complicated with uremia just referred to, occurred in cases with a temperature above 105°. Several of the patients were moribund when they entered.

Loss of consciousness was present in 84 of the cases; in 14 consciousness was not lost, and in two the record leaves the matter in doubt. In 20 of the 28 fatal cases the patient never regained consciousness after the initial stroke. The longest duration of such unconsciousness was thirty hours. In four or more a partial return of consciousness took place, and in the remaining three or four cases, consciousness fully returned, but not permanently.

The deaths, as a rule, took place within a few hours; but 11 of the 28 fatal cases lived twenty-four hours or more after the seizure. The longest survival was more than three days, and here the temperature had fallen, the patient had regained consciousness and was mending when the delirium returned. He had had a sunstroke two years previously.

The longest period of unconsciousness in a patient who recovered was thirty-six hours. Moreover, this person did not enter till the day after his seizure. So that the entire period of unconsciousness seems to have been two days and a half. Ten and fourteen hours of unconsciousness with ultimate recovery also occurred, but usually the favorable cases did not remain more than two to four hours without regaining their faculties.

Convulsions were a very frequent symptom. They are spoken of in 30 of the cases, and were present in at least 13 of the 28 fatal ones. They were tonic and clonic, sometimes local, again general. Universal rigidity and opisthotonos were at times present. Occasionally the convulsions were very violent. A curious spasmodic action which was seen in at least two of my own cases was the rapid darting out and withdrawal of the tongue. Unilateral spasm was occasionally observed. In a patient of Dr. Forster's there was noted "three minutes after death a slow bilateral rotary motion of the arms, beginning in the left and followed by the right. The upper arm was at right angles to body and hands were at shoulders, then both gradually swept down till hands were at umbilicus."

The reflexes were in many of the severer cases greatly diminished or abolished. The pupils were generally irresponsive to light; sometimes they were contracted, and sometimes dilated; often contracted at first, and later dilated; at times they were unequal.

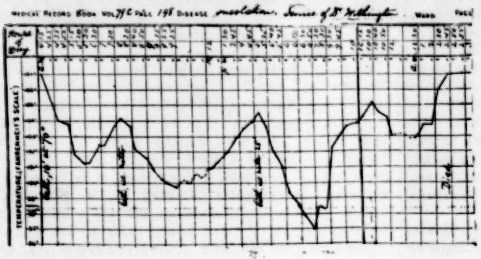
Relaxation of the sphincters and vomiting in unconscious patients were rather frequent.

Albumin was present in the urine in 22 cases, and was recorded as absent in 32. In about half the cases of albuminuria casts were also found. Whether the albumin and casts had been present before the sunstroke is not, of course, to be known, but in a few instances there is very little doubt that the patient was suffering from Bright's disease when he received the stroke.

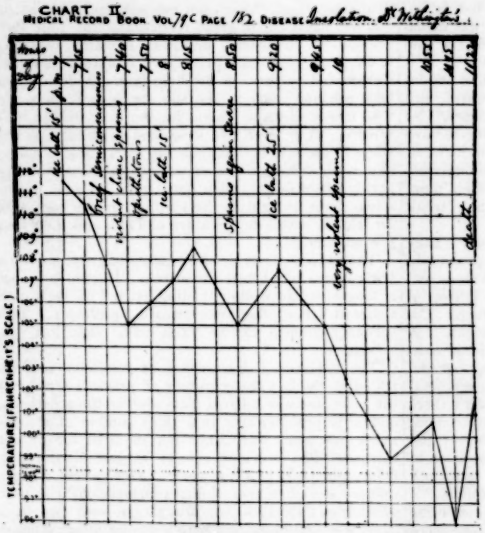
The habits of the patients regarding the use of alcohol, like other parts of the previous history are, as might be expected in patients brought in unconscious, often lacking in the records. Where this point is noted, alcoholic addiction was admitted in probably about the same proportion of cases in which it is found in the general run of hospital patients. In some cases, but not a large number, the individuals had been drinking considerable liquor just before the seizure, and in a few instances the heat-stroke brought on in its train symptoms of acute alcoholism. The excessive drinking of ice-water is also noted as having preceded the attack in certain cases.

In many of the most serious cases of heat prostration the patients had experienced prodromata of marked significance which should have warned them to protect themselves. For example, the woman already referred to, who washed dishes in a saloon, worked in a very hot place, and for three days had complained of headache, and a feeling of lassitude and weakness. A carpenter admitted to Dr. Shattuck's service, with a temperature of 109.4°, subsequently said that for two or three hours prior to his loss of consciousness, he had been getting weak, and that objects had looked blue to him. A laborer who was finally prostated, though not unconscious, said that he had had nausea and great restlessness for four days previously. Headache, faintness, sweating, vomiting, and cramps were other precursory symptoms too often disregarded by patients until too late. A farmer had been working much in the sun for several days, and was finally stricken down by the heat while in a theatre. A laborer felt weak and faint all one day while in the sun, but continued to work; the following day, while driving a cow on the street, began to stagger, but kept on for some time until he fell, unconscious; was brought to the hospital, in the service of Dr. Rotch, with a temperature of 111°, and died in a few minutes.

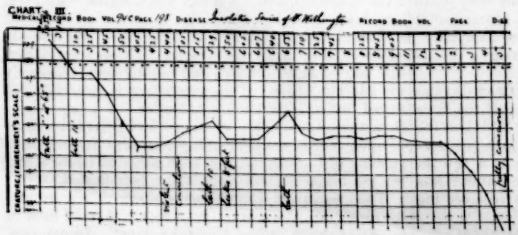
The sudden cessation of sweating was noticed by a few patients just before the attack. In one such case a 'longshoreman while "tending hatch" on deck of a vessel at 3 P. M., had been sweating profusely. This suddenly stopped and he "felt cold," then lost consciousness.



The tendency to recurrence of insolation is illustrated by the fact that a history of previous attacks of the same sort was elicited from nine of these patients, and it is probable that in a large number of the patients this point was either not inquired for or not learned. The previous attacks ranged all the way from eight years to a few weeks. One patient, a sugar refinery workman, was admitted unconscious with heat prostration July 12th, was discharged well two days later, was again admitted with a similar attack August 24th following, and again left the hospital "well" in two days.



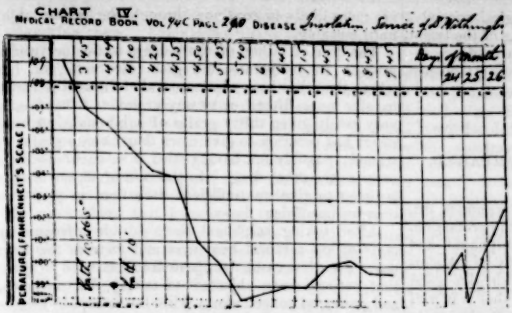
The treatment followed in most cases was the abstraction of heat by cold baths. These were generally started at 70° or 75°, and rapidly cooled down by the addition of ice. This proceeding is generally followed by a considerable reduction of temperature. Sometimes the chilling of the surface drives the blood in upon the viscera, and collapse occurs. In such cases rubbing of the surface, the application of heaters, and the exhibition of cardiac stimulants is indicated.



The ice-cap and rubbing with blocks of ice are useful supplements to the full cold bath. A cold bath in ice-water sheets proved a useful adjunct. In one very fleshy patient of Dr. Buckingham's who could not be got into the tub, the temperature was reduced by ice and the external use of ether.

In the earlier years after the introduction of the

antipyretic drugs — as antipyrine, etc. — they were used to some extent to combat high temperature in insolation, but this treatment has of late been generally abandoned in favor of the cold baths.



Rarely the temperature rose a degree or so while the patient was in the cold bath. But usually the fall was tolerably prompt. An examination of the thermometric records of the cases generally showed in most of the severer ones a secondary *rise* of temperature coming on a short time after the first fall, and usually not reaching as high a point as the original fever. Sometimes a third or even fourth rise of temperature would occur. The prognosis is grave in proportion to this tendency to subsequent recurrence of the fever. Renewals of the ice-bath sometimes caused a sudden drop of the temperature to a dangerously low figure, 96° or so. Here a copious use of heaters and other treatment against collapse as referred to above, is urgently indicated.

Of the after-effects experienced by patients following the permanent subsidence of the temperature the chief has been headache. This, with weakness and vertigo, persists, as is well known, sometimes for very long periods. Marked mental delusions were occasionally met with. In two cases mental excitement returned on the second day, and in another, violent delirium came back on the fifth day. This last patient had used alcohol to excess. An acute jaundice followed upon the heat-stroke in one or two patients.

The average period of retention in the hospital for the cases that recovered was exactly four days. That is, omitting one case which developed abscesses from the hypodermic injection of quinine, and was kept for five weeks.

Six of the fatal cases came to autopsy. The lesions found were chiefly subendocardial and pulmonary hemorrhages and hyperemia of the meninges. Abnormal fluidity of the blood was also noted.

From the clinical histories of insolation I subjoin a few charts to illustrate the graver types of the affection. Case I illustrates very well a typical fatal attack of sunstroke, and especially shows the recurrent failures of the heat-regulating mechanism to maintain itself after the temperature has been reduced by the cold baths. The patient, a laborer, left work at 3 P. M. on July 27, 1892, saying that he did not feel well. He went to his room, and at 7 P. M. was found unconscious. He remained thus all night, and as he seemed to be getting worse, he was brought to the hospital by the police ambulance, arriving at 4.15 A. M. He entered unconscious, and never recovered his senses more than enough to swallow a little milk. Convulsions were clonic and tonic and frequently recurrent. The chart shows three successive exacerbations of high temperature, and it is to be noticed that the patient finally died with the same temperature, 107°, that he had on entrance. It is further remarkable that the thermometer continued to show per rectum, at five-minute intervals for fifteen minutes after death, the same temperature of 107°.

II. A second case, which occurred nearly simultaneously with the foregoing, July 26, 1892, with the thermometer at 96°, but with a relatively low humidity (44 per cent. at 3 P. M.), showed the phenomenal temperature of 111.5° (rectum) and, as was to be expected, resulted fatally. Its chief features are shown by the accompanying chart, in which the vertical lines represent intervals of about fifteen minutes.

## Clinical Department.

### THREE CASES OF HEREDITARY RUMINATION.

BY EDWARD C. RUNGE, M.D.,
*Instructor in Physiology and Assistant Clinician to the Clinic of Nervous Diseases of the St. Louis Medical College, Medical Department of Washington University, St. Louis, Mo.*

CASES of human rumination are not very numerous, or, to be more accurate, do not often come under the eye of an observer. But cases in which hereditary transmission plays a part, are still rarer; from this point of view, the following may prove of interest.

Having read a report of a case of merycism, which I presented on April 16, 1894, to the Academy of Science of St. Louis, a gentleman of high scientific repute volunteered the confession of being a victim to the same habit. He is the picture of vigorous manhood, and has been enjoying excellent health all his life. The only vulnerable spots in his physical make-up are a furred tongue and somewhat flatulent bowels, which defects are readily explained by good eating and a comfortable life spent to a great extent over books and the microscope. He has been ruminating for a long time — to use his own words, "for ten or more years, probably much longer." This chronological uncertainty goes to show that the habit developed insidiously, without any evident exciting cause. To prove the utter unconsciousness of the process I cannot do better than quote from a note written in answer to a series of questions: "Breathing and our commoner performances, you know, are not the subject of very close observation, so that my answers are not as full as I would like them to be." The food stuffs that require repeated mastication, before following their natural downward course, are "any coarser particles — lettuce, potato, stringy asparagus, gristly meat, etc." The act occurs at any time after the meal, usually early, but occasionally as much as five or six hours after; when that late, the food is distinctly acid, otherwise it is possessed of its natural flavor. Mr. —— informed me that his father has had the habit of regurgitating coarse particles for many years, but that he ejected them without remastication. The latter complained of "heart-burn" at times, but this and the regurgitation were not coincident; his digestion was usually good. The father does not know of any other *mérycole* in the family. Some little time ago, my informant related to me that his boy, seven years old, had developed the ruminating habit, which was first noticed during a recent trans-Atlantic voyage. The child is apparently in perfect health. There is not a suspicion of hysteria, neurasthenia or any other neuropathic disorder in the entire family.

This is a most striking illustration of "hereditary" rumination, occurring as it does in three consecutive generations. The fact that the old man persistently refused to subject the regurgitated particles to repeated mastication, does not absolve him from being considered a *mérycole*. The involuntary phase of the process is as clearly manifest in his case as it is in his son's and grandson's. The prompt response of the sensitive gastric mucosa to mechanical stimulation by coarse food particles, the retroperistalsis set up, unaided by any effort on the part of the extrinsic abdominal muscles, and the yielding of the cardiac sphincter, all these occurring without a trace of nausea, and, lastly, the process ceasing to recur whenever the food reaches the proper consistency — these are the requisite elements that go to make up a case of genuine human rumination.

By his refusal to remasticate and thus render available the regurgitated food, the grandfather simply proved himself to be possessed of a smaller power of adaptation to changed conditions. He was fortunate in having been able to ingest sufficient food in such a shape as not to require any further mastication. If not for this, he would have shared the lot of Sauvage's *mérycole* who, yielding to the importunities of his spiritual adviser, ejected every food particle as soon as regurgitated, and in two weeks developed an alarming degree of emaciation, from which he did not recover until he returned to his possibly sacrilegious, but to him evidently natural habit.

While at work upon the first case of merycism, I subjected the patient's stomach to quite an extensive chemical analysis, following the course laid out by Alt, Juergensen, Boas and Sievers, who sought to explain the etiology of this phenomenon in some abnormalities of the secretory function of the stomach. The result of my examination was absolutely negative, and I candidly admit that I had expected just such a result. I still hold that the phenomenon of human rumination, if genuine, cannot possibly be caused by any deficiencies of gastric function, whether secretory or motile; to call it a "neurosis" shelves the difficulty but does not overcome it.

The three cases reported in this paper serve me as further proof that we must penetrate deeply into the mysteries of the laws of evolution in order to find a satisfactory explanation for this curious phenomenon. Human rumination, as I said on a former occasion, is

not a pathological entity, but a physiological anomaly, most probably produced by an awakening of the latent tendency to revert to ancestral types, a tendency inherent in all living organisms, and too well established to be refused most serious consideration.

## SULPHONAL AND TRIONAL COMPARED.

BY S. G. WEBBER, M.D., BOSTON.

During the last few years several hypnotics, differing in value, have been introduced to the profession. Among the drugs of this class two, sulphonal and trional, deserve especial favor; and it may be interesting briefly to compare them, as they both give good results, yet differ so much in their effect that it is well to know to what class of patients each is the more suitable.

Sulphonal is sparingly soluble in cold water, and is slow in its action. Sometimes as long as two or three hours are required for it to induce sleep. So slow is it at times that patients become impatient waiting for its effect, hence it is better to give it in the evening a while before bedtime. I have sometimes thought that the slowness of its action interfered with the induction of sleep, the patient becoming so nervous waiting for sleep that he was thoroughly aroused. The effect of a full dose, however, continues long; and it will often produce sleep the second night, and in a few cases even the third.

Trional is much more soluble. It produces sleep much more quickly, within a few minutes. In one case the drug was taken before preparing for bed, and its effect was felt so soon that it was an effort for him to get into bed. Its action is less prolonged than that of sulphonal. I have never known it to produce sleep on the second night as markedly as sulphonal, though patients may sleep well the night after taking it, but not from its direct effect.

The day after taking sulphonal there may be great drowsiness during the day. This is less likely to occur after a dose of trional, and if it does is much less intense.

In consequence of the more rapid action of trional, some patients much prefer it to the more slowly acting sulphonal. This is especially true of those who have difficulty in getting to sleep when they first go to bed. Those who suffer from this form of insomnia become impatient at their inability to sleep, and each minute finds them more restless; indeed, it is in part owing to this restless nervousness that they are unable to get to sleep, and for this reason they are desirous of seeing an early result from any medicine they take. To such patients it may be well to give trional.

Another class of patients have no difficulty in going to sleep when they first go to bed; but they wake in a short time and lie awake two, three or four hours, or may have no more sleep that night. To this class sulphonal is the better drug, as it does not interfere with the first early sleep of the night, and acts later so that the patient does not wake at midnight as usual.

The effects of trional do not continue so long towards morning as sulphonal. It gives good refreshing sleep for four or five hours, or perhaps six; then the patient wakes and does not sleep again. In such cases it is possible that the next time a larger dose will produce a longer sleep. The effects of sulphonal are more likely to continue through the whole night until morning.

The dose of either of these drugs is ten or twenty grains. In many cases ten grains are sufficient, but where there has been obstinate wakefulness it is better to give more, fifteen or twenty grains. I have only very rarely given thirty grains of sulphonal. I have never had occasion to give more than twenty grains of trional; possibly not having tried it in such obstinate cases as the other drug. In the case of either drug it is better to give one sufficient dose than to give two or more insufficient doses.

After taking sulphonal there is not infrequently more or less cerebral heaviness and distress the next day. In a few cases the discomfort has been so great that patients have objected to taking the medicine, and preferred to get along with less sleep. I have found much less of this unpleasant effect after trional. One patient, who refused to take sulphonal on account of this after-effect, had little or no discomfort after a dose of trional.

After fifteen or even ten grain doses of trional, I have known slight vertigo or dizziness to be felt before sleep was induced, if the patient rose from bed, lying down caused this to cease; but for a short time it was somewhat distressing. I do not remember this after the ingestion of sulphonal. It may be well, therefore, to warn some patients not to rise after taking trional, to wait until fully ready for the night before taking it, and then to stay in bed without getting up so as to avoid this unpleasant experience.

Sulphonal may be given in small doses, not more than five grains, to quiet restlessness in neurasthenia, hysteria and mania; given three times a day and, if necessary, during the night, it will often have a most soothing effect. I have not tried trional in this way, but should not expect such an effect, as it acts so much more quickly and its action it so much less lasting.

It will be readily seen from this comparison which of these two drugs to choose in combating insomnia; but it must be remembered that neither is a certain cure for this distressing symptom, and that the treatment must be directed to the patient's condition and not simply to the symptom insomnia.

# Reports of Societies.

## BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. G. MUMFORD, SECRETARY.

Regular Meeting, Monday, March 4, 1895, the President, Dr. C. J. Blake, in the chair.

Dr. J. J. Putnam read a paper on

### PSYCHICAL TREATMENT OF NEURASTHENIA.[1]

William James: I did not come here prepared to say anything, nor have I anything that I could say before such an assemblage as this. All I know of the subject is derived from books, but the facts which these books contain seem to me to form a body of phenomena which certainly impresses me, and I have been much pleased and interested to see that Dr. Putnam has taken them up seriously. It would seem if these are a natural class of phenomena that they must

[1] See page 505 of the Journal.

become more numerous as men become interested in observing them. I think that there is a considerable future for this mode of treatment.

Dr. Osgood: I have been very glad to hear this paper, because it seems to me it is time for some one to show us that for some unexplained reason the mind is neglected by physicians. By any form of treatment neurasthenia is not successfully treated unless means are used to withdraw the mind of the patient from his physical being and allow the functions of his body to return to their natural and automatic action. In cases where that is not done almost any form of treatment of this disease is liable to fail. Neurasthenia, of course, is accompanied by a weak and flabby body, by functional languor, absence of good sleep, appetite *nil;* but undoubtedly the root of the trouble is in the mind of the patient. To neglect that and treat physical symptoms alone, seems to me like eating nut-shells and throwing away the kernels. My own experience, as you know, for a number of years has dealt largely with suggestion. Hypnotism is a word which I wish might be banished from the language. About it cluster the misunderstanding and prejudices which so misrepresent the suggestive treatment. Hypnotism was Charcot's pathological and hurtful method of producing sleep. Whereas, a therapeutic sleep produced by gentle verbal methods very rarely fails to benefit the patient. In these five or six years, during which I have been using this treatment, of course I have had very many cases of neurasthenia, and it has been my good fortune to relieve, within a comparatively short space of time, a good many cases which had run the gamut of all drugs and other forms of treatment. It may be thought that I am an enthusiast in the use of suggestive treatment. That is not true. I have made a very thorough study of it, not merely in reading. Since I began to use suggestion I have kept myself practically familiar with the work of the leading men abroad who apply it, and am simply a convert and not an enthusiast. I have simply reached the conclusion that this is a remedy which in proper cases is of great value. A case of neurasthenia may not always be helped by this form of sleep, because all patients are not susceptible.

What this treatment directly does, it seems to me, is that an awakened will arouses an unawakened will. The treatment in my opinion should not always be confined simply to suggestions, for, medical remedies frequently aid suggestion, and I have also discovered, and it is a matter of great interest to me, that medicines, tonics like digitalis and iron, which are indicated and have failed to accomplish any good without the use of suggestion, under the use of the suggestion will be useful, and immediately produce their strongest effects. I must confess that I have been surprised during these years that more physicians have not made use of this treatment, because in susceptible cases it is rapid in its action, and it is more direct where it does act than any other form of treatment except surgery. If applied in the proper way it is absolutely free from danger, whatever may be said to the contrary. It is just as necessary to know how to apply suggestion as to know how to pass the catheter or how to use electricity; and it is simply the abuse of the treatment, the causation of hallucinations and that sort of thing which has brought reproach upon this method of sleep. No fair-minded man would think of taking advantage of his patient's mind, when it was in a deep sleep, beyond the actual needs of that patient's organism, any more than he would of stimulating his patient with whiskey beyond that patient's need in order to amuse himself with the drunken antics of his subject. Van Renterghem and Van Eeden came out in print some years ago very decidedly in a plea that all physicians who use the treatment should confine themselves wholly and strictly to the mental and physical needs of the patient. I believe that if physicians would only put themselves in the way of seeing suggestion applied, that their experience would be that of Bernheim, than whom there was never a greater sceptic, until he was dragged into the school of Liebault and forced to acknowledge the benefit of the treatment which he then began to use himself with results with which you are all familiar.

Dr. Prince: I think we all ought to feel very much obliged to Dr. Putnam for taking the bull by the horns and presenting this subject to us in such a satisfactory way, saying boldly what many of us have been thinking for some time, and formulating in a precise way what many of us have thought, but perhaps have not felt like proclaiming. That the mind has a deleterious influence upon the body I do not suppose any of us would pretend to contradict; and that in neurasthenia this influence is one of the strongest and most active factors, I think is a fact that impresses itself upon a physician the more he has to deal with this class of cases. Dr. Putnam has said that all those who have been most successful in the treatment of this disease have usually had special treatments of their own, but there has generally been a common principle running through all these treatments. I think if these treatments are carefully analyzed it will be found that there is one factor that is common in them all, namely, the psychical element. When I first started in practice I thought that given a case of neurasthenia, all we had to do was to make fat and blood, give the patient rest, build up the nutrition, and as we saw the fat and blood increase the symptoms would disappear. I soon found that this was a mistake. Another element was wanting, and that element I believe to be the psychical element. It is this element which is present in what is so strongly insisted on by Weir Mitchell and others, namely, taking the patient away from home. The psychical impression produced by isolation is complex in its action but effective. I have on more than one occasion attempted to treat a patient at home, and I think I may say in most cases where the neurasthenia has been of any gravity I have been unsuccessful. Charcot recognized this fact. I was fortunate enough to see Charcot a few months before he died. He conversed with me about this treatment. He said it is not necessary to feed them up and make them fatter, but to take them away from their homes. I said: "Dr. Charcot, I think there is one thing you forget. You forget the good big dose of Dr. Charcot you give them every time you see them." And that is another fact — the influence of the personality of the physician. That is a fact the physician himself cannot personally recognize. Those physicians who have been most successful in the treatment of neurasthenia do not, I think, fully realize how much of their success is due to the influence of themselves upon the patient. It is also a fact, I think, that many cases of neurasthenia in which we cannot trace the connection between the

mind and body nevertheless are really the result of a morbid psychical influence. I will cite one case illustrative of this, because it is a very striking one. I had a patient who was a typical case of neurasthenia. She was below weight, anemic, and had very bad digestion; had got into a condition where she took almost nothing in the way of food; had every kind of symptom referable to all parts of the body; and had been a nervous invalid some eight years. She had been under a number of physicians, and treated by all without success. I attempted to treat her by the Weir Mitchell method in her home. I recognized the fact, as I thought, that though she was debilitated, she was the subject of a large number of symptoms grafted upon her condition by mere process of habit. She was fattened up, and she weighed more, her digestion improved, and in many respects she was a great deal better; but when she attempted to resume her occupations she immediately broke down and largely went back into her old ways. I went to Europe at this time, and she consulted a Christian Scientist. In the course of two weeks she was cured, and is well to this day. There, undoubtedly was a case in which the symptoms were entirely due to the influence of mind on the body, and cured by a psychical process, although I could not see the connection between the two. There is much else I would like to say on the pathology of these affections, especially on the relation of the substrata of consciousness to bodily processes; but it is late and I won't take up the time.

DR. WEBBER: I have been very happy to hear this paper. I do not wish to take up time in adding anything to what has been said. I think about all the points have been touched upon; but I think, as has been remarked, that the mental influence was used a good many years ago, and that the success of many of the old practitioners was due to their personal influence upon their patients, not simply cases of nervous disease, cases of neurasthenia, but ordinary cases of sickness. It is an element which comes in play and is of very great use, that the patient's mind should be turned upon a cure, and that he should be reassured continually by the physician as much as a physician can honestly assure a patient that he is to get well; and I think it is the hopefulness and cheerfulness of the physicians, not only in former times, but now in general practice, which has added a great deal to their success. A doctor who is not hopeful, cheerful, cannot keep his patient's spirits up, is much less likely to be successful either in general practice or in treating these cases of neurasthenic patients. One reason for taking patients away from home is not only to get them away from the family and surroundings, but that they may come into more direct and personal relations with the physician. A neurasthenic patient at home thinks that the physician who calls upon her twice a day or once a day is making unnecessary calls. Often a patient thinks that a call every two or three or four days is as much as is needed, and the patient and friends become impatient because the physician makes so many calls. If the patient is taken away from home and put in a sanitarium, the physician sees that patient every day or twice a day, and keeps up a constant mental influence and exercises continually this influence instead of exerting it remittently; and the result is very much better. Suggestion plays an important part in helping towards recovery. I am glad that Dr. Putnam touched upon gymnastics. Graduated gymnastics is of very great importance; and breathing exercises, I should add, as being of very great value. When the patient is taught to breathe properly and take deep breaths, it is soothing and quieting. There must be more or less relaxation of other muscles besides those of respiration, so that the patient is in a more or less receptive condition, and I am not sure but it aids in suggestion. I should like to mention one case showing the power that the mind had over a patient. Some fourteen years ago a patient was under my care who had got into such a mental state that one drop of the tincture of belladonna produced dryness of the throat, one drop of tincture of nux vomica produced relaxation of the bowels, and two or three grains of bromide of potassium produced quiet and sleep; she had come to learn the physiological effect of the drugs. By using a little mystery, and giving the medicine to her masked, and by gradually working upon her mind, she got out of that. She thought that the little pills I took to her had a wonderful effect. There was really no medicine in the pills. The whole influence was purely mental in that case.

DR. PUTNAM: I have practically nothing more to say. In one sense, these special movements such as the Mind Cure are, as Dr. Folsom has said, only repetitions of many similar movements in the past, and the same might be said of other methods of using psychical influence. Nevertheless, each such event will always be instructive, both psychologically and practically, and is sure to have a character of its own, corresponding to that of the particular generation and community in the midst of which it occurs. My main object is to insist that physicians who are using their personal influence and manipulating the patient's mind for therapeutic ends, should not do so blindly and in simple reliance on their instincts, but should increase the scientific value of their work by systematizing their own methods and by studying in detail the methods of others.

## AMERICAN MEDICAL ASSOCIATION.

FORTY-SIXTH ANNUAL MEETING, BALTIMORE, MD., MAY 7–10, 1895.

(Continued from No. 20, p. 497.)

### SECTION ON SURGERY. — FIRST DAY.

THE Section was called to order and opened by the Chairman DR. JOSEPH RANSOHOFF, of Cincinnati, O., who in lieu of an address read a paper entitled

### CONCERNING STONE IN THE KIDNEY AND ITS OPERATIVE TREATMENT.

Clearness in the diagnosis and skill in the operative treatment of surgical diseases of the kidney are among the conquests of the closing decades of our century, but there still remain many problems pertaining to the diagnosis and treatment of primary stone in the kidney.

Stone in the kidney is not a rare affection, yet in the majority of cases found at autopsies, no tangible symptoms were developed during life. On the other hand, no other affection of the kidney is so often erroneously supposed to be present as stone. In seven cases of nephrotomy, by the author, for stone, the search was fruitless in two instances, yet all the symptoms were present. The presence or absence of crys-

tals in or from the urine is not a reliable diagnostic point. Far more important is the presence of red blood-discs at every examination, and especially so when associated with acid pyuria.

The cystoscope is very valuable as an aid in diagnosis, for with it we can eliminate vesical disease as well as locate by means of the ureters the kidney affected.

Nephro-lithotomies, as in hernia, may be divided into those of choice and necessity. In the unobstructed we may choose the time for operative interference; in the strangulated, delay means death.

The choice of operation must be between simple incision, and extirpation or partial resection of the kidney. Large size, confirmation and multiplicity of the calculus should not weigh in favor of nephrectomy, since with the longitudinal incision along the renal convexity ample room for manipulation can be obtained. Incision along the convexity is least likely to wound the larger vessels and the hemorrhage is parenchymatous, and may be reduced to a minimum by temporary pressure. Stone in the pelvis of the kidney should, if possible, be removed through an incision in the cortex. The concluding act of every operation upon the kidney should be fixation in its normal position.

In conclusion the following theses are presented for consideration:

(1) Absolute diagnosis of stone cannot be made.

(2) Nephro-lithotomies must be divided into those of choice and necessity. In anuria and profuse hematuria delay is fatal.

(3) Pyuria and hematuria, as evidences of beginning destructive changes, are positive indications for operative exploration.

(4) The oblique incision is preferred for the ease with which it permits the exploration of the entire kidney.

(5) Acupuncture is not to be relied upon.

(6) Incision should be made along the convex border, and only when the circulation is controlled by digital compression.

(7) Incisions into the pelvis for exploration and for removal of a stone are to be avoided.

(8) Primary nephrectomy for stone should be reserved for extreme cases.

(9) Primary union by suture, where feasible, makes nephro-lithotomy an ideal operation.

(10) Tight packing of the kidney wound and perirenal space endangers the nerve-supply of the colon.

(11) Nephrorraphy should form the closing act of every operation which has seriously disturbed the relations of the kidney.

### AERO-URETHROSCOPY

was the title of a paper read by Dr. William K. Otis, of New York City.

Little, if any, change has been made in urethroscopic tubes since the invention of the original illuminating apparatus. In 1892 the first single instrument combining the source of illumination with the air apparatus was made.

This instrument is heavy and cumbersome, and the distance between the glass surface of the diaphragm and the meatus is over two inches and a quarter. In making applications the diaphragm must be removed, laid aside and replaced, making an annoying break in the rhythm of the operation. The illumination from a concave mirror is inferior to that from a plano-convex lens.

In the author's instrument the diaphragm is arranged to swing on a pivot, and urethral tubes of any length or calibre may be used. The claimed advantages are:

(1) Ready access to the urethral field for the purpose of making local applications under the direct control of the light.

(2) Minimum distance between the eye and the urethral mucous membrane, hence a better and clearer view of the field.

(3) Extreme lightness.

(4) Simplicity of construction and moderate cost.

There is difficulty in obtaining a thorough appreciation of the morbid conditions present in the many obscure cases which present, where the urethra is implicated. Despite its many drawbacks, this instrument furnishes us an aid to diagnosis which no urethroscopist of the present day can afford to ignore.

### THE VALUE OF URETHROSCOPY IN CHRONIC URETHRITIS, WITH DEMONSTRATIONS OF THE NITZE-OBERLAENDER, CASPER, AND POSNER URETHROSCOPES AND OTHER URETHRAL INSTRUMENTS

was the title of a paper by Dr. Ferd. C. Valentine, of New York. This paper was practically a demonstration of instruments.

The Posner Urethroscope is a prolongation of the meatoscope without the obturator. It is made in two forms: one with the tube vertically cut off, the other terminating obliquely. The illumination is thrown in at the top funnel.

The Casper is more extensive. The tubes are metal and longer than the Posner and have an obturator at the visual end of the rim, with an arrangement of condensors and prism by which the electric light is reflected into the urethra. This instrument requires much experience in its use to be of value.

In the Nitze-Oberlaender the urethral tubes have a light-carrier inserted, by which means the light is placed at the point to be examined. Two small tubes carry a current of water around the light to protect the urethra from undue heat.

Cystoscopy has great value. By it we not only eliminate the bladder in doubtful cases, but we are also enabled to examine the mouths of the ureters and find, almost to a certainty, which kidney is affected; and by its aid we can catheterize the kidneys and get the urine uncontaminated by the bladder.

Dr. Otis considered the external light better than one placed within the urethra. The internal light required a cumbersome, complicated and expensive apparatus for the purpose of protecting the urethra from the heat of the light. With the aero-urethroscope you get all the light necessary.

Dr. Deever, of Pennsylvania, thought it almost impossible to be absolutely correct regarding the diagnosis of renal stone, and that the presence of red blood-discs in consecutive examinations of urine was of the greatest importance. He believed the oblique incision best and that it should be a posterior operation. He believed the disturbance to the colon by the packing was due to the pressure on the bowel itself, which obstructed its lumen and was not due to pressure upon the nerves.

He regarded the urethroscope more as a diagnostic instrument than one adapted to treatment.

Dr. Valentine thought that the inflation of the urethra with air obliterated the striæ and distorted the picture.

Dr. Otis stated that while air distention did distort the urethral membrane, by turning the diaphragm you could allow the air to escape and get the normal picture.

Dr. Homer Gage, of Worcester, Mass., read a paper on

MOVABLE KIDNEY.

He cited a case of a woman who had been operated upon the right side for this affection, and who shortly afterwards developed the same condition on the left side. Just before the operation, while lifting a stove she felt something give way on the left side. Three silk sutures were used in this case, and after two years there has been no recurrence. The only symptom this patient had was local pain.

Another of his cases had a train of symptoms along with the pain. In December he operated, and used six carbolized sutures, but did not get firm hold upon the kidney. She was free from pain until the following April, when the symptoms returned. The second operation was performed in December. He split the capsule on the outer border, and passed five sutures through the fascia. The pain again returning, she entered the hospital for removal of the kidney. Upon exposing the kidney adhesions were plainly visible, and its apparent mobility was due to the relaxed and flabby condition of the tissues. Since removing the kidney she has remained well.

Case I was interesting as a double affection and absence of accompanying symptoms; and where this absence of complicating symptoms exists the success of the operation is greater. Case II had all the complicating symptoms.

W. E. B. Davis, M.D., of Birmingham, Ala., also presented a paper on "Movable Kidney," which was read by title only.

Dr. Wyman, of Detroit, thought sutures should always be passed through the kidney substance itself. He also thought the extreme laxity of the peritoneum was responsible for failure of fixation. The peritoneum forming the natural support of the kidney, it should be drawn back into the wound and sutured there.

Dr. Weeks, of Portland, Me., uses silk sutures, passing them through the substance of the kidney, capsule and muscular tissue and fastening to the posterior part of the incision.

The paper was further discussed by Drs. Fergusson of New York, Willard of Philadelphia, Robbins of California, Fenger of Chicago, and Davis of Alabama.

THE RADICAL CURE OF HYDROCELE,

a paper by Dr. D. C. Hawley, of Burlington, Vt.

The only known method of absolute cure is the complete obliteration of the tunica vaginalis. Injection with iodine is painful, causes great swelling, confines the patient to his bed from three to five days; and three to four weeks elapse before a complete cure is obtained. Carbolic, while being less painful, requires the same length of time.

Dr. Hawley's method is to make an incision two inches in length along the anterior surface of the tunica, allowing the fluid to escape. The sack is irrigated, and its interior irritated by rubbing with the finger-tips. It is then packed with iodoform gauze. The edges of the tunica are stitched to the skin with black silk sutures and the patient kept in bed. The next day the gauze is removed, and strips of adhesive plaster applied around the scrotum causing equal pressure, and a light dressing of gauze is applied. In four or five days the sutures should be removed; should a sinus exist, it should be treated upon general principles. In from six to twelve days the wound is entirely healed. Its advantages are shorter duration of treatment, probability of radical cure in every case, and the ability to inspect the condition of the testicle. General anesthesia is unnecessary, as the operation is done under cocaine.

Dr. Maclean said, of all the various plans brought forward, he knew of none giving better results than injection with iodine. He used the strong, and in some cases Churchill's tincture of iodine. The patient should stand up, a large trocar should be plunged into the sack, and every drop of fluid pressed out before he injected two drachms of the strong tincture. The scrotum should be violently shaken immediately after withdrawing the canula. He has always allowed his patients to go about their business, and did not confine them to bed nor the hospital. He had never failed by this plan except in one instance, where there was an enormous double hydrocele with complications.

Drs. Gaston, of Atlanta, and Vance and Rodman, of Kentucky, endorsed Dr. Maclean's plan.

SECTION ON SURGERY. — SECOND DAY.

WHAT ADVANCE HAS BEEN MADE IN THE SURGICAL TREATMENT OF HERNIA?

This paper, by Dr. W. B. DeGarmo, of New York, reviewed the various methods of operation for the past twenty years.

Of all the various methods he thought that of Bassini was the best. He believed in opening up the entire canal and removing everything, including the fat, which if left in acted as a wedge and reopened the canal. The sooner surgeons recognized the sack as a foreign body and completely obliterated it, the better the results would be. For suturing he thought kangaroo tendon better than silk.

Dr. Weeks, of Maine, wished to know whether all cases were to be operated on for radical cure. He thought that cases which could be controlled by a properly fitting truss should not be operated on, and in children under three years the operation was usually fatal; also, that the greater the number of appliances used, the greater the difficulty in accomplishing a cure. He favored the Halstead plan; the only distinction being that the cord is placed immediately beneath the skin and, including all muscles, stitched to Poupart's ligament.

Dr. John B. Deaver, of Philadelphia, Pa., read a paper on

APPENDICITIS.

The writer said there were many sceptics as to the course of this disease and its radical cure.

The diagnosis was easily established. Upon palpation a localized point of tenderness could usually be found, which was of great value. Excruciating tenderness indicated pus. Temperature was not reliable, but a sudden fall indicated perforation. The point of tenderness was frequently referred to the left side. Foreign bodies were often retained in the appendix, causing no symptoms until a catarrhal inflammation caused by a cold; suppuration would then ensue.

Early operation made the prognosis better. If the general peritoneal cavity had been invaded, the prognosis was bad. With perforation into the bowel recovery was the rule; into the bladder, the prognosis was very bad.

Operation was the treatment for all cases as soon as the diagnosis could be made. We had no way of foretelling whether perforation, gangrene or pus would ensue, or that it would be a simple catarrhal inflammation.

As to the danger of operation, one hundred operations without a single fatality required no comment. Early operation was more of a conservative treatment than a radical procedure. One attack was sure to be followed by another. Early operation was comparatively easy; but pus once formed, the operation demanded the best of judgment and skill.

The median incision should be avoided, as it was necessarily a large one, and the peritoneal cavity could not be so well protected from infection. The abscess to be drained before removing. Unless the appendix was removed the operation was not a curative one. McBurney's operation was the best for chronic cases and prevented hernia.

DR. GASTON, while admitting early diagnosis and operation to be imperative, thought it was not always easy to determine that you had a case of appendicitis. He had seen a case where all the usual symptoms were absent but pus was abundantly present.

DR. MCGONIGAL'S experience was recovery in all early operations, but death where the operation was delayed for four or five days.

DR. QUIMBY, of New Jersey, disagreed with the writer; he thought medicine and nature should be first given an opportunity, and that it was a serious mistake to treat every case as a surgical one. In small places where expert surgeons were not available, what was to be done? He treated this disease as he would peritonitis.

DR. WYMAN, of Michigan, said his experience was limited to cases where suppuration had already taken place, the delayed diagnosis being due to the powerful contraction of the abdominal muscles. As to the cause of the disease; he believed there was a geographical distribution of it, as existed in malaria, and that the presence of a foreign body was merely a coincidence.

DR. MURPHY, of Chicago, said a diagnosis could best be made within twelve hours after the first attack. The variety of the infection governed the symptoms. Where a blistered condition of the peritoneum existed, as though parboiled, the case was a bad one, and far more fatal than the mere presence of pus.

DR. MARCY, of Boston, endorsed Dr. MURPHY'S views.

Rigidity of the muscles on the right side of the abdomen, in the opinion of DR. HAWLEY, was evidence enough for operation in every case.

DR. WILLARD believed in early diagnosis and lateral incision.

DR. RANSOHOFF, of Cincinnati, thought the removal of the appendix was not necessary in cases of circumscribed abscess to bring about a radical cure. This could be accomplished by drainage.

In closing the discussion, DR. DEAVER claimed that where the appendix had not been removed, there was a recurrence in fully fifty per cent. of the cases.

### RADICAL INTERFERENCE IN DISEASES OF THE CHEST.

by DR. J. MCFADDEN GASTON, of Atlanta, Ga. This paper was a plea for early operations, especially in empyema.

DR. SMITH, of California, in experimenting upon the rabbit, found by packing the chest with gauze the hemorrhage could be stopped, and recovery of the rabbit ensued. If this was possible in an animal with so low a vitality, why could not the same be done with man with as good results? He claimed as much could be done with the pleura as with the peritoneum.

The paper was further discussed by others, with the conclusion that the best results followed an early diagnosis, with resection of as many ribs as was necessary to establish complete drainage.

### TREATMENT OF MALIGNANT TUMORS BY THE TOXINES OF THE STREPTOCOCCUS OF ERYSIPELAS.

This paper was read by DR. NICHOLAS SENN, of Chicago. Its use proved a failure in all cases where he used it. Actual attacks of erysipelas and injections must differ in the effects produced; because in one instance, by limiting it to the superficial lymphatics, in certain cases these pathways must be obliterated, and in exceptional cases, by obstructing these pathways, a limitation of the extension or a complete cure of the disease might be possible. In many cases where cures had been claimed, the diagnosis had not been verified by clinical or microscopical examinations.

His toxines were derived from three different sources. In nine cases he had used from twenty-five to seventy-five injections of from three to fifteen minims. He not only failed to obtain a cure, but in some instances the injections appeared to aggravate the local and general condition of the patient. The cases in which this treatment had been resorted to were all inoperable; and as nothing else could be done for this class of cases, he would continue his experiments, but he believed in a year or two this remedy would be relegated to the past.

By invitation from the Chair, DR. W. B. COLEY, of New York, opened the discussion. He had treated 84 cases during the past four years. They were all malignant: 43 sarcomas and 27 carcinomas. Eleven sarcomas and two carcinomas were cured. With 11 successful cases to its credit, he did not think the remedy stood in much danger of being relegated to the past.

The questions to be answered in Dr. Senn's paper are: (1) Have toxines any curative effect? (2) Is the cure temporary or permanent? (3) What form of tumors are susceptible to it?

The first question was answered by eleven successful cases. Three of the cures at present, being of two years' standing, with absolutely no symptoms of a recurrence, answered the second question. As to the third question; until the present he had advocated its use in nothing but sarcoma. As these tumors yield differently, according to their forms, in some cases no success whatever was obtained.

While DR. SAYRE, of New York, had had no personal experience with the remedy, he had seen some of Dr. Coley's cases before treatment, and again one year after treatment. In no single instance was there any evidence of a return of the disease.

DR. FENGER, of Chicago, had used it in twelve cases without any benefit resulting.

DR. WYETH, of New York, thought the following might reconcile the different reports on toxines: Eleven years ago he injected arsenic around a tumor. It caused great pain, with widespread suppuration, eventually resulting in the man's recovery. He had used Dr. Coley's toxines in a case of epithelioma, with no result. Might not the good results obtained by Dr. Coley be due to the inflammatory action of the injection destroying the rank cells of the growth?

Dr. HERRING removed a growth reaching from the abdomen down to the knee. After the operation an attack of erysipelas ensued, after which the growth apparently proceeded more rapidly. This was repeated several times, and each time appeared to aggravate the disease more than ever.

DR. KEEN, of Philadelphia, said that while he had absolute faith in Dr. Coley's statements, he had no faith in the treatment. He used it for two reasons. He was not prepared to condemn it, and when he met such cases he would use anything that held out any hope. He would continue its use in all such cases until convinced of its hopelessness. His toxines were obtained from Dr. Coley. He used them in cases of sarcoma and carcinoma, with disappointment, except possibly in one. This was a large angio-sarcoma of the brain. It was too large to be removed entire. He removed portions at two successive operations and subsequently injected the toxines. Two months after ceasing the injections there was no apparent improvement whatever. Some time after this, when he again saw the patient, the wound had healed over, and a great shrinkage had occurred. Whether this was due to the toxine and would be a cure, he did not know. He had seen cases of abdominal tumors pronounced as sarcoma disappear of themselves.

In reply to Dr Wyeth's question DR. COLEY said, that in many cases the tumor appeared to be simply absorbed; there was complete absence of any breaking down or inflammatory action.

### AN ORIGINAL OSTEOPLASTIC OPERATION FOR THE REMOVAL OF LARGE VASCULAR TUMORS GROWING IN THE VAULT OF THE NASO-PHARYNX, ANTRUM OF HIGHMORE, SPHENO-MAXILLARY AND PTERYGO-MAXILLARY FISSURES.

An interesting paper with this long title was read by DR. JOHN A. WYETH, of New York; the case being a desperate one, nothing was left but a formidable operation.

As a precautionary measure a canula was inserted in the median cephalic vein, and a quantity of salt solution prepared for immediate use, if necessary. The incision was commenced along the temporal arch, carried down parallel with the nose to the alæ nasi, then turned outward and upward, making an oblique incision. The tissues were dissected loose, and carried over, exposing the bone. A key-hole saw was then inserted, separating the malar from the frontal bone. The hemorrhage was terrific; and at this point a pint of salt solution was injected. After removal of the malar bone, by depressing the zygomatic bone, he had full access to the cavity, and the growths were removed. The tissues were replaced, but bone-sutures were omitted. Recovery was uninterrupted, and the patient has excellent motion of the eye. The whole operation occupied but one and one-half hours, and about five pints of salt solution was injected in all.

### TUMORS OF THE MAMMARY GLAND,

by DR. W. L. RODMAN, of Louisville, Ky. It consisted of a plea for early radical operation in all cases of breast tumor. Not only the tumor itself, but the entire breast, with all underlying structures, including the muscles, should be removed; otherwise you risked a recurrence of the trouble.

### FOREIGN BODIES IN THE ESOPHAGUS WITH A REPORT OF FIVE ESOPHAGEAL TUMORS,

by DR. A. VANDER VEER, of Albany, N. Y., was read by title only.

### IS TOTAL EXTIRPATION OF THE RECTUM EVER JUSTIFIED?

was the title of a paper by DR. J. M. MATTHEWS, of Louisville, Ky., who said: Like many kindred operations, while strongly advocated by many, it has but little to recommend it. They are done chiefly to test its efficacy and the methods of others. We have periods in which there is a rage for certain operations, but he is the best surgeon who studies his case from all standpoints, as great responsibility rests upon his decision. Do we always stop to think whether the new is as good as the old operation? Is it justifiable? Is the patient ever cured of a malignant disease by the operation? Is he relieved or benefited by it?

The author thought not. His reasons for deciding against this operation were that it was an exceedingly difficult thing to decide whether systemic infection existed or not. By the time the growth had assumed sufficient size to attract the patient's attention and cause him to seek medical assistance, many of the surrounding tissues were already involved. It was one of the bloodiest operations known. You could not follow the rule of cutting wide of the mark without invading vital parts; and if such was the case, of what avail to extirpate the rectum and leave surrounding infiltrations? Under such admitted circumstances when was the operation justifiable?

### COLOTOMY AND EXTIRPATION IN CASES OF CANCER OF THE RECTUM,

by DR. L. H. ADLER, of Philadelphia.

These were two recognized operations, cancer of the rectum rarely manifested itself early enough to admit of much benefit ensuing from a radical operation. The writer had never seen one case benefited by extirpation. But colotomy retarded the growth of the tumor, relieved the pain, and substituted a painless death for a painful one. It prevented intestinal obstruction, enabled the patient to sleep, eat, and pass his remaining days in comfort. It was the least dangerous of the two operations.

DR. KEEN, of Philadelphia, endorsed Dr. Rodman's views regarding breast operations, by removing the entire breast, underlying tissues, including the muscles, and all structures likely to be involved. The incision should be carried above the clavicle, along the border of the sterno-mastoid muscle. Regarding the mortality of the operation, we had got better results in this country than in England, where out of 489 operations there were 46 deaths. In American operations to the number of 464, there were but four deaths.

Regarding extirpation of the rectum, the mortality had been small and the relief immense. In two cases operated on two years ago for removal of the entire

rectum, he removed the coccyx and a large part of the sacrum and both patients were well today. In both cases he had first done a colotomy. In another case he removed the rectum, uterus, ovaries, tubes and the posterior wall of the vagina, and the woman was to-day perfectly comfortable.

Dr. Jacobson thought that the surgeon who looked down upon extirpation as the bloodiest of operations was not well posted on the present methods. He knew of no operation for malignant tumor less bloody. He referred, of course, to cases where the surrounding tissues were not infiltrated. He had never lost a case.

Dr. Davis never saw this operation without considerable hemorrhage. He endorsed colotomy, and claimed every relief from colotomy that could possibly be obtained in extirpation, which he regarded as a very difficult operation.

Dr. L. McL. Tiffany thought extirpation should be done in all cases where a diagnosis was made early.

Dr. Marcy, of Boston, thought the rectum should be excised if seen early enough.

In closing the discussion Dr. Matthews said every one who had discussed his paper had agreed with him in the main. Total extirpation in operable cases were the ones he spoke of; and it was one of the bloodiest of operations. Continuing, he asked, Are you justified in extirpating in these cases, where all these men who advocate it have just admitted they never seek aid until other structures are invaded? Dr. Keen's report is of cases operated upon only two years ago; after colotomy cases have lived six years. Can extirpation show better or as good results? All these advocates first performed colotomy; what then was the object of the extirpation?

Dr. Rodman, in closing the discussion on the breast, said that Dr. Keen's foreign statistics went back as far as 1870, and this accounted for the large average mortality of the Germans; but he thought the German statistics of the past five years were equally as good as the American. The reason the English had such a high mortality was because they did not keep up with the times.

Dr. D. D. Stewart, of Philadelphia, presented a paper on

### Electrolysis in the Treatment of Sacculated Aneurysm, through Introduced Wire, with Report of a Successful Case.

He inserted a gold wire, of sufficient calibre to form spirals, in the centre of the cavity. Ten feet were passed in. The current was passed without interruption for seventy-five minutes. Before the expiration of half an hour the needle was able to stand up in the cavity without support. The operation caused no pain. Three weeks afterwards the operation was repeated because the upper part of the sack was not sufficiently occluded. This time but two and a half inches of wire could be inserted.

## Section on Surgery.— Third Day.

Dr. Carl Beck, of New York, read a paper on

### Asepsis in Private Practice.

This was practically an exhibition of a portable sterilizing apparatus. He claimed that with our present methods, almost any operation done in a hospital could be done equally as well in the patient's home.

The room in which the operation was to be done should be prepared the day previous by an assistant; and then nothing in it should be disturbed for several hours preceding the operation. The patient should have a warm bath the day before.

The apparatus consisted of a series of four pans or trays, which fitted into one another, which when closed could be carried in an ordinary surgeon's-bag. The heat was supplied by two alcohol lamps. A small apparatus of the same description was exhibited, which when closed could be carried in the pocket. This was intended for sterilizing pocket-case instruments.

### Ileus.

A paper illustrated by charts and plates, by Dr. J. B. Murphy, of Chicago.

By the term ileus, we mean a plexus of symptoms: where there is pain in the abdomen of greater or less severity, accompanied by nausea or vomiting, or both, and inability to evacuate the bowels.

The surgeon is interested in the intestinal tract only from a mechanical standpoint. It is a long muscular tube with various points of strictures and contractions, such as at the pylorus, ileo-cecal valve, etc. This canal has a mechanical purpose, and with this mechanical action only are we interested.

Causes of intestinal obstruction are paralysis of its muscles; mechanical obstruction and spasmodic contraction. Of the dynamic variety, we have paralysis from operation on the gut.

In intestinal operations, how much can we interfere with the mesentery without producing paralysis of the ileus? This depends upon the position of the ligature. The blood-supply is from the mesenteric arteries, and again from the parallel artery, which is not accompanied by a vein. Upon the dog you can cut off the mesenteric supply for six and one-half inches without causing paralysis or necrosis; but if both vessels are ligated, anything over one-half an inch, causes a necrosis.

What becomes of the strangulated and constricted bowel, and why? After the twisting, the venous circulation is first disturbed; then damming of the bowel, cessation of the circulation in the mesenteric vessels, and lastly in the parallel vessels. The parallel vessel being protected by a cushion of fat, it takes a long time for it to give way. There being no vein to return the blood great congestion of the bowel ensues; and if sufficient time has not elapsed to cause a thrombosis, the bowel can be placed back into the abodmen after the obstruction has been removed.

When excision of a bowel section is necessary, cut off a little more of the gut on the convex side than on the mesenteric side; otherwise you will have a necrosis of the bowel.

We have paralysis from spinal affections, such as fractures, injuries to the afferent nerve, etc. He had seen a case of this kind where for a considerable length the bowel was distended to three times its ordinary circumference, and the distention was not due to fluid or gas. It is also obstructed by reflex paralysis, such as obstruction to the cystic duct from calculus, renal calculus and spasmodic contraction. The latter is especially frequent in lead-poisoning. Local paralysis occurring in peritonitis, is an important cause and one of the most difficult to differentiate.

Regarding differential diagnosis, in dynamic ileus you can by careful auscultation of the abdomen determine the absence of peristalsis; and the presence or

absence of peristalsis in early obstruction is of more importance than any one sign or symptom known.

SCIENTIFIC USES OF THE SURGICAL FLAP,

by DR. GEORGE WILEY BROOM, of St. Louis, Mo.

Attention was called to the fact that the particular point of amputation was not as important as the technique. If this is properly carried out and the cicatrix where it ought to be, the artificial limb-maker can readily adjust artificial limbs to any variety of stumps.

In speaking of the drainage-tube he claimed that it exposed the wound to 178 varieties of cutaneous bacteria. A blood-clot in a wound was not a foreign body, and as blood possessed bactericidal properties, it was not a source of danger.

SURGICAL TECHNIQUE OF ASEPTIC WOUNDS,

by DR. HENRY O. MARCY, of Boston.

Suppuration means that something has been wrong in the technique or its carrying out after operation.

The parts should be protected by towels wrung out in bichloride solution. Frequent sponging of the wound is harmful. The so-called drainage resulting from the use of chemicals has been greatly overestimated. Drainage-tubes are still too frequently used. Tendons of animals make the best sutures. They are stronger and lighter than silk, and do not absorb too quickly. In the application of buried sutures we should use no undue constricting force.

For the coaptation of wounds the running sutures are best.

DR. B. MERRILL RICKETTS, of Cincinnati, O., read a paper on

FLAT-FOOT.— SUPRA-MALLEOLAR OSTEOTOMY, WITH REPORT OF A CASE.— PHOTOGRAPHS AND SPECIMENS OF FEET OF MAN, ORANG, BABOON, CHIMPANZEE AND GORILLA.

The mastoid process in man's skull is only rudimentary in other animals, and is due to the upright position in walking. Children are born flat-footed. Savages wearing no shoes are always flat-footed. Civilization tends to obliterate flat feet. Flat-foot is principally due to failure of the tarsal bones to become rigid. It becomes aggravated by age. The chimpanzee has but little arch. The posterior part of the gorilla's os-calcis touches the ground.

The manner of dressing the feet in early life is a prominent factor in producing deformed feet. All flat feet which cause pain or deformity should be operated upon. Trendelenburg's operation is the best.

GALL-STONES IN THE COMMON DUCT, AND THEIR SURGICAL TREATMENT,

by DR. CHRISTIAN FENGER, of Chicago.

In the great majority of cases these stones are floating, and in manipulating you may push them up into the hepatic duct and out of reach. These floating stones act as ball-valves.

In eighty per cent. of the common-duct cases instead of a dilated gall-bladder, we find it small and atrophied.

Symptoms of floating stones are repeated attacks of pain, but not of sufficient duration to cause much jaundice. These attacks of pain are repeated until there comes a final one causing death.

As we can never foretell this final attack we should operate as soon as diagnosis is established. Operate by the usual incision, removing all adhesions until you get down to the duct; and then sometimes it is impossible to find the stone, owing to its having slipped back through the hepatic duct.

Out of forty-four operations the mortality has been eighteen per cent. Of the writer's three cases, all recovered.

DR. MARCY had operated only three times on the common duct. In the first case he abandoned the operation, and the patient died ten days later. In the second case he laid the entire duct open; the patient recovered. The third case died because the patient was poisoned before the operation.

The paper was further discussed by DRS. GASTON and WEEKS.

In closing, DR. FENGER said the duct should invariably be closed by a double row of sutures and drainage always adopted.

SKIN-GRAFTING AFTER THE METHOD OF THIERSCH,

by DR. J. C. OLIVER, of Cincinnati, O.

Its frequent application is limited by three causes: weak granulation, large blisters, and replacing cicatricial tissue.

EXSECTION OF THE KNEE-JOINT, WITH REPORT OF A CASE OF COMPLETE DISLOCATION OF THE KNEE, OF NINE YEARS' STANDING, WITH ESPECIAL REFERENCE TO METHODS OF FIXATION.

This paper by DR. S. F. FORBES, of Toledo, O., was interesting from the method of fixation. Nine years previously the knee was completely dislocated and never reduced. The leg was bent at an angle of forty-five degrees, shrunken and poorly developed.

The incision divided all the structures; a slice one and three-eighths inches thick was removed from the femur, and three-eighths of an inch from the end of the tibia. The surfaces were brought together; and six catgut sutures, three on each side, and one silver suture, inserted. The periosteum was drawn down and stitched with gut, and the external flap treated in the usual manner. Layers of iodoform gauze were applied; next absorbent cotton followed by flannel roller, and the whole covered with a plaster bandage reaching from the toes to the groin. Strips of wood were inserted with the bandaging.

Three weeks afterwards the bandage having become stained with discharge, upon examination it was seen that the edge of the upper cuff had necrosed and was being sloughed off. One week afterwards, the slough being detached, the silver suture was seen lying loose and was removed. Two weeks later the wound healed; and in seven weeks more the plaster was removed. The patient was discharged with a good straight limb ten weeks after the operation, and at this writing she walks without the aid of crutch or cane. She wears an iron support two inches high under the shoe.

The conclusions were, that in knee exsection direct fixation is unnecessary, and that external support gives instant and permanent fixation.

DR. MACLEAN said that while Jonathan Hutchinson of England condemns exsection, he (Dr. Maclean) had had good results following it. He uses no internal fixation; no silver wires, or ivory pegs, etc.

Replying to a question of Dr. Garcelon's, Dr. Maclean said most of his tubercular cases were old chronic ones where the active process had stopped. He had

operated on several cases where the disease was active.

Dr. Davis, of Philadelphia, wished to know what part the silver suture Dr. Forbes inserted, played in the good result. He believed the bandage should go as high as the waist.

Dr. Weeks thought if the apposing surfaces of bone were in exact position you required no internal fixation. A posterior splint of tin reaching up to the ischium was the best fixation.

In closing the discussion, Dr. Forbes said that as all the muscles were divided in this operation, he failed to see how any muscular action could disarrange the limb, and did not think it necessary to carry the bandage up to the waist.

Dr. E. A. Tracy, of Boston, described

THE NEW SURGICAL SPLINTING.

The splint is made from crushed wood-fibre. While moulding the splint the patient should be placed in the proper position; after moulding the splint is dried over a kitchen fire. Its edges should be covered with chamois, and when applied, fastened to the limb by roller bandages. Its advantages are extreme lightness, perfect adaptation to the limb, and great strength.

A SIMPLE METHOD OF DRESSING FRACTURES OF THE EXTREMITIES AUXILIARY TO THE BANDAGE.

This consisted of a practical demonstration by Dr. John E. Link, of Terre Haute, Ind.

He used shavings of birch-wood about six inches wide and ten in length. These shavings were so flexible that they could be wound around the finger. Moistened roller bandages were wound around the limb in one direction, no reversing or twisting being done. Between the various turns of the roller bandage the shavings were inserted. The shavings remained exactly where you placed them, and you obtained absolute rigidity of the limb without increasing its weight beyond that of the roller bandage.

In discussing the last two papers Dr. Thomas H. Manley, of New York, said he was glad to see plaster bandage being driven out, for he believed the number of deformities were increased by its use. The only objection to the crushed wood-fibre was its cost; which barred it from hospital use for the present. He regarded Dr. Link's shavings as the ideal treatment for fractures in children.

SECTION ON SURGERY. — FOURTH DAY.

Dr. Thomas H. Manley, of New York, read a paper on

DEFORMITIES FOLLOWING FRACTURES OF THE SHAFTS OF BONES.

In complicated fractures in adult life, more or less deformity will sometimes result regardless of the line of surgical or mechanical therapy adopted.

Cases are divided into two classes: The preventable, and those beyond our control. In the majority of cases, if we treat our cases rationally, we will secure fair restoration of function and normal contour of limb. When both bones of the forearm are completely broken, or the fracture extends through a joint, or impaction is present, can we always prevent deformity?

The author's observation of several thousand fractures inclines him to believe that in a considerable number of such cases deviation from the normal outline follows.

Hyperostosis with excessive callus is always observed in badly adjusted fractures. This not only disfigures and impairs the use of the limb, but may also lead to serious pathological conditions by pressure on the main vascular conduits and nerve-roots.

In fractured femora the great difficulty lies in being compelled to treat the patient as well as the fracture. Gross distortion generally implies maladroitness or neglect in treatment.

Non-preventable cases are those dependent on extrinsic circumstances and those following organic or constitutional disturbances. They are pathological.

Proyhylaxis is of the first importance. The problem is to preserve vitality and secure osseous repair without disturbing the reposition of the fragments.

If not attended by loss of bone or excessive shortening. rectification can be accomplished in the early stages of repair. After osseous solidification is complete it is a serious question whether radical surgical interference should be adopted as a routine treatment. It should not be done unless the functional integrity is seriously impaired or the deformity very great.

The operations are osteoclasis, osteotomy and osteectomy. These operations are valuable in young and growing subjects, but beware how they are applied to the humeral or femoral shafts of matured development. In many cases coming under the author's notice, life itself was imperilled; and in a few recovery succeeded only with a permanent ankylosis of the limb and muscular atrophy.

None of the various operations devised for correcting deformities after a Pott's, Colles' or elbow fracture promised anything in the way of improvement sufficient to compensate for the risk to life which they always involve; and a few cases which were so treated, and who afterwards came under his notice, were not only not improved, but they were worse than before the operation.

The following papers were read by title only: "Foreign Bodies in the Esophagus, and a Report of Five Esophageal Cases," by A. Vander Veer, of Albany, N. Y.; "Hypertrophy of the Thyroid Gland: An Experimental Study," by Wm. S. Halsted, of Baltimore, Md.

The following officers were elected for the ensuing year: President, C. A. Wheaton, St. Paul, Minn; Secretary, W. L. Estes, South Bethlehem, Pa.

*(To be continued.)*

## Recent Literature.

*A Text-Book of Pathology. Systematic and Practical.* By D. J. Hamilton, M.B., F.R.C.S.E., F.R.S.E. Professor of Pathology, University of Aberdeen. Macmillan & Co. 1894.

The second volume of this work in two convenient and neatly bound parts of about 550 pages each has recently appeared. The special pathology of the various organs begun in Volume I is concluded, and chapters are added on Malformations and Animal Heat and Fever.

The arrangement of the work is exceedingly unfortunate. For example, the subject of Practical Bacteriology was disposed of in Volume I, at the end of

Volume II, Systematic Bacteriology occupies a hundred pages under the heading "Diseases due to Vegetable and Animal Parasites." The bacteriology of certain diseases, however, such as diphtheria, typhoid and cholera is described in the section devoted to the Pathology of the Special Organs. The arrangement in Thoma where all bacteria are treated of in a chapter under the heading "General Etiology" is much more to be recommended.

Much space is devoted to the consideration of physiological and clinical subjects which have little or no place in a work devoted to Pathology. "Pain in Hepatic Disease" covers almost half a page; "The Act of Micturition" and "Stammering" occupy each over a page; and ten pages are given up to "The Movements of Respiration," "The Respiratory Centres," and "Respiratory Volume"; and forty-two pages to the "Morbid Conditions of the Urine." On the other hand, less than four lines are devoted to the Appendix and its lesions (although Typhlitis and Perityphlitis take up nearly half a page), and eight lines are sufficient for the Inflammatory Affections of the Pancreas.

The deficiencies of the work cannot, perhaps, be more clearly brought out than by noting the manner in which the author has treated two subjects of vital importance, namely, Lobar and Lobular Pneumonia.

Under Lobar ("croupous") Pneumonia he considers at some length Friedländer's pneumo-bacillus as the causal agent. The micrococcus lanceolatus of Fraenkel and Weichselbaum, according to Welch the only causal agent of true lobar pneumonia, is referred to in small print only as a possible occasional cause. Welch's classical monograph on the latter organism is not even mentioned. In regard to Friedländer's bacillus we think Thoma voices accurately the present opinion held by pathologists when he says that the pathogenic significance of this bacterium for man is questionable. After giving Welch's view above, what shall we say to this statement by the author? "Multiple fat embolism from a simple fracture of a bone, and in an individual with a powerful heart, frequently induces a croupous pneumonia, in all respects like that following from the action of specific agents!"

The chapter on Lobular ("catarrhal") Pneumonia shows the greatest lack of knowledge of the recent work done in this field. The exudation is described as consisting of fluid and of desquamated alveolar cells. "In cases where the disease becomes chronic, the discharge assumes a more and more solid character, the tubercle bacillus develops in its midst and caseation follows. It thus constitutes a tubercular pneumonia." Not a word is said about the various organisms concerned in the production of lobular pneumonia, the varying character of the exudation dependent on the causal agent and the outcome of each affected area as determined by the organism or organisms producing it, beyond referring to the bacteria present in lobar pneumonia.

The illustrations are numerous, but are neither very attractive nor very instructive, especially those illustrative of finer histological details. The work certainly cannot be recommended to students as a good text-book on pathology, although a standard pathology written in English is greatly needed, because the author does not treat his subjects logically from an etiological standpoint, and is not abreast of the times in his information and teaching.

## TRANSFUSION OF BLOOD OR INFUSION OF SALT SOLUTION.

IN an article under this heading in the *Münchener medicinische Wochenschrift*, April 2d, von Ziemssen calls attention to the fact that in spite of simplification of method, and in spite of the considerable number of cases which he had been able to report of the curative effect of repeated transfusions of blood in the same individual, the method of infusion of salt solution is given almost uniform preference in surgical practice, and blood transfusion considered of comparatively little value in comparison. The reason for this is evident, namely, that in the majority of the surgical and obstetrical emergencies in which either infusion or transfusion must be employed, the infusion of salt solution gives a simpler and more rapid means of restoring the lost bulk of fluid in the vessels, and is, therefore, far preferable to the more complicated operation of blood transfusion. On the other hand, the effect of salt infusion is at the best only transitory, and it becomes necessary, according to von Ziemssen, in most cases to follow it sooner or later by an infusion of blood.

The indications for choosing one or the other method are usually plain. For instance, in the acute anemia resulting from sudden and profuse hemorrhage, salt infusion is to be chosen. In anemia resulting from disease of the blood-making organs, on the other hand, in which the percentage of hemoglobin and the number of red blood-corpuscles falls even below that which results from sudden and profuse hemorrhage, no one would think of resorting to salt infusion. In simple anemia resulting from profuse hemorrhage in a healthy patient, the restoration of the normal condition of the blood is immediately begun and carried on by the blood-making organs; in pernicious anemia, etc., the blood-making organs are so diseased as to be incapable of effecting repair of the blood tissue.

In case of frequently repeated hemorrhage from internal organs, as in typhoid, ulcers of the stomach, etc., salt infusion, although it momentarily restores

the heart's activity, leaves much to be desired on account of the fleeting nature of its effects.

It is in such cases as these that von Ziemssen recommends transfusion of blood. He reports the case of a patient upon whom infusion of a litre of salt solution was performed, *ex indicatione vitale*, with marked temporary improvement. The operation was performed in the evening, and the following morning the patient's condition again became critical, and a loud systolic murmur appeared at the heart's apex. An arm-to-arm transfusion of 175 cubic centimetres of blood was performed. Immediately after the operation the patient sunk very low, but was revived by an injection of camphor, and the percentage of hemoglobin was from 32 to 40 per cent. on the following day. The anemia was rather resistant to treatment, but finally yielded to subcutaneous injections of sodic arsenite, and the patient left the hospital in two months, well.

In von Ziemssen's opinion, the salt infusion in this case had an excellent, but temporary effect; and without the transfusion which followed it, the result would have been fatal. He recommends that in all cases where the effect of salt infusion is temporary, it be followed by blood transfusion, and considers it questionable to wait more than twelve hours before resorting to this procedure. He finds that even during the operation the color of the skin and mucous membranes is improved, and that the subjective feeling of improved strength is quite marked for some hours after the operation; and he considers the good effects of the transfusion to be due as much to the fact that the blood-making organs are excited to activity, as that the number of red blood-corpuscles is directly increased.

In our experience with infusion of salt solution which has been chiefly confined to surgical cases, we have found that in a very large proportion of cases the effect, though always excellent, was but temporary, and that it was necessary in order to render its effects permanent to follow it up with copious and repeated enemata of salt solution and stimulants, or even to repeat the operation. In one case of hemorrhage from the ovarian artery following a laparotomy, in which the abdomen was reopened and the ovarian artery tied, the patient being enabled to bear the operation only by means of an intravenous infusion of salt solution which was performed at the same time, the effect of the infusion was marked, and the patient was put to bed with a better pulse than she had before the operation. Three hours later, the symptoms of acute anemia — absolute pallor, restlessness, and complete failure of the pulse — again returned, and infusion was repeated with the same result as before. The result was more permanent, however, the effect being kept up by copious and repeated rectal injections of salt solution, and the case progressed to recovery. Other cases might be cited in which the same treatment was successful. Whether the stimulating effect of a transfusion of blood upon the blood-making organs would have led to a better result it is difficult to say. At any rate, the same beneficial effect was noted in these cases from repeated salt infusion, that von Ziemssen found from his blood transfusion.

It is certainly true in these cases that in the first place the vascular system is depleted by the hemorrhage; then the tissues are emptied of serum taken up by the depleted vessels in order to enable the heart to act. The pressure in the vessels is so lowered by the hemorrhage that osmosis takes place from the lymph spaces into the capillaries, so that the lymph-vessels as well as the blood-vessels are depleted. The bulk of salt solution given at the first infusion fills the blood-vessels temporarily, but is quickly taken up by the tissues, reducing the blood pressure, and again reducing the volume of fluid with which the heart has to work, and causing the symptoms of acute anemia to recur. The second infusion fills the vessels again, and the tissues being already supplied with fluid, do not absorb it from them. Hence equilibrium is restored, and the effects of the second infusion are permanent.

If a sufficient amount of fluid is injected at the first operation, the second may be unnecessary, but it will always be a good rule to follow up an infusion by copious enemata of salt solution, and, if necessary, to repeat the operation.

## A REPORT OF ONE THOUSAND EXCISIONS OF THE THYROID.

At the German Surgical Congress at Berlin, on April 17th, Kocher, of Berne, reported his results in one thousand thyroidectomies for goitre. This enormous and wholly exceptional experience, which would be hardly possible for a surgeon not a resident of Switzerland, renders his contribution to our knowledge on the question of thyroid operations of the greatest importance.

Twelve years have elapsed since he reported one hundred cases of complete extirpation of the thyroid, with observations upon the cachexia strumipriva consecutive to the radical operation.

Since that time he has abandoned the radical operation, and has practised partial extirpation of the goitre, with the result that in nine hundred cases operated on since that time cachexia strumipriva has resulted in only one case. In this case the cachexia was due to the fact that after the excision of one-half of the thyroid gland, the other half atrophied. On the other hand, all the cases of total extirpation have gone on to cachexia, except in cases where fragments of the gland have been left behind and produced recurrence of the disease. Alterations of the voice, paralysis of the vocal cords, etc., can almost always be avoided in carefully performed operations. They have been observed in seven per cent. of the cases, but have disappeared in the non-malignant types of the disease.

Eliminating the malignant cases, the mortality in eight hundred cases becomes a little higher than one per cent., eleven cases in all having died. Some of the cases were desperate when brought to the clinic

(one moribund, one intra-thoracic goitre with general edema and hydropericardium). Among other causes of death may be mentioned one of interstitial nephritis; two of influenza followed by pneumonia; three of the exophthalmic type, in whom the conditions for operation were very poor, in virtue of the size and brittleness of the vessels, so that the ligation of only three of the arteries and not of all four, was possible. He now prefers to operate by ligature of the thyroid arteries rather than by excision in these cases.

One death was due to bronchitis, after the inhalation of ether. No deaths resulted from chloroform anesthesia. Kocher always begins the anesthesia with chloroform and continues it with ether; in extremely cachetic subjects he has employed with success local anesthesia with cocaine.

Two deaths were produced by infection, both being in operations for recurrent disease. In one series of 272 operations there were no deaths. The operation is often difficult, especially when the disease extends into the thorax. For simple goitre, non-malignant, or exophthalmic, Kocher had only three deaths in nine hundred excisions, which is certainly a most excellent record.

We are to be congratulated upon the fact that prophylaxis and cure of goitre by thyroid feeding is the order of the day. The author's clinical experience has demonstrated that enlargement of the thyroid often diminishes under prolonged thyroid alimentation.

The administration of phosphates, according to the researches of the Polish physician Zakrzewski, can also lead to the atrophy of goitre. The phosphate of soda has also been given in Basedow's disease, with the result of the disappearance of the disease and its symptoms, a fact which corroborates the view that the disease is an auto-intoxication, due to an abnormal thyroid secretion, although the origin of the disease may be in an abnormal nervous impulse.

Rehn, of Frankfort-on-the-Main, has just successfully treated a case of Basedow's disease by extirpation of the tumor. Vascular goitres are very difficult of removal, and he had had three deaths from the operation. From the result of his operation in the case of Basedow's disease he is led to believe that we have to do in this disease with an auto-intoxication by the thyroid secretion.

Krönlein said that he was completely convinced of the efficacy of the treatment of Basedow's disease by excision of the thyroid. He had cured the eight cases upon which he had operated. All the symptoms did not at once disappear, the exophthalmus persisting for the longest time. In his two hundred cases of goitre he has had no deaths. After chloroform anesthesia he had sometimes seen a pneumonia, which he had not observed when ether and morphine had been employed exclusively.

Mikulicz had found that feeding with the thymus as well as the thyroid gland produced a diminution in the size of goitres. He has successfully treated eleven cases of Basedow's disease by operation. Trendelenburg, of Bonn, had operated in six cases of Basedow's disease — once by excision, which operation was followed by a severe hemorrhage; once by ligature of three arteries; four times by ligature of all four arteries. No cachexia had been produced, and all the cases had been greatly relieved by the operation. Rydygier, of Cracow, had ligatured all four arteries twenty times without producing cachexia.

## MEDICAL NOTES.

THE NEW PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS. — Mr. Christopher Heath has been elected president of the Royal College of Surgeons of England, for the remainder of the term left vacant by the death of the late Mr. Hulke.

THE GERMAN CONGRESS OF GYNECOLOGY. — The Sixth Congress of the German Association of Gynecologists will be held in Vienna June 4th to 7th ult. The subjects for discussion will be "Endometritis and Rupture of the Uterus." Clinical demonstrations will be given at Chrobak's clinic.

THE STREPTOCOCCUS ANTITOXIN. — The *Wiener klinische Wochenschrift* is informed that the streptococcus antitoxin discovered by Marmorek at the Pasteur Institute in Paris, and successfully demonstrated in experiments on animals to be a remedy for erysipelas, has already been employed in about fifty cases of this disease in the hospitals of Paris, with most excellent results.

THE PURIFICATION OF DRINKING WATER. — According to *La Médecine Moderne*, at a discussion at the French Academy of Sciences on the question of furnishing pure drinking water to the French troops in Madagascar, M. Friedel presented a new disinfectant, "monol," by which it was possible to render swamp water, or even water impregnated with vegetable poisons, pure, palatable and harmless.

SPLENOPEXY. — At the German Surgical Congress Rydygier, of Cracow, reported that he had successfully performed splenopexy three months before on a patient with a movable spleen. Splenopexy is a difficult operation on account of the danger of hemorrhage. Rydygier made an incision in the median line and dissected up the peritoneum at the level of the eleventh and twelfth ribs, so making a pocket in which he lodged and fixed the spleen. The fixation sutures were passed through the gastro-splenic ligament. Up to time of report the spleen had remained in place.

A MAN WITH FIVE HUNDRED SPLEENS. — Albrecht[1] reported at the Vienna Medical Society on April 26th, the autopsy on a man of twenty-five years who had died of chronic nephritis, in whose abdominal cavity were found five hundred spleens of various sizes, some so small as to be hardly visible, and others varying from the size of a pin-head to that of a walnut. The largest spleen, the size of a walnut, lay in the position of the normal spleen, and was provided

[1] Vienna correspondent of the Münchner med. Wochenschrift.

with the regular splenic artery and vein. The earlier reported cases of accessory and multiple spleens have shown that the additional spleens were situated in the positions which their development would render probable, but in this case they were scattered all over the peritoneal cavity right and left, in the diaphragm, on the suspensory ligament and in the capsule of the liver, in the greater omentum, along the descending colon and ileum, even in Douglas's pouch. The tissue of these scattered spleens was indubitably proved by microscopical examination to be true splenic tissue.

The Albert Medal of the British Society of Arts. — Sir Joseph Lister was on April 9th presented with the Albert Medal of the Society of Arts by the Prince of Wales, as president of the Council of the Society. The medal was awarded to Sir Joseph Lister in recognition of "the discovery and establishment of the antiseptic method of treating wounds and injuries, by which not only has the art of surgery been greatly promoted and human life saved in all parts of the world, but extensive industries have also been created for the supply of materials required for carrying the treatment into effect."

Antitoxin in the Antipodes. — In the *Australasian Medical Gazette* of March 15th is an account of six cases of diphtheria treated with Behring's and Aronson's antitoxin at the Sydney Children's Hospital. Three of the cases are classed as very serious, and in three of them tracheotomy was required. Five of the cases recovered, and one died of post-diphtheritic cardiac paralysis after the local condition had considerably improved. Out of six cases treated at the Brisbane Children's Hospital, two died. At the meeting of the Queensland Medical Society of February 12th, a committee was appointed to request the colonial secretary that the government bacteriologist be asked to undertake the manufacture of antitoxin.

### BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — During the week ending at noon, May 22, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 51, scarlet fever 26, measles 122, typhoid fever 9.

Examination for the Massachusetts Medical Society. — The usual annual examination for admission to the Massachusetts Medical Society will be held by the Censors of the Suffolk District on Thursday, June 6, 1894, at 2 P. M., at 19 Boylston Place.

The Small-pox Epidemic at Claremont, N. H. — The origin of this epidemic illustrates very well the method of the sudden outbreaks of small-pox in places remote from the original source of the disease. Dr. Irving A. Watson, the Secretary of the New Hampshire State Board of Health, reports that the disease was brought to Newport, N. H., by a man who returned from Chicago, and came down with small-pox immediately after his return, the case not being recognized as small-pox. A man to whom he communicated the disease proved to be a walking case, and distributed small-pox in the town of Claremont. A woman who likewise contracted the disease from the first case, distributed it in the town of Croydon, so that two rather active local epidemics were started.

Public Health in Connecticut. — The *Bulletin* of the Connecticut State Board of Health for April, 1895, states that: "The month of April was notable for several epidemics in various parts of the State. One reported by Health Officer Fitzgibbons, of scarlet fever in Bridgeport, originated in a public school. It was necessary to close the school. Another of scarlet fever was reported by Dr. H. E. Wilcox, Health Officer of Windham, in which he thinks there may have been 600 cases, although only 231 were reported to him. Notwithstanding the extensive spread of this disease, there have been but few deaths, so mild is the type of the disorder at this time. Dr. Congdon, Health Officer of Salem, reports scarlet fever 'developed one year after exposure.' The probable fact is, a recent exposure to some wearing apparel, that had not been disinfected. Whooping-cough is epidemic in East Haddam and New Canaan." The epidemics of typhoid fever at Stamford and New Milford, both due to infected milk, have already been noted in the Journal for May 9th and May 16th respectively. With regard to the latter epidemic the *Bulletin* states that: "In this outbreak the physicians of the town neglected to report their cases to the health officer, on the excuse that they did not know the disease was typhoid fever. Hence the extent of the epidemic was not recognized until it attracted public attention. Immediate reports to the health officer and prompt suppression of the sale of the infected milk would probably have prevented a part of the cases. There could not well be a more convincing illustration of the importance of some authoritative supervision of the ways and methods of milk production for public use. So long ago as 1881, fifty typhoid epidemics from infected milk had been traced in England, and now all English dairies are subject to the supervision and control, in a sanitary sense, of health officials."

### NEW YORK.

Licenses for Dental Practice. — The Legislature has passed and the Governor has signed a bill vesting the power to grant licenses to practise dentistry in a State Board of Dental Examiners, and assimilating the licensing of dentists to the licensing of physicians.

The Appropriation for the Dependent Insane. — The State Senate has passed the bill of the Finance Committee providing the annual appropriation for the care and maintenance of the dependent insane. The bill imposes a tax of one mill on each dollar of real estate and personal property, and the total sum to be raised is $4,200,000 an increase of $2,800,000 over last year, owing to the taking in under the State Care Act of the insane of New York and Kings Counties.

Public Health of New York. — The reports of the Bureau of Vital Statistics show a very satisfactory state of the public health. During the week ending May 18th there were 771 deaths, which is 44 less than in the preceding week, and 109 less than the average for the corresponding weeks of the past five years. The mortality from pneumonia, however, still continues high. During the week 123 deaths from it were reported, which is 24 more than occurred from phthisis. Diphtheria was the cause of 36 deaths.

Dr. Bozeman's Button Suture. — On May 12th a considerable number of medical friends were present at St. Francis Hospital, Jersey City, where Dr. Nathan Bozeman, of New York, operated for the closure of a vesico-vaginal fistula; applying, as usual, his button suture. In his invitations to the operation Dr. Bozeman announced that this date was the fortieth anniversary of the invention and employment of the button suture as a strictly aseptic suture for all forms of perforating lesions in the walls of the vagina and cervix uteri.

A Case of Quadruplets. — A German Jewess in Brooklyn, a patient of Dr. Louis Pulvermacher, recently gave birth to four children at a time. Drs. A. S. Nicholson and C. C. Henry were called in consultation, but the labor proved fatal. Of the four children, three were males and one a female, and two of them died shortly after birth. The two surviving infants were doing well, according to the last reports. Each of the quadruplets weighed more than four pounds, and their combined weight was eighteen and a half pounds. The mother was a little past forty years of age and had previously given birth singly to five children, all of whom are now living. The oldest is eighteen years old.

Columbia University. — At a meeting of the trustees of Columbia University held May 6th, President Seth Low announced that he would donate, as a memorial of his father, the late A. A. Low, of Brooklyn, the sum of $1,000,000 for the erection of the new library of the University. It was also announced that Mr. Wm. C. Schermerhorn, Chairman of the Board of Trustees, had made a gift of $300,000 for the erection of the Natural Science building, or any other building that might be selected by the board. On the recommendation of the National Academy of Sciences the trustees voted to make the first award of the Barnard medal for the most important discovery in physical or astronomical science to Lord Rayleigh, the discoverer of argon, a constituent of the atmosphere. The late Dr. F. A. P. Barnard, President of Columbia, in his will provided for the award every five years, beginning in 1895, of a gold medal for "Meritorious Service to Science," the competition being open to citizens of all countries.

Public Baths. — At a meeting of the Board of Health held May 2d, action was taken in regard to the erection of free public Baths in various parts of the city. A recent act of the Legislature makes provision for such baths, and the Board decided to ask the Board of Estimate and Apportionment to purchase land and build seven houses. President Wilson called in consultation Mr. John P. Faure and Prof. Wm. H. Tolman, of the Committee of Seventy's Sub-committee on baths, and also Dr. Simon Baruch, who has devoted much attention to the subject of balneology. Mr. Faure presented a report, based on the work of his committee, showing the great need of public baths, especially on the crowded tenement districts of the east-side. The recommendations were as follows: "Bath-houses to be built on an ordinary city lot, 25 by 100 feet, to have two stories suitable for at least forty baths, twenty on each floor, in addition to spray baths for children in the basement. The baths on the street level should be arranged for men, those on the second floor for women. The spray or rain-water system of baths should be adopted because there is no waste of water. The cost of erection should be very moderate, and the system is characterized by cleanliness and simplicity. The bath-houses should contain divisions for the use of the cleanly and of those not cleanly. Each should have a system of fumigating clothes when necessary. In tenement districts public wash-houses should be opened in connection with the baths, thereby relieving many homes of one and two rooms of the unhealthy conditions of laundry work." Six sites for the proposed bath-houses were also recommended. Dr. Baruch said that much good had been accomplished by the various baths already provided by some of the charitable societies. He estimated that seven buildings of ample size could be erected for $140,000. The Committee of Seventy's estimate was $25,000 for each house. The question of introducing baths in the public school buildings was also discussed, and the proposed plans for this were heartily approved by the Board.

## Miscellany.

### RECENT MEDICAL LEGISLATION IN MINNESOTA.[1]

That Minnesota is in the van of progress as regards keeping up a high standard of attainments among those allowed to practise medicine within the State, has been acknowledged ever since the passage of the first medical practice act ten years ago. By that act applicants for a license must have attended at least three courses of lectures of six months each. The legislature just adjourned has gone a step farther, and has passed a bill providing that of all graduates of a later date than 1898 must have attended at least "four courses of medical lectures, in different years, of not less than six months' duration." From this it is evident that no student who after this year enters a medical school with a three years' course will be admitted to practise medicine in Minnesota unless he does enough post-graduate study to comply with the requirements.

The legislature was also liberal to the Medical Department of the State University, and gave it a grant

[1] Northwestern Lancet.

of $40,000 for the purpose of building a laboratory. This makes a total of $150,000 appropriated for buildings alone for this department during the last four years.

## THERAPEUTIC NOTE.

QUININE IN WHOOPING-COUGH. — G. Theodor Fischer, of Rochester, N. Y., influenced by the monograph of Baron in the *Berliner klin. Wochenschrift*, 1893, No. 48, on this subject, has employed the treatment and dosage recommended by Baron, since June, 1894, in his practice at Rochester, N. Y., in twenty-seven cases. In summing up his experience in an article in the *New York Medical Journal* for May 11, 1895, he comes to the conclusion that quinine, given in proper doses, is the best remedy for whooping-cough at present known, for the following reasons:

(1) It diminishes the number of attacks essentially in five days at latest; (2) it reduces even the most vehement whooping-cough to a mild bronchitis in twelve to fifteen days; (3) it influences most favorably a possibly existing broncho-pneumonia; (4) it often stimulates the appetite.

# Correspondence.

## COLLODION IN PLASTIC OPERATIONS.

SALEM, May 13, 1895.

MR. EDITOR: — A quarter of a century ago, there appeared in the JOURNAL (April 14, 1870) a decidedly original and readable article on "The Surgical Lessons of the Late War," by Dr. Asterisk, A.M., M.D., LL.D.

His paper illustrated in a most graphic manner the value of *ichthyocollæ preparata Spaldingii* in medical and surgical practice; but, like many much-vaunted new remedies, this one has apparently passed into oblivion.

Speaking seriously, there is a therapeutic agent of undoubted value in many cases of plastic surgery that is less employed than its merits deserve; reference is made to the officinal collodium of the *United States Pharmacopœia*.

By its use the inconvenience and pain of sutures can frequently be dispensed with. For example, when inversion of the lower eyelid is present, as is not uncommon in elderly people, and which naturally causes much annoyance, it is sufficient (Noyes), not infrequently, to apply two or three coats of collodion on the skin below the in-turned lashes, and repeat its application every two or three days for some weeks, till either relief follows or the patient consents to have a strip of skin excised. When the latter is done, fibres of cotton saturated with the collodion will keep the edges of the wound in perfect apposition during the healing process, sutures not being called for.

Its contractile property is also of value after the out-scooping of cysts on the eyelids. They are ordinarily incised through the tarsal surface, and when evacuated the sac sometimes becomes much distended by hemorrhage and occasionally an abscess is the sequel. Collodion applied on the skin over the site of the chalazion expels the blood and brings the walls together and so promotes immediate union. This is favored by inserting a drop of castor oil in the line of the incision, which it tends to keep open for a day or two.

Since calling attention in these columns a year or two ago to the use of collodion on distended tear-sacs it has, in several instances, continued to be of help in abridging the treatment of this not uncommon affection.

Very respectfully,

DAVID COGGIN, M.D.

## METEOROLOGICAL RECORD,

For the week ending May 11th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

From whooping-cough New York 6, Philadelphia 4, Brooklyn 3, Boston, Cincinnati and Haverhill 1 each. From cerebro-spinal meningitis New York, Worcester and Lynn 2 each. Cleveland and Somerville 1 each. From

erysipelas New York 5, Philadelphia, Pittsburg and Brockton 1 each. From small-pox Philadelphia 3, Cincinnati 2.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530 for the week ending May 4th, the death-rate was 17.5. Deaths reported 3,551; acute diseases of the respiratory organs (London) 290, whooping-cough 90, measles 80, diphtheria 49, diarrhea 39, fever 24, scarlet fever 22, small-pox (London) 1.

The death-rates ranged from 10.6 in Nottingham to 26.7 in Burnley, Birmingham 16.9; Bolton 20.1; Bradford 16.6; Bristol 13.3, Gateshead 15 2, Hull 21.4, Leicester 12.4, Liverpool 23.2, London 23.9, Newcastle-on-Tyne 16.6, Manchester 23.9, Portsmouth 11.9, Sheffield 18.4.

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FIFTEEN DAYS ENDING MAY 15, 1895.

W. A. WHEELER, surgeon, detailed as Chairman Board for physical examination of applicants for appointment in Revenue Cutter Service, May 13, 1895.

J. H. WHITE, passed assistant surgeon, detailed as Recorder Board for physical examination of applicants for appointment in Revenue Cutter Service, May 13, 1895.

P. M. CARRINGTON, passed assistant surgeon, granted leave of absence for fourteen days, May 4, 1895.

J. O. COBB, passed assistant surgeon, granted leave of absence for fourteen days, May 1, 1895.

---

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 11, 1895, TO MAY 17, 1895.

CAPTAIN CHARLES RICHARD, assistant surgeon, will when relieved from duty at the Military Prison, Fort Leavenworth, Kansas, proceed to and take station at St. Louis, Missouri, for duty as attending surgeon, and examiner of recruits.

CAPTAIN PETER R. EGAN, assistant surgeon, is relieved from duty at Fort Custer, Montana, and ordered to Fort Assiniboine, Montana, for duty, relieving MAJOR CHARLES B. BYRNE, assistant surgeon. MAJOR BYRNE on being thus relieved is ordered to Fort Snelling, Minn., for duty.

MAJOR WILLIAM C. SHANNON, surgeon, upon the expiration of his present leave, is ordered to Fort Custer, for duty.

FIRST LIEUT. DRANE C. HOWARD, assistant surgeon, will be relieved from duty at Fort Snelling, Minn., upon the arrival there of MAJOR CHARLES B. BYRNE, surgeon, and will then proceed to Fort Custer, Montana, and report for duty, at that post.

CAPTAIN ALONZO R. CHAPIN, assistant surgeon, having been found by an Army Retiring Board incapacitated for active service on account of disability incident to the service, is by direction of the President retired from active service this date, May 10, 1895.

Leave of absence for four (4) months, to take effect on being relieved from duty at Fort Thomas, Kentucky, is granted CAPTAIN WILLIAM J. WAKEMAN, assistant surgeon, U. S. Army.

Leave of absence for one month and fifteen days, to take effect on or about June 16, 1895, is granted MAJOR WILLIAM E. WATERS, surgeon, U. S. Army.

The extension of leave of absence on surgeon's certificate of disability, granted MAJOR WASHINGTON MATTHEWS, surgeon, is further extended four months, on surgeon's certificate of disability.

---

## AMERICAN SURGICAL ASSOCIATION.

Programme of the Annual Meeting to be held at the New York Academy of Medicine, Nos. 17 and 19 West 43d Street, New York, May 28, 29 and 30, 1895. Members of the Medical Profession are cordially invited to attend the meetings of the Association, except when it is in the Executive Session.

### TUESDAY, MAY 28th.

*Session* 9.30 A. M. *to* 1 P. M. — Roll Call. President's Address. Executive Session. Discussion on the Operation for the Radical Cure of Hernia. By Drs. William T. Bull, of New York, Charles McBurney of New York, Henry H. Mudd, of St. Louis, John E. Owens of Chicago and John H. Packard of Philadelphia. Results of the Treatment of Hypertrophy of the Prostate Gland by Castration, Dr. J. William White, of Philadelphia. Discussion by Drs. L. S. Pilcher, of Brooklyn, Roswell Park, of Buffalo, and William S. Halsted, of Baltimore. Operative Treatment of Cancer in Various Localities: 1. Anatomical Arrangement of the Lymphatic Vessels in the various regions, by Dr. F. H. Gerrish, of Portland, Me.

Clinic at Bellevue Hospital, 2 to 3.30 P. M. (Dr. Dennis and the Visiting Staff.) Clinic at Presbyterian Hospital, 4 to 5.30 P. M. (Drs. McCosh and Bridden with Drs. Pilcher and Wight.)

### WEDNESDAY, MAY 29th.

*Session* 9.30 A. M. *to* 11 A. M. — Operative Treatment of Cancer in Various Localities (continued): 2. The Female Genital Organs including the Uterus and Vulva, Dr. John Homans, of Boston. 3. The Lips, Tongue, Floor of Mouth and Pharynx, Dr. P. S. Conner, of Cincinnati. 4. The Breast, Dr. J. S. Wight, of Brooklyn. 5. The Male Genitals, Dr. Hunter McGuire, of Richmond, Va.

Clinic, New York Hospital, 11.30 A. M. *to* 1 P. M. (Drs. Weir, Bull, Hartley and Murray with Drs. Gerster and Abbe.) Clinic, Roosevelt Hospital, 59th Street and 9th Avenue, 3 to 5 P. M. (Dr. McBurney, with Drs. Lange, Fowler and Rushmore.)

### THURSDAY, MAY 30th.

*Session* 9 30 A. M. *to* 1 P. M. — Operative Treatment of Cancer in various Localities (continued): 7. The Rectum, Dr. Arpad G. Gerster, of New York. Discussion by Drs. L. McLane Tiffany of Baltimore, Theodore A. McGraw of Detroit, C. H. Mastin, of Mobile, and L. S. Pilcher of Brooklyn. The Present Status of Anesthesia: 1. Circumstances under which chloroform is preferable to Ether as an Anesthetic, Dr. G. W. Gay, of Boston. 2. Influence of Ether upon the Kidneys, Dr. Robert F. Weir, of New York. Discussion by Drs. T. F. Prewitt of St. Louis, H. R. Wharton of Philadelphia, J. D. Rushmore of Brooklyn, Robert Abbe of New York and F. E. Lange of New York. Discussion on the Restoration of Joint Function after Fracture. By Drs. W. H. Carmalt of New Haven, L. A. Sayre of New York, N. P. Dandridge of Cincinnati, J. B. Roberts of Philadelphia, E. H. Bradford of Boston and John Ashhurst, Jr., of Philadelphia.

*Afternoon*, 3 P. M. The Bacteriological Aspects of Pus and Suppuration, Dr. Roswell Park, of Buffalo. Discussion by Drs. W. S. Halsted of Baltimore, L. M. Tiffany of Baltimore and John Parmenter of Buffalo. Gunshot Wounds of the Heart, Dr. Claudius H. Mastin, of Mobile. Injuries to Pneumogastric and Phrenic Nerves, Dr. Roswell Park, of Buffalo. Dislocation of the Ulnar Nerve at the Elbow, Dr. Henry W. Wharton, of Philadelphia. Ligature of the Innominate Artery, with the Report of a Case, Dr. H. L. Burrell, of Boston. Immediate Suture of the Gall-Ducts and the Gall Bladder after Extraction of Stones, with Cases, Dr. J. W. Elliot, of Boston. A Case of Cholecystotomy, Dr. S. H. Weeks, of Portland, Me. Personal Experience with Mad Dogs, Dr. Basil Norris. Hernia of the Bladder as met with during Operations for Inguinal and Crural Hernia, Dr. Christian Fenger, of Chicago. The Radical Cure of Hernia by a New Procedure, Dr. John H. Packard, of Philadelphia. Ligature of the Spermatic Cord in the Treatment of Hypertrophy of the Prostate, Dr. J. Ewing Mears, of Philadelphia. Congenital Esophageal Pouch, Excision, Immediate Suture of Esophagus, Recovery, Dr. S. J. Mixter, of Boston.

---

## RECENT DEATH.

GEO. A. PERKINS, M.D., M.M.S.S., died at Salem, May 18th, aged eighty-two. He graduated in medicine at Harvard in 1844, and went to West Africa as a medical missionary. He returned to Salem in 1849, and practised there until 1863, when he became post-surgeon at Forts Lee and Pickering. He was interested in macroscopy and chemistry, and was a member of numerous scientific and social organizations. He was one of the original staff of the Salem Hospital.

## TRANSVERSE SEPTA OF THE VAGINA.[1]

BY A. K. STONE, M.D.

During the summer of 1893 there came to the out-patient clinic at the Massachusetts General Hospital three cases of transverse septum in the vagina. All three occurred in young women who had never borne children, and in none was there any history of injury or instrumentation which would account for the condition. The rarity of this anomaly was forced upon me, for, questioning a number of gynecologists and obstetricians in Boston, Baltimore and Washington in regard to the frequency with which they had met transverse septa, with very few exceptions they stated that they had never seen such a condition.

While visiting the Columbia Hospital in Washington, in company with Dr. J. F. Scott, I chanced to mention the subject; and the house physician, Dr. Murphy, said that such a case was then in the hospital, and that he had seen still another in the out-patient clinic. Dr. Scott has since then seen a case in private practice. With great kindness he has placed his cases at my disposal, and I take this opportunity to acknowledge his courtesy.

My cases are briefly as follows:

Case I was an unmarried woman of twenty-one or twenty-two years, who came to the examining-table because of symptoms which made me suspect the possibility of pregnancy. She was well developed, and everything about the external genitals appeared normal. The hymen was not intact. About two inches from the introitus the examining finger came upon a barrier to further advance. Finally a small opening was found which with considerable difficulty allowed the admission of the tip of the finger, which could then be made to feel the os beyond. The os was soft and the uterus enlarged, and pregnancy of about four months diagnosed. With the speculum the obstacle which had prevented the free examination was found to be a thin membranous septum completely blocking the whole lumen of the vagina with the exception of a small central opening. The membrane was elastic and had no different appearance from the rest of the mucous membrane of the vagina. Anteriorly the septum was in close connection with the vaginal portion of the cervix. There was no thickened portion that would in any way make one suspect the septum to be of inflammatory origin. All injuries were denied. Menstruation had always been regular and normal up to the time of the pregnancy. I lost track of the patient in spite of my attempts to have her confined at the Boston Lying-in Hospital; and as she also changed her address, I have not been able to obtain any account of the confinement.

Case II was a young unmarried woman who feared pregnancy, and was in every way a duplicate of the first case, excepting that there appeared to be a few bands running from the cervix and connecting with the membranous septum. Menstruation here had been normal. This patient, too, has been lost sight of, in spite of attempts to trace her.

In each of these cases the opening through the septum was of nearly one-half inch in diameter, and the edges were thin and sharp, and presented no inflammatory conditions. The septum formed an almost closed pouch at the upper portion of the vagina, into which if the semen once gained entrance, there would be a condition most favorable for conception.

Case III is somewhat different. This patient had a uterine displacement and some endocervicitis consequent to this. Examination of the cervix was attended with great difficulty, from the constant tendency of the speculum to slip. Careful investigation into the cause of this showed that about two inches from the introitus there was a distinct narrowing of the lumen of the vagina by a ridge of tissue. This ridge was scarcely perceptible to the examining finger when introduced in the ordinary manner, but a distinct thickening could easily be made out if the finger was passed so as to press against the vaginal wall. There was no history here of previous injury or of any operation. Neither was there any tendency to contraction. The ring was so high up that when the Sims speculum was introduced the tip caught upon the ridge, and instead of falling into the posterior cul-de-sac slipped forwards. Hence the difficulty which led to the discovery of the condition.

Dr. Scott's cases are as follows:

Case I was a colored girl about eighteen, who was well formed and well developed. She had always menstruated regularly and had never known that she was in any way different from other girls. She presented herself at the Columbia Hospital, in Washington, early in November, 1893, being then nearly at full term. On examination the os could not be found, but about one and three-quarters inches from the entrance of the vagina the finger came against a smooth, soft, yielding membrane which completely occluded the vagina. At the centre alone there was a little roughness. Examination with the speculum showed a small opening which would admit the entrance of a uterine probe. The edges of the opening were somewhat thickened, as though at some time there had been a slight inflammation. The membranous septum could not be stretched enough to make a bimanual examination to determine the position of the head of the fetus. About a week later, labor pains came on and the os evidently dilated in a perfectly normal manner, for the head entered the vagina and bulged the septum, which held firm and resisted for several hours the further advance of the head. A probe-pointed bistoury was passed through the opening, and the membrane was slit in several directions to the vaginal wall and the remainder of the labor was rapid and normal.

Case II was a white woman, age thirty-three, who had been married for two years. Menstruation first appeared at fourteen, but was not seen again until she was seventeen. At this time she suffered severely, and the lower abdomen swelled considerably, and at times there was difficulty of urination. With the recurrence of menstruation at seventeen, "there was an awful quantity of it, and the flow was black and tarry." Since then there have been several periods of intermission in the flow. When first seen she was habitually suffering with free menstruation continuing for fifteen days at a time. The menstrual flow was described as being like "coffee grounds." There was severe pain all this time, but no clots were passed. After the "tarry-like" flow had ceased a very offensive flow, like the "yolk of an egg," followed. The

[1] Read, by invitation, before the Obstetrical Society of Boston, March 9, 1895.

patient was habitually constipated, often going for twenty days without any movement of the bowels.

Passing the finger into the vagina an obstruction to its further advancement was met at the depth of one and one-half inches from the hymeneal orifice. With the aid of the speculum an opening to the right and anterior to the centre was found, which just admitted the passage of a uterine sound into a spacious cavity beyond. By rectum the uterus was to be felt, small and straight and much flattened and in comparatively normal position. There were no adhesions, and the uterus was freely movable.

An operation was performed April 6, 1894, under chloroform. A probe-pointed bistoury was used to cut the opening large enough to introduce the finger. A catheter was passed into the bladder to define the course of the urethra, and then the opening was much enlarged. The septum was very dense and tight, and fully one-eighth of an inch thick. After cutting, the parts were forcibly distended by the fingers to the normal size of the vagina. The vaginal mucous membrane retracted much both upwards and downwards from the cut septum. The vagina was then packed snugly with iodoform gauze, and the denuded surface left to granulate. The packing was removed daily, and the vagina washed with lysol (1–100) and repacked.

Since the operation the patient states that the tenderness in the lower abdomen, which she has had for years, has disappeared.

The literature of this subject, with one exception, is confined to the reports of single cases; and it is rare that any one man has had an opportunity to see more than two such cases. Therefore it may be of interest to give a partial *résumé* of some of the cases already reported, in addition to the above-mentioned five cases.

Amédee Maurin, in 1875, reported a septum with three openings more than half-way up the vagina. This patient had menstruated regularly, but had had no children. The septum was removed, and there was no further history. This case is interesting, as the reporter thinks that the septum was due to an inflammatory process which was the result of small-pox which the patient had contracted at the age of twelve, though there was no direct history to be obtained to point to such a conclusion.

More recently Dr. Osmont, of Caen, has reported a case where a woman of thirty was confined, and after a long labor was delivered by forceps. Later she presented herself at the hospital with a recto-vaginal fistula, and with a transverse septum in the vagina still intact. The head had descended until it had reached the septum, and after several days had torn through the posterior wall of the vagina and so, *via* the rectum, had passed round the obstruction and into the vagina again, whence the instrumental delivery took place. The septum in this case had a small opening, and menstruation had been regular since the age of fourteen. This septum was situated three and a half centimetres above the hymen.

Ostermann states that he has found for the most part that the septa occur in the upper third of the vagina, though he found that there had been but little work done upon the subject in France and still less in Germany. In the discussion of this paper Oderbrecht reported a case occurring in the upper third of the vagina where the woman was sterile. The septum was cut, and a favorable result was obtained. Here the opening would simply admit of a probe, and the menstruation was painful. Grimm, at the same time, reported a case which he has under observation at the present time. The patient was a Japanese girl of eighteen; and though there was only a pin-hole opening through the membrane, there were no unpleasant symptoms at the menstrual period.

In three successive years cases were reported to the Obstetrical Society in London. In Smith's case the catamenia had been regular, though scanty and accompanied with some pain. The patient had been married for a number of years, and coitus had probably taken place through the urethra, which was dilated so that it admitted two fingers with ease. One and one-half to two inches above the vaginal opening there was a membrane, which at time of delivery and at previous outpatient examination presented no opening. In one part there were some apparent granulations which may have covered an opening previously present, otherwise there must have been some communication *via* the bladder. The patient came to the hospital while in labor. The septum was divided and dilated, and a safe delivery effected.

Boulton's case was evidently one where the remains of a longitudinal septum played an important part. The patient came to the clinic saying that she was not like other women, for after the regular menstrual flow, which lasted for three days, she had a discharge of "green waters" for several days. A septum was found, one and one-half inches in depth, in which no opening could be detected with the examining finger. When, however, the vagina was dilated with a speculum, two small openings were found on either side of the vagina; and on further examination it was found that a triangular shaped septum extended from the transverse septum nearly to the os. This case should rather be classed as a rudimentary double vagina than as a transverse septum.

Gervis found in a patient, presenting herself because of a urethral caruncle, that the vagina ended in a double cul-de-sac, and in the left side there was a small opening leading into the upper portion of the vagina. Menstruation had begun at fifteen years of age, and had continued ever since without trouble. There had been a slight leucorrhea, which promptly disappeared when the septum was removed. Carter also reported a thick septum through which the menstrual blood escaped by a very small opening, the process taking a very long time. This was operated upon with relief.

Doléris's case was that of a patient who came to the hospital in the course of a miscarriage at the sixth month. She had had regular catamenia since her seventeenth year. Examination under chloroform showed a very short vagina ending in a cul-de-sac which communicated with the upper part of the vagina by an opening which would admit of only the passage of a filiform sound. The patient returned to her home, but came back in a few days with the membrane bulging through the vaginal opening and the opening enlarged to one-half to three-quarters of an inch in diameter under the softening and dilating influences of the labor. The membrane was torn, and the fetus delivered in a few minutes.

In 1889 Cullingworth reported two cases in the *Lancet*. In the first, a widow, age thirty, presented herself for an offensive vaginal discharge. Catamenia

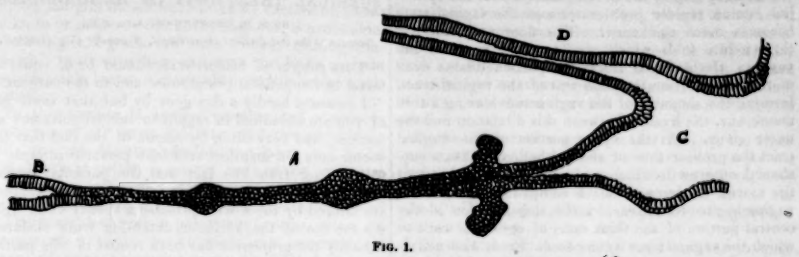

Fig. 1.

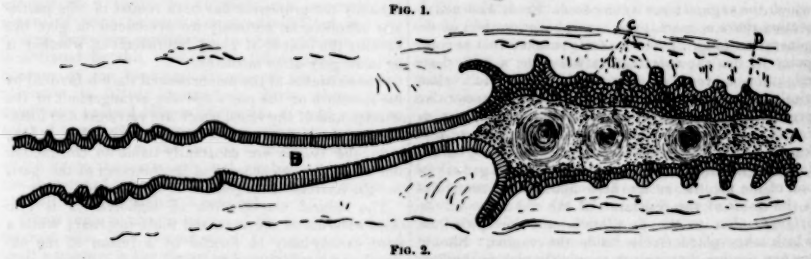

Fig. 2.

had come on at fourteen, and had been regular though preceded by pain. In the intervals there had been an occasional brown discharge, which at last became constant and offensive. The vagina was one and three-quarters inches in depth; and in the anterior part, a little to the right of the median line, was an aperture large enough to admit of the passage of a uterine sound. The opening was stretched and then torn to the vaginal wall, and after a few days' packing with gauze and wearing a glass speculum, the patient was discharged. Two months later there was no erosion, and except for a little ridge to mark the spot, the vaginal walls were smooth and normal. The second case was a woman, age twenty-three, who was admitted in labor because no os could be made out. Catamenia had appeared at twelve years of age, and had been regular until after marriage. There was habitually a slight discharge between the periods, but without ill odor. A membrane was found about midway in the vagina, and a little posteriorly to the centre was a nodule, and at the side of the nodule an opening which with difficulty admitted the tip of the forefinger. The opening was dilated and the septum torn, and the labor was finished without any further incidents. When discharged there was only a slight ridge to be felt along the anterior wall.

Heyder gives a very full report of a case seen by him. The patient was six months pregnant, and came to the hospital because of hemorrhage following a fall. There was found, one-half to three-quarters of an inch above the hymen, a septum through which there was only a pin-hole opening, situated near the symphysis and about one-twelfth of an inch in diameter. Menstruation had begun at fifteen, and continued quite normally and regularly. The membrane was split in the middle line and removed close to the vaginal wall with scissors. The vaginal mucous membrane was then united with fine stitches. The septum at its base was about one-twelfth of an inch in thickness. The membrane showed no sign of scar-tissue on most careful examination. When full term was reached, the woman was delivered in a perfectly normal manner.

Dr. J. R. Chadwick has reported a case operated on by him, in which he gives a diagram of the pelvis, showing the condition.

In the course of the history of the above-mentioned cases, there is only one in which there has been any report of the histological structure of the tissue of the septum, and in this there was no inflammatory scar-tissue found. In almost all of the cases there has been no history of instrumentation or inflammation and we must conclude that it is most probable that this rare condition is usually congenital. No attempt has been made so far as I know, to explain this phenomenon which presents many difficulties, and the theory which seems to me most probable, may not be supported by subsequent investigations.

The Wolffian ducts which form the genital tract fuse together during the third month of fetal life. The process begins about two-thirds of the way down the genital tract, and extends both upwards and downwards. It may be that the septum is the result of the fusion beginning in two places, and thus a band is left separating the upper and the lower portion of the vagina. Boulton's case is probably an example of such an incomplete fusion of the Wolffian ducts; but the majority of cases probably are due to the persistence of conditions belonging to a later stage of fetal development.

The fusion of the Wolffian ducts is completed by the end of the third month; and, in the course of the fourth month, the genital tract which has been already by a sharp bend differentiated into an upper (or uterine) and a lower (or vaginal) portion, becomes flattened, and the epithelial surfaces meet and grow together, forming an epithelial lamina (Fig. 1) which, near the opening into the uro-genital sinus, is thickened, presenting on section a T-shaped appearance.

The next step in the development is that the epithelial lamina rapidly proliferates and the vaginal tract becomes much thickened. The floor and roof are thrown into folds which persist as the rugæ of the vagina; the external thickened portion dilates even more in proportion than the rest of the vaginal tract, forming the ampulla of the vagina and leaving a thin membrane, the hymen, between this dilatation and the outer sinus. At the upper portion of the vaginal tract the proliferation of the epithelium makes a cup-shaped outgrowth which embraces the lower end of the uterus. During the sixth month the lumen of the vagina begins to appear by the degeneration of the central portion of the thick mass of epithelial cells of which the vaginal tract is composed. From Tourneux's section there appears to be several distinct foci of degeneration (Fig. 2), and it seems possible that at some point in the vaginal tract between these foci there might be a group of cells which could retain their vitality and not be involved in the degenerative process and thus a transverse septum of the vagina result. That this condition is different from that known as an imperforate hymen may be seen from the fact that the hymen does not arise from a growth of one of the papillæ, as has been affirmed by some, but is the result of the resistance of the end warts of the original tubes to the proliferation of the epithelium which takes place freely inside the vagina. Should for any reason the vaginal opening which at the fifth to sixth month is a mere fistulous tract with a diameter of only one-tenth to fifteen-hundredths of a millimetre (0.1 to 0.157 mm.) remain closed or fail to connect with the sinus, the condition of imperforate hymen results.

The fact that such a condition as transverse septum may exist and not be discovered until the woman is in labor, makes this anomaly of practical value to the obstetrician, for although the septum seems to offer a decided hindrance to labor, yet when it is recognized, simple division of the membrane is sufficient in most cases to allow a speedy delivery and effect a permanent cure.

TEXAS STATE MEDICAL SOCIETY. — At the annual meeting of this Society, held at Dallas on April 23d to 27th, Dr. P. C. Coleman, of Colorado, was elected President, Drs. Wagley, Kennedy and Bass, Vice-Presidents, and Dr. H. A West, of Galveston, Secretary. The next meeting will be held at Fort Worth on the fourth Tuesday in April, 1896.

## SURGICAL TREATMENT OF HEMORRHOIDS.[1]

BY E. H. TROWBRIDGE, A.B., M.D.,
*Surgeon to the Out-Patient Department, Worcester City Hospital.*

THIS subject of hemorrhoids should be of equal interest to the general practitioner and to the surgeon.

I presume hardly a day goes by but that some one of you are consulted in regard to this troublesome affection; and very often by reason of the fact that the doctor does not manifest sufficient personal interest in the case, or from the fact that the patients become tired of further dabbling with palliative measures, they are allured by those who promise a speedy cure, without the use of the knife, or detention from business. Possibly the profession has been remiss in this particular affection, for certainly we are bound to give our patients the benefit of every improvement, whether it be in surgery or in medicine.

The existence of the hemorrhoidal state is favored by the structure of the parts and the arrangement of the arteries, and of the veins, which are valveless and tortuous; in this locality more than in any other in the body, the vessels are constantly liable to contraction and relaxation, on account of the function of the part, and the intricate arrangement of the muscles.

The natural classification of hemorrhoids is into those external to the anus, and those internal; while a third variety may be formed by a fusion of the external and internal masses.

The external pile may consist of a tag of skin which, when irritated, becomes inflamed and hypertrophied, or it may be a bloody tumor caused by the rupture of a vessel; the clot becoming organized and undergoing a fibrous change, and the submucous and the subcutaneous tissue becoming hypertrophied, there results a large mass at the anal orifice.

The internal pile consists of tortuous and dilated veins and arteries, attended with more or less exudate in the submucous and subcutaneous tissue. These masses are soft and spongy; may be large or small; may be easily irritated, inflamed and ulcerated. The large pile generally protrudes at stool while the small pile is not so likely to prolapse. The blood-vessels being easily distended and the mucous membrane being thin, rupture readily takes place and hemorrhage results. It is this hemorrhage which constitutes the dangerous element of the internal pile; at each stool the patient may lose a large amount of blood, which in time renders him anemic and debilitated.

The special feature of the external pile is pain, which is aggravated after stool and when the pile is inflamed; the pain is intensified, by the patient sitting, standing or walking; the recumbent posture is the only one which offers relief.

The diagnosis of the hemorrhoidal condition can be readily made by ocular inspection; but in every case, never fail to examine digitally and that by the little finger; this is long enough to reach to the highest point where the piles are liable to exist, and by reason of its small size it gives the patient less pain than when any of the other digits are used in the examination.

Finding this affection existing in our patient, what method of treatment shall we adopt in order to effect a speedy cure, and that, too, agreeably to the patient and without pain?

[1] Read at the meeting of the Worcester District Society, January 9, 1895.

The treatment of the external hemorrhoid is very simple; the pile should be thoroughly excised by either the knife or scissors; the knife, however, is preferable. In excising it, I grasp the mass without making traction with small volsellum, and with the knife encircle the base; this leaves a clean, even surface which heals readily.

To this surface is applied vaseline, and a powder consisting of six parts iodoform and two parts boric acid; and the dressing of sterilized gauze and boric-acid absorbent cotton is placed next to the parts, and a T bandage adjusted. The wound is attended to daily, and convalescence is brief and uninterrupted.

There are, however, a great many cases where on account of a slight constipation, the hemorrhoidal plexus of veins becomes temporarily dilated, and the dilated parts are constricted by the sphincter, which is irritated by this varicose condition; then, too, on account of the heat and dryness of the rectum, the sphincter is tightly contracted. Now, where these conditions exist, I believe in the use of cold water to relax the sphincter muscle and to relieve the congested vessels, and also in the use of a soothing ointment, which keeps the parts soft and pliable. In this way the threatened permanent condition of hemorrhoids is aborted, and the patient is relieved.

I now come to the discussion of the treatment of the internal pile. The method which I have practised, and shall advocate, is the clamp and cautery.

The other methods, besides the clamp and cautery, are (1) injection of carbolic acid and glycerine, (2) crushing, (3) caustics, (4) ecraseur, (5) excision, (6) strangulation by ligature.

I suppose every person here has been taught that the ligature method was *the* one to use; and being schooled to this method, it is somewhat difficult to abandon it, even for a better one. I am convinced, however, if you once use the clamp and cautery as I believe it should be used, you will never torture your patient with the ligature.

The method which I have used for the last three years is as follows: Patient to be prepared the day previous by saline laxatives, and on the morning of operation the lower bowel is *thoroughly* cleared out by enema. After complete anesthesia the parts are shaved, and irrigated with bichloride solution.

After thoroughly stretching the sphincter, by the thumbs, the pile-bearing area rolls out, presenting to view the various masses. These should be grasped one by one by the volsellum, and raised sufficiently to allow the clamp to be applied.

The ivory plate of the clamp should grasp the pile completely at the anus, at the junction of the skin and mucous membrane, and also in a line *longitudinal* to the bowel, *never obliquely* to that. After the clamp is tightened, then with a pair of curved scissors cut off the mass close to the clamp, and then apply the cautery at a red heat until the base *ceases* to bleed.

After removing all the hemorrhoidal masses in this way, there will be formed at the base of each pile, a cicatrix, longitudinal to the bowel, and these cicatrices will radiate from the anus, like the spokes of a wheel. I emphasize this point of applying the clamp in the longitudinal line of the bowel, for then we have the cauterized bases uniformly arranged in lines about the anus, and after they are healed, there is a uniform appearance of the part and if any contraction should result, it would be uniform.

You can readily see that if the pile is grasped obliquely by the clamp and removed, we will then have a series of irregular cauterized lines, some in one direction, and others in other directions, to which after they are healed, the cicatrices are liable to give an irregular and uneven appearance, and if there should be any contraction, it would be irregular about the anus.

In the most recent work on this subject, the illustration, showing how to grasp the hemorrhoid by the clamp, represents the clamp applied at an angle of about forty-five degrees to the longitudinal line of the bowel, while it should be in the direct longitudinal line of the bowel.

The wound is dressed in the same manner as mentioned after excising the external hemorrhoid, namely, vaseline should be applied, and then a powder, consisting of six parts iodoform and two parts boric acid, dusted on, then sterilized gauze and boric-acid absorbent cotton placed on the parts, and finally a T-bandage; sometimes a gauze tampon is inserted in the rectum, when there is a tendency to ooze.

The great bugbear in the use of the clamp and cautery is hemorrhage; but, I ask, why should hemorrhage be any more of a bugbear here than in any other surgical operation? On this account, there are very few, comparatively, who employ the clamp and cautery, and the operators who still use the old ligature method justify their use of it by saying that there is no danger of hemorrhage; well, there certainly ought not to be, after tying off as tightly as possible these masses. But there are other means besides the ligature to control hemorrhage.

The clamp serves the purpose of a hemostatic, as it grasps the pile; the blades are tightly pressed together, and held there by the thumb-screw, and firm pressure is thus maintained during the time it takes to cut off the pile and use the cautery. I have never experienced any hemorrhage in any of the cases I have operated upon.

I desire to present briefly, a few cases from many operated upon, illustrating the superiority of this method over all the others. These cases are not selected, but taken at random, from my notes.

Case I. Dr. P., dentist, age thirty-nine. Operated upon in October, 1893. Dr. P. had suffered for a long time with internal hemorrhoids; they had especially troubled him while standing, and thus incapacitated him from attending to his patients. Being unable to endure the misery any longer, he was referred to me by Dr. Fay, for operation.

After stretching the sphincter, a rosette of piles presented themselves. The operation was done at the patient's residence, and in a room heated by a coal stove. The operating-table was placed near by the stove, and I here used a common poker to cauterize the bases of the hemorrhoidal masses. The wound was dressed with vaseline and the iodoform-boric-acid powder. The patient made uninterrupted and rapid recovery; there was no pain; no retention of urine; no severe soreness; no long detention in bed.

Case II. Mrs. B., wife of a physician, age fifty-two. Operated upon in May, 1893, with clamp and cautery. This patient being a large, fleshy person, suffered exceedingly from hemorrhoids of the muco-cutaneous variety. Extreme irritation of the rectum, pain, soreness and tenesmus were the principal symptoms, and these symptoms she had endured a long time, though alleviated by palliative measures.

Operative treatment had been frequently advocated, but

being fleshy, she feared the ether. The operation was performed, as before stated, and the patient kept in bed about two weeks. The anal surface was dressed with the iodoform-boric-acid powder and vaseline.

This patient told me the other day, that she was in perfect health, and had never experienced any symptoms which would remind her of the fact that she had suffered from piles.

CASE III. Mrs. K., age twenty-two. Operated upon on December 30, 1893. A mass of hemorrhoids presented themselves, after stretching the sphincter. These had given her trouble for a long time.

They were removed by the clamp and cautery. In this case I used a hot poker for cauterizing; the parts were dressed with vaseline and the iodoform-boric-acid powder. Patient made uninterrupted recovery, and was free from any pain or discomfort during convalescence; there has been no vestige of the former trouble.

CASE IV. Mrs. H., age thirty-four. Operated upon Friday, July 13, 1894. Mrs. H. had suffered from internal hemorrhoids since graduating from school, and by reason of the loss of blood at the stools, had become very anemic. After examining the patient, an operation was advised, and she readily consented to have it done at the earliest opportunity.

The hemorrhoidal masses were large, and entirely encircled the anus. These were removed by the clamp and cautery, and parts dressed as in the other cases.

Mrs. H. was seen on the 14th, 15th, 17th and 20th; and on the 23d, a week from the following Monday after the operation, she went to Fitchburg. From the time of recovery from the ether, there was not the slightest pain or discomfort; no trouble in micturition. On the fourth day following, the bowels were gently relieved by a saline laxative. A few weeks ago, this patient came to my office, and I asked her in regard to her present state of health. She replied that she was in perfect health; she had gained in flesh, and the anemic condition had disappeared.

CASE V. Mr. W., from North Brookfield, age fifty. Operated upon in October, 1894 (Friday, 12th). This patient had suffered more or less during the past twenty years; for the past eighteen months had been unable to do any work. First saw the patient on the 11th of October. At that time a large mass of muco-cutaneous, inflamed and irritated hemorrhoids presented; they were very painful when sitting and in walking. These were removed by the usual method with clamp and cautery. Anal surface dressed with the iodoform-boric-acid powder and vaseline.

Saline laxative administered on fourth day, and bowels moved without pain. Patient was free from pain during all the time after the operation; no retention of urine; no soreness.

Mr. W. went home on Saturday the 20th, just a week from the day following the operation.

CASE VI. Mrs. D., widow, age thirty-two. Operated upon July, 1893. This case I operated upon for Dr. Fay, and I cite this in contrast to the others, as here I used the ligature on account of some trouble with the cautery. This patient had become anemic, on account of the hemorrhage attending the internal piles, and was forced to undergo the operation.

The hemorrhoids were ligated, and the wound treated in the usual way. I expressed to the attending physician, that I regretted using the ligature, as I was sure the patient would experience the torture and misery which usually follows.

In this case, patient was confined to bed for over two weeks; the ligatures did not come away until about the eleventh day; on recovery from the ether, the pain was excruciating, and hypodermics of morphia were required, more or less, for a week following the operation, also inability to pass the urine gave the patient additional pain, and required the use of the catheter. When the bowels were first evacuated, after the operation, the patient suffered exceedingly, as the ligated masses acted as an obstruction, and when the sphincter ani dilated and contracted, these ligated stumps were subjected to pressure and irritation.

I resolved that I would never operate again with the ligature.

It is hardly necessary for me to cite numerous other cases, all bearing the same favorable evidence, in behalf of the clamp and cautery.

As compared with the other methods, what shall we say?

The carbolic injection is dangerous and inefficient, and is liable to cause peritonitis, embolism and pyemia; and if a cure is effected, it takes a long time, and causes the patient much suffering.

The crushing method I have not tried; but it is liable to cause sepsis on account of the jagged base of the crushed pile and sloughing is liable to result.

The use of caustics is to be avoided for the same reason: danger of sepsis.

Of all the methods hemorrhage is most liable to occur in the use of the ecraseur.

The ligature, while it is the simplest of the radical cures for the internal hemorrhoid, causes the patient severe pain from the time of operation until the ligatures come away; retention of urine, from a few days to a week or more, is the almost universal rule; difficult and painful defecation; confinement in bed from twelve to fourteen days.

If there is any one present who has undergone the ligature operation, I think they can sympathize with the speaker, in saying that they are not very desirous to repeat the experience of the first ten days following the operation.

The Whitehead method, that is, excising that portion of the mucous membrane which contains the hemorrhoidal plexus is not all that was promised for it. It should be employed only in selected cases. Full and complete paralysis of the sphincter muscle is absolutely necessary. The operation is difficult, tedious and bloody; and if non-union occurs, there is retraction of the mucous membrane, and a large circular granulating area left, which may be the source of sepsis. Retention of urine is also liable to exist for a week or ten days.

In the case of the clamp and cautery, none of the above mentioned consequences or complications occur.

The operation can be done (1) expeditiously, and with little loss of blood; (2) the cauterized base of the pile is rendered aseptic by the cautery; (3) there is no pain following the operation; (4) retention of urine is extremely rare (I have never seen a case where the patient suffered from retention); (5) convalescence is brief and uninterrupted — confinement in bed from three to seven days is sufficient.

Such in brief are the advantages in operating with the clamp and cautery.

## Clinical Department.

### EARLY CURETTING IN PUERPERAL SEPSIS.[1]

BY HORACE E. MARION, M.D.

MRS. ——, twenty-eight years of age, fell in labor on the morning of the 25th day of January, 1895. Second pregnancy and second child. Her first con-

[1] Read, by invitation, before the Obstetrical Society of Boston, March 9, 1895.

finement was without incident. Labor, still in the first stage, was well underway when I first saw her. Before making an examination, the toilet, if I may use the word, of the vagina and pudenda, as well as my own hands, was carefully attended to.

Presentation O. L. A. The labor was perfectly natural, and terminated within four hours. No examinations were made after the first, except to protect the perineum during the passage of the head. There was no tearing of the soft parts. The patient was not in the least exhausted. The baby was a girl and weighed seven pounds. The placenta, apparently intact, followed in about ten minutes. Sterilized napkins were used.

For five days the temperature and pulse, taken by myself, were absolutely normal. At my visit on the sixth day patient complained of having passed a sleepless night, with pain in the head and back of the neck. Temperature and pulse 100. Very slight odor to the lochia, and slight tenderness to pressure upon the uterus, which seemed about as large as it was twenty-four hours after labor. There was nothing else, so far as I could learn after careful examination, to account for the elevation of temperature.

On the following day, the seventh, the temperature was a little higher. Pulse about as the day before. Bowels had been moved freely. Condition of the uterus about the same, with no more odor to the lochia. Headache not relieved. On the morning of the eighth day the temperature was 102° and pulse 110. Headache and insomnia. Flow of milk very much diminished. Lochia about the same in character as the day before. Vaginal douche had been used.

Bimanual examination showed the uterus larger, with flabby walls, os patulous. Specular examinations revealed no lesions of vaginal walls or of the cervix. With the usual aseptic precautions the cervix was seized with double hook and the interior of the uterus was carefully and thoroughly curetted with large sharp curette, resulting in the removal of a piece of tissue, presumably placental, from two to three inches square. No microscopic examination was made and no cultures were taken; it was slightly offensive. The uterine cavity was left packed with iodoform gauze, which was removed on the following day. The temperature fell at once, as may be seen by the chart, and recovery was rapid, the uterus promptly returning to a normal condition. The internal medication was two grains of quinine three times daily and Dover's powder as necessary.

I have selected this case for no special reason except that it is the last one in a limited obstetrical practice that required any interference. I have purposely given a detailed account of it because it seemed so very simple. So simple, indeed, that, had not the indications been met as they were, it might have eventuated in a very decided and possibly fatal case of puerperal septicemia. I regret that no cultural test was made.

It is from this Society, and such as this, that the science of obstetrics in general practice must be advanced; and I cannot too strongly emphasize the indications for and the method of curetting the puerperal uterus laid down by Dr. Edward Reynolds in his excellent paper read before the Massachusetts Medical Society at its last annual meeting.

The point I wish to bring out in this case is the timely use of the curette, to ascertain if there is within the uterus a possible source of sepsis. The interior of the uterus was *carefully* gone over with a sharp curette, as we believe, without any injury to the endometrium. As the tissue removed, be it placental or otherwise, was not in an advanced stage of necrosis, we were content, without deeper curetting, to leave the uterus packed with iodoform gauze. Of course, had it been evident that the deeper structures were involved, I should have removed everything down to firm uterine tissue, as Dr. Reynolds insists upon.

I have never used the cervical speculum in these cases. The canal is so large and patulous there can be but little danger of retained douche; besides where gauze is used for packing, the cavity of the uterus is readily drained. Moreover, in severe cases, the interior of the uterus, down to and about the os, should be thoroughly curetted.

The country obstetrician, especially in the past, has labored under the great disadvantage of being either without a nurse at all, or what is quite as bad, having a nurse with a limited personal experience and absolutely without training, always ready to account for any symptom that may arise and to apply a remedy therefor.

Thanks to our many and excellent training schools, this condition of things will soon pass away.

With a nurse faithful to her training and a physician who has the courage of his convictions, sepsis in midwifery will be rare indeed.

## CASE OF SEPTUM OF VAGINA.

BY S. W. TORREY, M.D., BEVERLY, MASS.

Patient, single, about twenty years old, applied to me in March, 1892, for relief from suffering from dysmenorrhea and general pelvic discomfort. Examination showed intense hyperesthesia of entire vagina up to within three-quarters of an inch of the cervix, where the finger struck against a tight transverse septum, cord-like in its tenseness, and so sensitive that the slightest rubbing of the finger over it caused the patient to cry out with pain. The surface of the cervix, as far as it could be examined visually beyond the septum, was red and rough from friction upon the band.

After two or three weeks of treatment by ichthyol on cotton between the cervix and the septum, with improvement in the inflammatory condition but none in the neuralgic, the patient entered my hospital; and her subsequent history, from my case-book, is as follows:

April 21st, patient fully etherized, as slightest touch to septum caused pain under partial anesthesia. Even when under deep anesthesia stretching the septum evidently gave pain, as patient writhed with discomfort. When vagina was distended by Sims's speculum it was seen that the probable cause of the local pain and general neurasthenia was the chafing of the cervix upon the tightly-drawn, cord-like septum. The septum was divided in two places, close to wall of the vagina; no ligatures required. Iodoform gauze to cervix, and large glass vaginal plug inserted.

April 23d. Result of operation entirely successful; pain relieved, and Sims's speculum applied without giving discomfort. Boric-acid to cervix; tampon to upper part of vagina.

Patient discharged from hospital April 25th. My

notes show that local treatment for the cervicitis extended over two months after dividing the septum, and that persistence in the use of ichthyol was followed by cure. There was no stenosis of vagina as a result of the division of the septum. Careful questioning of the patient revealed no traumatic cause for the abnormal condition of the vagina, and I believe the septum to have been congenital.

## Medical Progress.

### RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

(Continued from No. 20, p. 490.)

#### RESECTIONS OF THE ILEO-CECAL COIL FOR STRICTURE AND FISTULA.

W. S. Magill, of Chicago, has contributed a paper on the above subject to the *Annals of Surgery*, December, 1894, with a review of 104 cases. He says that excision of the cecum should be attempted in every case of primary neoplastic tumor where extensive infiltration of the vicinity or ganglia is not present to forbid the intervention.

Tuberculosis or inflammation localized at the ileo-cecal coil should determine its resection in every case in which the immediate operation is possible without surpassing the patient's power of resistance, provided that other tubercular localizations be not so extensive as to render the advantage of this radical operation only temporary.

Examination of reports of tubercular cases leads to the hypothesis that operated appendicitis with unsatisfactory results — persisting fistula, repetition of accidents, induration, etc. — is amenable to resection, and that primary excision of the ileo-cecal coil would be less dangerous than and preferable to excision for fistula. A careful diagnosis should therefore be made to determine this point before operating.

Invagination in the region of the cecum is frequently complicated with cancerous disease; and in any case of resection the excision should be extensive to assure the result.

The longer the time that separates the actual condition of the parts from a state of acute inflammation, the better are the results of the operation assured.

Fistula of the ileo-cecal coil can safely be treated by resection, if no extensive suppuration has invaded, nor been allowed to enter, the iliac fossa.

An irreducible cecum may be excised with safety.

After resection, in all cases, the continuity of the digestive tract must be immediately established and secured against leakage. The only exception might be made for acute obstruction.

The continuity has been sought by uniting the intestine, with sutures, with a lateral anastomosis with absorbable plates, with a terminal or lateral implantation of the ileon into colon, best effected with the anastomotic button.

The greater part of the mortality of resection of the ileo-cecal coil is directly imputable to the insufficiency of the sutured intestine. Many of the recoveries show the leakage of intestinal contents through the line of sutures, by the formation and persistence of stercoral fistulæ.

The length of time required for operation is maximum for sutures.

With the exception of a fault of too little excision, not a reproach is found for resection followed by ileo-colostomy with absorbable plates or with the anastomotic button.

These last two methods have time-saving advantages.

These statements correspond with the results of the plates and buttons which Magill has demonstrated in his article.

The conclusion is, therefore, justifiable that sutures are not to be used for establishing the continuity of the digestive tract after resection of the ileo-cecal coil.

He then follows with an account of the preparation of the patient and the operation in detail — the closure of the abdomen and the post-operatory care. Bibliography is appended. The article is of value for reference.

#### INCISION FOR APPENDICITIS.

Charles McBurney,[12] has found that following appendicitis, in a certain number of cases, ventral herniæ occur. He has advised an operation which is of value. It is as follows: The skin incision should be made. The section of the external oblique muscle and aponeurosis should correspond, great care being taken to separate these tissues in the same line, not cutting any fibres across. This is easily accomplished. When the edges of the wound in the external oblique are now strongly pulled apart with retractors, a considerable expanse of the internal oblique muscle is seen, the fibres of which cross somewhat obliquely the opening formed by these retractors. With a blunt instrument, such as the handle of a knife or closed scissors, the fibres of the internal oblique and transversalis muscles can now be separated, without cutting more than an occasional fibre, in a line parallel with their course, that is, nearly at right angles to the incision in the external oblique aponeurosis. Blunt retractors should now be introduced into this in turn and the edges separated. The transversalis fascia is thus well exposed, and is then divided in the same line. Last of all the section of the peritoneum is made.

Two sets of retractors must be in use, one holding open the superficial wound from side to side, the other separating the edges of the deeper wound from above downward. A considerable opening is thus formed, through which, in suitable cases, the caput coli can be easily handled, and the appendix removed. The appendix having been taken away, the wound in the peritoneum, which is transverse, is then closed by suture. The similar wound in the fascia transversalis is also sutured. The fibres of the internal oblique and transversalis muscles fall together as soon as the retractors are withdrawn, and with a couple of fine catgut stitches the closure can be made more complete. The wound in the external oblique aponeurosis is sewed with catgut from end to end. When the operation is completed it will be seen that the gridiron-like arrangement of the muscular and tendinous fibres, to which the abdominal wall largely owes its strength, is restored almost as completely as if no operation had been done. In performing this operation he has noticed several advantages.

In the first place, muscular and tendinous fibres are

[12] Annals of Surgery, July, 1894, p. 38.

separated, but not divided, so that muscular action cannot tend to draw the edges of the wound apart, but rather to actively approximate them. Excepting during the incision of the skin, almost no bleeding occurs. The fascia transversalis not being drawn away by the retraction of the deepest layer of muscular fibres, this fascia is easily completely sutured, and thus greater strength of repair is assured. No muscular fibres or larger nerves having been divided, pain after operation is almost absent. The operation requires rather more time than the usual one, and a larger number of assistants is needed, for four retractors are in use during part of the time. The opening into the peritoneal cavity is not large, but may be made larger if necessary, by continuing the separation of the fibres of the internal oblique and transversalis, and dividing the conjoined aponeurosis in the same line with scissors. In the opposite direction the separation of muscular fibres may be carried as far as the crest of the ilium.

### TREATMENT OF ARTIFICIAL ANUS.

Chaput[13] records 35 cases of artificial anus and stercoral fistulæ which he has treated. After an exhaustive survey of these cases he has formulated the following conclusions concerning the treatment of this class of cases: He says that artificial anus can be treated by four different methods:

(1) By the application of enterotomy, followed by obliteration of the fistula. (*a*) Enterotomy is indicated when the cases are uncomplicated and the aperture is easily accessible, together with a thin and long partition. When the spur is long and thin it is advisable to adopt Richelot's method, that is, section between two pairs of forceps and immediate suture. If, however, the spur is long and somewhat thickened, it is better to make the suture between two long pairs of forceps, which are allowed to remain in position. Enterotomy is contraindicated when the spur is very thick or inaccessible, or when the aperture is closed by the mechanism of angular wounds. (*b*) After destruction of the spur, the stercoral fistula is closed. Small fistulæ are closed by lateral enterorrhaphy, during which operation the margins of the fistula are freely separated from their surroundings, and then united with two tiers of sutures, the peritoneum being opened or not according to the requirements of each individual case. In the case of large fistulæ, lateral enterorrhaphy may be employed, but the peritoneum should not be opened.

(2) Resection is as a general rule contraindicated; but when in the course of a lateral enterorrhaphy the intestine is easily friable and is largely lacerated, it is necessary to resect the two ends and reunite them by appropriate sutures.

(3) When enterotomy is for some reason contraindicated, it is sometimes advisable to employ longitudinal enterorrhaphy without resection. This operation is done by making a circular incision in the skin around the artificial anus, and opening the peritoneal cavity. The two ends are drawn out, a longitudinal slit is made in each, and then the margins of the slits of the same side are sewed together with sutures. This operation is indicated when in the course of a lateral enterorrhaphy considerable constriction is met with just below the lower end. When the intestine is very friable it is contraindicated.

[13] Archiv. Gen. de Med., September and October; British Medical Journal, December 15, 1894, p. 94.

(4) Enteroanastomosis, followed by ligature of the two ends between the point of anastomosis and the stercoral aperture, is a simple, easy and benign operation. It is indicated when the intestine is very friable at the seat of the artificial anus, or when there is a considerable constriction of the bowel in the neighborhood of the external aperture, and also when the inferior end is obliterated at the level of the artificial anus.

### AMPUTATION AT THE HIP JOINT.

F. T. Paul[14] reports several amputations at the hip-joint. The method he uses for controlling the hemorrhage is very simple. He states that the want of a good method has been severely felt, and is evidenced by the number of suggestions which have been made with a view to overcome this difficulty; and it is only because no method is so satisfactory as to be universally adopted that he mentions the simple plan of fixing an Esmarch's tourniquet adopted in his cases. It has proved reliable and effectual, and in no case was there any more troublesome bleeding than in an ordinary amputation through the thigh. The operation employed was a large anterior flap cut from without inwards, disarticulation, and a shorter posterior flap cut from within outwards. The femoral artery was always tied as soon as the anterior flap had been cut, from fear of accidents; and he thinks this should be the rule, as half a minute's free bleeding from the femoral artery would probably be fatal in one of these exhausted children. The mode of fixing the elastic tourniquet is almost childishly simple. Two pieces of calico bandage are placed in position, one crossing the opposite shoulder and the other the opposite hip. The tourniquet is applied over these pieces of bandage round the innominate bone, being hitched above the crest of the ilium in front and the tuberosity of the ischium behind. Then the free ends of the bandages are carried back to the shoulder and hip and tied sufficiently tight to prevent slipping when the limb is removed. This takes off some of the elastic strain over the external iliac artery, so a roller bandage is pushed under the tourniquet at this spot to increase the pressure on the vessel. The plan described is certainly less severe than Wyeth's method with steel mattress needles, and is equally secure; at any rate, he has used it in all his cases, and he feels that he can recommend it with confidence, for he attributes the success obtained almost entirely to the absence of any appreciable loss of blood, due to the satisfactory manner in which the tourniquet controlled the vessels.

*(To be continued.)*

## Reports of Societies.

### THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

REGULAR Meeting March 9, 1895, the President, DR. JAMES R. CHADWICK, in the chair.

DR. C. M. GREEN read a paper on

### PELVIC INFLAMMATIONS.[1]

of which the following is an abstract:

Under the general heading of pelvic inflammation

[1] This paper will appear in the Sixth Series of the Boston City Hospital Medical and Surgical Reports.

[14] Lancet, January 26, 1895, p. 214.

are included the various forms of salpingitis, ovarian abscess, pelvic abscess, and those conditions variously designated under the terms of perimetritis, parametritis, pelvic cellulitis, and pelvic peritonitis: vaginitis and uncomplicated endometritis are excluded. This classification is adopted in accordance with the present views of pelvic pathology and etiology. It is now generally accepted that the various stages of pelvic inflammation are but differing degrees of one and the same morbid process, of which the cause is to be found, in the vast majority of cases, in some form of septic or specific infection. Whether the pathogenic micrococcus effects an entrance by impure sexual contact, by septic instruments or examining fingers, a flame is lighted which may be limited to the Fallopian tube, or which may extend through either the fimbriated extremity or the tube wall, and sweep through the pelvis, involving the ovary, the pelvic peritoneum and cellular tissue, resulting, perhaps, in abscess formation which may destroy not only the uterine appendages, but the life of the patient as well.

The degree to which any pelvic inflammation may attain of course depends chiefly on the nature and the virulence of the infecting virus, and is also influenced, to some extent at least, by the environment of the patient, and by the promptness and intelligence of the treatment.

Most cases of pelvic inflammation can be classified under one of the following five heads:

(1) Salpingitis.

(2) Tubo-ovarian inflammation.

(3) Pelvic inflammation, with exudation preventing accurate diagnosis.

(4) Pelvic abscess.

(5) Peritonitis with retro-displacement of the uterus.

[The clinical course of these forms of inflammation was then considered, and methods of treatment outlined.]

DR. J. C. WARREN said that in deciding between laparotomy and opening the vagina in pelvic abscess, he has found by experience that it is better to perform laparotomy than to open the vagina unless the abscess appears to be making a determined effort to get out through the vagina.

DR. G. HAVEN preferred the abdominal route, having used the vaginal only twice. Laparotomy is more exact; you know and see just what you are about, and the results are more speedy.

DR. EDW. REYNOLDS would disagree with the last speaker, for he believed that where the abscess could be opened by the vagina there was far less shock and danger. The ultimate results, too, are very good. He is surprised to find how adhesive conditions of the pelvic organs melt away. When, however, the abscess is confined to the tubes, the abdominal route is the best.

DR. J. G. BLAKE said that for twenty-five years he has been opening these abscesses by the vaginal route, and has been very successful, not exposing the patients to the danger of laparotomy.

DR. EDW. REYNOLDS believed it was important to distinguish the two classes of abscess. The encysted abscesses should be opened vaginally, but those of the tubes should be removed by laparotomy.

DR. M. H. RICHARDSON said there was great danger in draining a large abscess through the abdomen, from streptococcus infection. He had seen many of these cases, and he believed it was dangerous to apply one rule to them. He would generally operate through the vagina, unless the case was such that it could plainly be reached from above.

DR. J. C. WARREN said that there is now with improved methods of technique much less dread of laparotomy for pus-tubes than formerly. In large specimens he takes the precaution to aspirate the pus first. He thought there was more chance of satisfactory results by laparotomy than by the vaginal method.

DR. GREEN said in closing the discussion, that he believed there was no real difference of opinion, among the best surgeons, as to the treatment of pelvic abscess. When the tumor lies low in the pelvis, with bulging of the pus sac into the rectum and vagina, evacuation of the pus from below, with irrigation and drainage, is attended with good results. But when the tumor is high in the pelvis and does not point on its inferior border, it is certainly not good surgery to approach the pus from below. Such cases are best treated by abdominal section, with a view not only to evacuating pus, but to removing diseased, and perhaps disorganized, appendages.

DR. HORACE E. MARION read, by invitation, on

### EARLY CURETTING IN PUERPERAL SEPSIS.[1]

DR. J. G. BLAKE said he had lately seen two cases of bad puerperal sepsis at the North End. One he curetted; the other he sent to the City Hospital. Both recovered. He believed that many die without appropriate treatment, and that something should be done to protect the community against ignorant and dirty midwives.

DR. E. REYNOLDS said that Dr. Marion's case illustrates the point he had taken in a former paper, that if the curette is used early, life is saved and, moreover, the pelvic organs are left intact. Whereas, if the operation is delayed, although life may be saved the patient is often left a gynecological invalid. If in doubt whether the case is sepsis or not, use the curette. Any risk that may attend its use is infinitesimal compared with the danger from neglect in not using it. He has frequently been called to hopeless cases of sepsis where an early use of the curette would have saved life.

DR. GEORGE HAVEN wished merely to emphasize the remarks of the last speaker, and mentioned a case where he had used peroxide of hydrogen to help in cleaning the uterus.

DR. M. H. RICHARDSON asked about the danger of air embolism from peroxide of hydrogen.

DR. G. HAVEN is not afraid on this account, and thinks there is no danger. In Cæsarean section, air enters freely into the uterus, but air embolism never results.

DR. M. H. RICHARDSON said air embolism is one of those rare accidents that comes when least expected. He himself should be afraid to use the peroxide.

DR. EDW. REYNOLDS said that danger of air embolism exists only before the sinuses are closed by coagula.

DR. C. W. TOWNSEND said he had recently many times in the out-patient department of the Lying-in-Hospital to enforce the rule, "when in doubt consider the case sepsis." There had been a number of cases of grippe among the puerperal patients, but when not sure as to the diagnosis he had treated these cases as sepsis. Grippe untreated generally recovers, which

[1] See page 538 of the Journal.

is not the case with sepsis; while it does no harm to wash out the uterus of a patient with grippe.

Dr. Haven said that Dr. Marion had referred to diagnosis by bacterial examinations. He had not found this of value, for in examinations taken from normal cases with normal temperatures about all the kinds of bacteria had been found except the Klebs-Löffler and the colon bacilli.

Dr. J. C. Warren said that there is danger of perforation in curetting the uterus. He had seen a sound passed through without any force. In this case he did laparotomy and sewed up the hole.

Dr. E. Reynolds said that a sharp curette should be used, with a broad head and a flexible shank that can be bent.

Dr. S. L. Abbot, as one of the oldest members of the Society, said that he believes that septic conditions must have increased of late years. He has never seen a death from puerperal fever, nor even a case of it, and no special precautions were taken in those days. He had had many difficult operative cases without sepsis.

Dr. J. R. Chadwick said that he agreed with the reader as to the use of the curette, but not in every case, for in early cases he has found the inter-uterine douche alone all that was necessary. It is merely a question of getting at it early. He has never lost a case in his own practice, but he has in consultation where he was called too late. He has had such good results from permanganate of potash that he has not changed.

Dr. A. K. Stone reported, by invitation,

CASES OF TRANSVERSE SEPTA OF THE VAGINA.[3]

Dr. S. L. Abbot has seen one case of this anomaly. The septum was half-way up the vagina, with a central opening that admitted only the tip of the fore-finger, the patient was in labor. The septum thinned as the head came down and suddenly gave way by tearing.

Dr. C. M. Green saw a case at the Boston Lying-in Hospital where the septum was close to the cervix. With the finger no opening could be detected. The septum was so thin that it was bored through with the finger and torn.

Dr. J. W. Elliot thought he had seen two or three cases of transverse septa, but it is possible that some of them were cicatricial.

Dr. Haven saw a case a short time ago. The septum was close to the cervix.

Dr. J. R. Chadwick had seen one partial case and one where there was only a pin-hole opening.

A case seen by Dr. S. W. Torrey, who was present at the meeting, was afterwards sent to the Secretary for publication.[4]

A Too Radical Improvement. — The physician was surprised to find the head of the household at the door with a shotgun. "Why, what's the matter?" stammered the doctor. "That there medicine you gave my wife she says is makin' her feel like a new woman. And I want you to understand that no new woman business goes on in this house. First thing I know, she'll be out makin' speeches." — *Toronto Truth.*

## AMERICAN MEDICAL ASSOCIATION.

FORTY-SIXTH ANNUAL MEETING, BALTIMORE, MD., MAY 7–10, 1895.

(Continued from No. 21, p. 525.

SECTION IN MEDICINE.— FIRST DAY.

Dr. E. W. Kellogg, Milwaukee, Chairman; Dr. W. E. Quine, Chicago, Secretary. The former delivered an address on

RECENT ADVANCES IN THE PRACTICE OF MEDICINE.

It is extremely fitting that the Association should meet in a city where nearly half a century ago, its first annual gathering was held. From the field first occupied by the Section on Medicine slice after slice has been taken by the growth of the various specialties, yet the growth of the Section while perhaps not as rapid as those of Surgery and Gynecology is nevertheless distinctly apparent.

At the first annual meeting, the question of anesthesia was still a debated one. It had then been introduced as a relief from pain for all surgical procedures, yet the conservatism of the day gave it anything but a cordial reception. The anti-malarial effect of quinine was barely recognized, while its mode of action was of course unknown. The salicylates and antipyretic drugs were then unheard of as therapeutic resources. In 1877 came the promulgation of the germ theory of disease which was very seductive, but which led at first to the drawing of unwarrantable deductions. Of our more recent advances, some are more apparent than real. Our people are prone to follow fads, and the medical profession is no exception to the general rule. The temple of medicine has been building but slowly; and some of the stones set there in the first flush of zeal from some pretended new discovery have had to be removed in the calmer light of further investigation. Antisepsis has reached its topmost height, and already the crest of its wave is scattering into foam. We are learning that it is better to avoid the causes of disease than to remove its effects, and that good hygiene is preferable to therapeutics. The last year has witnessed the advent of the serum-therapy. This is either a tremendous farce, or else the greatest therapeutic advance since the days of Jenner. Noteworthy results have already been reached with diphtheria. Our serum must be pure, our diagnosis based upon bacteriological findings, rigid antisepsis followed, and the remedy be used early. If one-half of its claims be true, it is well worthy of a further trial. The claims of its advocates, however, are met by the denials of its opponents. Its uselessness in secondary infections is already manifest. Our experience with tuberculin and the fact that diphtheria so often recovers under any treatment should lead us to be cautious.

A hopeful sign of the times is the reaction against the use of heart-depressing antipyretics except under very extraordinary circumstances.

Our knowledge of the contagiousness of tuberculosis and the knowledge that travellers go up and down the land scattering bacilli broadcast, should lead the profession to dispel the ignorance of the laity on this most important topic and to their urging the enactment of proper legislation.

Dr. John C. Hollister of Chicago, read a paper on

NEW DEPARTURES IN THERAPEUTICS,

He said that to judge of the medical theories of any age we have only to examine its therapeutic system. Medicine has long been compelled to act on the defensive, because we have been so ignorant as to etiology and have been compelled to employ our remedies empirically; but owing to the revelations of the microscope and laboratory, therapeusis has now become aggressive and we are on the verge of an era from which will date the renaissance of medicine.

Twenty years ago the two great theories of pathology were the cellular and humoral. Hence arose two systems of therapeutics, towards which in these last years the tide was again strongly set. We now recognize an organic therapy or the therapy of substitution and a sero-therapy. The former is based upon the view that all vital activity has a cellular genesis, and that an equilibrium of all these activities means perfect health. An impairment of cell integrity means impaired function. Remedial agents are valuable as they affect cell-vitality, and cells themselves have a defensive *vis vitæ*.

Cell-stimulation leads to the production of proteids, albumins and nucleins which oppose toxines. Slight irritation increases cell-antitoxicity. The white cells under such circumstances, do not act as phagocytes, but they throw themselves around invading bacilli, and the latter are thereby subjected to greater antitoxic influence.

Cells, too, seem to have the power of selecting special pabulum. Hence arose the theories of Brown-Séquard as to the value of organic extracts. With two such preparations the reader of the paper has had personal experience during the past two years. The first is red bone-marrow, with which he has had better experience in simple anemia than he had previously had with arsenic, iron and oil. The second is nuclein, which has been shown to possess a certain power to neutralize toxine effects in the animal economy, and which has been derived from the spleen, bone-marrow and thyroid. In the alimentary canal it possesses a distinct antiseptic power. It stimulates the brain and nerves and energizes invalids and the aged. It has been shown to have antidotal power in diphtheria.

The serum-therapy is a logical outgrowth of the germ theory of disease. It has been learned that specific microbes can be isolated, and that they produce specific diseases. More recently it has been found that a germicidal power resides in blood-serum. Artificial immunization, first established for anthrax, has proven a possibility for other maladies, and the potency of antitoxin seems to be increased by repeated inoculations. Hence arises the very important question of dosage and of the necessity of establishing a standard of immunizing power.

In regard to diphtheria, the opinion prevails that sero-therapy has reduced the mortality from 44 per cent. to 21 per cent. One observer had a mortality of 18 per cent. in 525 cases where it had previously been 21 per cent. When, during a certain period, the supply of serum failed, the mortality rose to 51 per cent. Others have failed to report such good results.

The general consensus of opinion in Germany seems to be (1) that the remedy is harmless; (2) that we may see good results from its use; (3) that, as to its immunizing power, results are not yet complete enough to determine its positive value.

On the other hand, it has been shown that serum of one animal when transferred to the circulation of another has a decided globucidal effect on the latter's blood; furthermore, that in the mixed infections so often clinically seen (bacilli and cocci coexisting) the remedy is without decisive power. If the serum shall finally turn out to be injurious, are there any other remedies at our command for use in microbic maladies?

Recently Edinger, of Freiburg, knowing the antiseptic power of mucous secretions and especially of saliva, and that in the latter there is a relatively large percentage of thio-cyanate of potassium, has artificially combined the latter with quinoline to form a new compound that he calls a rhodonate of methyl-pyridine. It has been found that the growth of the Löffler bacillus is inhibited in one hour by a 1–1,000 strength of this solution; that of the staphylococcus aureus, in the same time by a strength of 3–200. It is not caustic like carbolic acid or poisonous as mercuric chloride.

DR. W. E. QUINE, of Chicago, stated that he could unequivocally endorse the claim for good effects of red bone-marrow upon chlor-anemia and also in apparent cases of progressive pernicious anemia. In one case of splenic leucemia treated therewith over a period of several months the increase of red cells had been 17 per cent., and that of hemoglobin 8 per cent., yet the multiplication of white cells went on with even greater rapidity than before, thereby greatly increasing the total blood volume. As to the diphtheria antitoxin, he had observed as deleterious effects, urticaria and one case of transient bloody albuminuria. On the other hand, he had seen a very striking eversion of threatening laryngeal and nasal diphtheria, where it appeared that without the injections death must certainly result in from twenty-four to forty-eight hours. He counselled, however, a cautious attitude toward the serum.

DR. F. B. TURCK, of Chicago, believed that there was a wide field of usefulness for nuclein in the auto-intoxication from gastro-enteric disorders. Nuclein was not a specific but a valuable addition to our therapeutic resources.

The second paper was read by DR. W. BLAIR STEWART, of Atlantic City, N. J., on

CALOMEL: A STUDY OF ITS PHYSIOLOGICAL ACTION AND THERAPY IN 144 CASES OF GASTRO-INTESTINAL DISORDERS. IS IT A DIURETIC, PER SE?

Much of the calomel we buy is impure, or adulterated. Large doses cause griping and pain in the adult. It may be improperly purified in manufacture or may be altered by atmospheric changes. The corrosive chloride is the most common abnormal ingredient. Fatal cases of calomel poisoning are in reality cases of bichloride poisoning. Calomel also may be practically inert from containing barium, calcium or lead. We should always, therefore, test our calomel. It should never be given with chlorides or acids, and not while digestion is going on, owing to the danger of bichloride formation in the stomach. If we will thoroughly trituate (not merely mix) our drug with milk-sugar, our results will be far more gratifying and our dosage greatly reduced.

The remedy is heavy and naturally slow of absorption, owing to the large size of its individual crystals, and the consequent small area of distribution over the alimentary tract. It can be easily detected by the

ammonia test in so small a proportion as 1–1,000. Dr. Stewart gives to an adult one-tenth of a grain (for an ordinary so-called "bilious" state) every half-hour till one grain is taken or until evacuation ensues. In patients previously costive, a small dose of the magnesium citrate is a valuable adjuvant. The combination of soda with calomel is rational, as bichloride formation is prevented and the remedy best absorbed under conditions of alkalinity.

No diuretic effect *per se* has ever been noted. Indirectly it may so act by its general stimulus on all the emunctories. Diuretic effects were not directly observed in one case of scarlatinal nephritis and in one of cardiac mitral dropsy, though both did well on the usual alkaline diuretics.

Calomel is believed to stimulate bile-secretion by its direct action on the liver cells. In diarrhea it is partly absorbed and partly exerts a local antiseptic action. It neutralizes toxines, prevents germ formation and increases peristalsis. It is applicable to diarrhea from improper food, to bilious diarrhea in adults, to dysentery and the bowel flux of typhoid fever. A small dose of podophyllin could be advantageously combined with it in adults and ipecac in children. Valuable results also were found in the diarrhea of alcoholism in so small doses as 1–50 grains combined with 1–100 podophyllin every three or four hours.

Dr. H. D. Didama, of Syracuse, inquired if such small doses were not converted in the system into bichloride, and if the good results were not really due to the latter. If the drug was a direct stimulant to the liver cells larger doses would naturally be the more desirable.

Dr. H. A. Hare, of Philadelphia, maintained that calomel is not converted into the bichloride by the HCl in the stomach, so far as we can judge from laboratory tests, yet clinical experience would seem to indicate that it was so changed. Calomel is a purgative, and the bichloride a cholagogue. There is reason to believe that the calomel is changed in the bowel by the alkaline juices into a gray oxide. As to its pharmaceutical contamination, the testing of a large number of the commercial triturates and powders had not revealed any corrosive sublimate, but some oxide had been found in the soda compounds.

Dr. Stewart, in reply, claimed that laboratory tests in glass vessels with fitted reagents were not comparable with the vital processes in the human body; hence the divergency of results. One is a chemical process, and the other physio-logico-chemical. As to the effect of calomel as a cholagogue, we know that when we give it we get bilious stools. He himself has found bichloride in chemical preparations.

The closing paper of the session was read by Dr. Elmer Lee, of Chicago, on

### THE TREATMENT OF ASIATIC CHOLERA.

After an enumeration of symptoms, and of the various remedies which had been found useless in the disease (including Ferran's and Hafkin's inoculations), he declared pure water to be the only remedy of any practical value whatever. In this disease no germs are found outside the canal in any living tissue whatever. We should introduce warm water by the mouth, and so endeavor to flush down the upper end of the small bowel. It was impossible to use too much. From one to ten quarts daily should be taken. The colon should be irrigated from one to four times daily. If the patient vomits, wait a few minutes and then again give a bulk of water equal to that ejected. Careful attention should be paid to preventing a loss of bodily heat. The writer exhibited a model of an improved fountain syringe and nozzle.

Dr. Hollister had found good effects from tannic-acid injections, and in the use by the mouth of freshly prepared infusions of cinnamon. Neither remedy could by experiment be shown to be markedly germicidal on the comma bacillus. The cinnamon infusion was also useful in children, to lessen the gastro-intestinal irritability of summer diarrhea.

## SECTION IN MEDICINE. — SECOND DAY.

Dr. Frank E. Parsons, of Philadelphia, read a paper on

### SOME POINTS CONCERNING THE ETIOLOGY OF TUBERCULOSIS.

He spoke of the pre-tubercular condition, so called, as an abnormal state which was suggestive rather than symptomatic. The tubercle bacillus alone plays only a partial rôle, for unless the favorable soil exists it is unable to produce the disease. The results of autopsies show that many such bacillary invasions occur, but come to nought from the unfavorable intrasystemic environment which the germs encounter. To bring about a development of the disease, suppuration is necessary and this in turn is dependent on stasis.

Tuberculosis seizes upon those parts where lymphoma or lymphangitis have altered the circulatory condition. It is to be regarded, therefore, as a symptom of lymphatic stasis rather than as a disease *per se*. Lymph stasis arises acutely, as from burns, or in a more chronic manner as from the long-continued abuse of alcohol. As a result, waste products accumulate in the system and become poisonous when not removed by lymphatic drainage.

An excessive waste of tissues from any malnutritive condition naturally causes stasis. It is well known that the venous blood in phthisical patients has a brighter hue than the same blood in health, and that this is due to a deficiency of oxydizable phosphorus; for it has been found that if phosphorus be fed to phthisical patients the venous blood soon returns to its normal hue. The sequence of changes from waste accumulation is first stasis, next a nerve-cell paralysis, and finally an increased blood-supply; all of which precede the bacillary entrance. This fact suggests the fallacy of tuberculin injections, for only those animals are affected who would suffer from lymphatic stasis, no matter what the injected material might consist of. The writer would conclude, therefore, that pulmonary tuberculosis was due primarily to lymphatic stasis, and that the tubercle bacillus was a phenomenon expressive of the disease and was hence symptomatic and not etiological. The so-called scrofulous condition was a pre-tubercular state.

The discussion was postponed until after the reading of the next paper by Dr. DeLancy Rochester, of Buffalo, N. Y.

### REPORT ON THIRTY-FOUR CASES OF TUBERCULOSIS TREATED BY CARASSO'S METHOD.

The sheet-anchor in this plan of treatment, suggested by Carasso, of Genoa, is the use of menthol supplemented by creosote for general disinfection. A piece of linen ten centimetres square is folded once so as to

make a rectangle, and is secured by proper tapes over the nostrils. The latter are at first greased inside so as to prevent irritation. On this pad are poured a few drops of essence of peppermint. The patient is directed to take every fifteen minutes eight or ten deep inspirations with closed mouth. Internally, one teaspoonful is given (every three hours in half a glass of water) of the following mixture: creosote 8 parts, alchohol 550 parts, glycerine 250 parts, chloroform 20 parts, and essence of peppermint 8 parts. Superalimentation is also resorted to, as the patient is given meat cooked to taste, two or three litres of sterilized milk daily, and 400 grammes of good wine. The sputa are most carefully disposed of so as to prevent auto-reinfection.

Carasso reported 44 cases. Many were well advanced, but none with cavities were included. In all bacilli were found. Of this number six died; and in 38 the morbid process seemed to come to a standstill. The average duration of treatment was sixty days.

Dr. Rochester has given the plan a trial in 34 cases of phthisis in the Erie County Hospital. Of these 28 had cavities of varying size, four, infiltration of the right upper lobe, and two of the left upper lobe. In all the process was active and attended with afternoon fever. They had been on oil and in two instances creosote previously; and all had been doing fairly well. The Carasso plan was tried with the omission of the wine. Whiskey was given if a stimulant seemed necessary. He was sorry to state, however, that in two months all his cases were doing badly. Even the two creosote cases, after one week of treatment, began to fare like the rest. All suffered from gastric disturbances, and some vomited. In one instance the pad over the nostrils was complained of as interfering with the breathing; but all the others breathed better and coughed less, though the daily amount of sputum did not seem to lessen.

There are certain physiological objections to this method. The amount of fluid recommended by Carasso practically means one pint every three hours from 6 A. M. till 9 P. M., with one additional pint during the night. So much meat and milk are incompatible under the circumstances, as the lactic acid ingredient would overcome the natural HCl of the stomach. Moreover, in most phthisical cases the stomach is dilated, and, in short, such a plan if rigorously followed out would upset the majority of healthy stomachs. Furthermore, an analysis of the internal remedies given shows that they are especially liable to disturb the digestive action of the stomach. From his personal experience therefore, the writer would conclude that the internal combination of remedies was unphysiological and upsets the stomach, and that the inhalations of the peppermint seemed of decided value and deserved a further trial.

The discussion was opened by DR. DELANO AMES, of Baltimore, who had treated in this manner some 90 cases at the Johns Hopkins Out-Patient Department. Sixty of them had been under observation for about twelve months. His conclusions tallied exactly with those of Dr. Rochester. Carasso had claimed that the bacilli disappeared in from eighteen to sixty days. In two of Dr. Ames's cases the bacilli disappeared — one a patient who was a while in the Adirondacks, and the other a girl who lived in the most unsanitary environment. He believed that the stomach disturbances were unavoidable. Half of his cases had gained in weight at first. The amount of liquid given was entirely too large. The solids should be increased and the liquids diminished. Starches, sugars and fats should be added to the diet. In all of Carasso's cases the lungs alone were affected. This was true in three-quarters of his own cases. The treatment did lessen bacilli and night-sweats, and he believed that the peppermint did undoubtedly lessen dyspnea. As to its general antiseptic effect, we must first demonstrate that it is excreted unchanged through the kidney or other emunctory. This we have thus far been unable to do.

DR. CHARLES DENISON of Denver, Col., said that he had tried to secure an immunizing serum by experiments on dogs by the injection of tuberculin, tuberculocidin and anti-phthisin, but had thus far failed. Severe urticaria and constitutional symptoms had arisen. He did not believe it possible to increase the efficiency of a remedy by passing it through animals. Out of over six thousand injections of tuberculin and tuberculocidin he had not had a single abscess, while this accident had happened in two out of twenty cases of serum-injection made by another observer. The only way to cure tuberculosis is to increase the resisting power of the individual. To attain this result climate and high altitude are all-important. We must, if possible, prevent the disease by rendering the blood immune. Experiments have shown that the number of red cells increases in both men and animals as they live in successively higher altitudes, one series showing under these conditions an increase of sixteen per cent. in the course of a single month. Febrile cases are not as a rule suited to high altitudes. Out of 127 cases treated systematically by him 27 are now living. He has had no bad experience with tuberculin, and cannot understand the current prejudice against it.

DR. KARL VON RUCK of Asheville, N. C., took exception to Dr. Parson's pre-tubercular stage. He does not believe that ulceration and suppuration result from stasis alone. The condition which we call tuberculosis is not due to stasis, but to the bacillus. Animal experimentation is far too complete for us to doubt this. He places little faith in peppermint inhalations, while admitting that menthol will relieve cough. When we think of the difficulty the surgeon has to render any patent surface sterile, it is folly to think that by any inhalation methods, we can disinfect the walls of pulmonic cavities. He would endorse the views of Dr. Denison as to the efficiency of high altitudes. Many wrong deductions have been drawn from the results of injecting various substances into animals. We do not establish immunity but merely toleration just as we do with the alkaloids. He has tried the serum of Dr. Paquin, of St. Louis, on guinea-pigs, and they all died within forty-eight hours. On examination the serum was found full of bacilli of various kinds.

DR. PARSONS in closing, dwelt upon the coexistence of gastric catarrh with pulmonary phthisis, naturally the stomach would become upset with any treatment, and this organ needed its own appropriate treatment. He had no faith in the good effects of creosote on this disease, and regarded it of little value internally.

DR. ROCHESTER further stated that he regarded as pre-tubercular anything which reduced the natural powers of resistance. He does not believe in heredity (except in the ten cases or so where bacilli have been

found in the fetus), though of course a weak constitution can be inherited. So-called congenital cases were probably infected at a very early age by the mother's sputa or through her milk. It was noteworthy that the alleged transmission was generally through the maternal and rarely through the paternal line. He is accustomed to give creosote in claret wine or in mucilage of acacia.

TREATMENT OF TUBERCULOSIS; LATEST REPORT OF CASES TREATED WITH BLOOD-SERUM,

by DR. PAUL PAQUIN, of St. Louis, Mo.

In January, 1895, he commenced the treatment of his cases with blood-serum. Their number is now twenty-two, all in either the second or third stage. They have received daily injections for two months, have gained from one and a half to twenty-two pounds, and are now all living. All were originally emaciated, had bacilli, and had suffered from hemorrhages. Two other cases had died in from three to five days before the treatment was commenced, but they were practically *in articulo mortis* when first seen. No other treatment whatever was employed. When the serum was stopped they grew worse, but improved upon its resumption. The effect of treatment was to diminish the activity of the tubercular process, lessen hemorrhage, improve appetite, lessen cough and nervous irritability. Sero-therapy has also a useful application in surgical tuberculosis, as in knee-joint disease.

In regard to the source of the serum, it must be admitted that the horse is not absolutely immune to tuberculosis. The serum seems to change in power after several withdrawals from the same animal. During the recuperation from the debility caused by the blood-letting, the animals seem to develop toxines of some sort, and hence there is a great variation in the effects produced upon the patients by the injections. The fluid is best preserved by the addition of a little camphor, and from ten to thirty minims are injected daily. In a few instances flushing of the face with a subsequent change to a purplish hue has been observed, lasting from four to five minutes, and occasional chills. It is believed that this severe reaction follows from the needle chancing to be inserted directly into a blood-vessel. Arthritic symptoms have also been observed, especially in people previously rheumatic. The urine is considerably diminished, and in one case albumin was found.

In answer to inquiry, Dr. Paquin said that he immunizes the horse by injecting into the jugular vein first of all, culture fluids containing the toxines of bacilli, then dead bacilli, and finally living bacilli; these injections continuing till all constitutional reaction on the part of the animal has ceased.

In the discussion, DR. KARL VON RUCK, of Asheville, N. C., declared that no animal was absolutely immune toward tuberculosis. To decide this question positively as to the horse, we must kill the animal and examine the tissues, both as to pathology and bacteriology. Dr. Paquin's animal experimentation was as yet incomplete, and no proof had yet been brought forward that the serum had any curative value on either animals or men. Dr. von Ruck had injected some of the serum into guinea-pigs, and they had all promptly died in forty-eight hours. Dr. Paquin had spoken of the spores of tubercle bacilli. He himself had never seen any, and it was doubtful whether this variety of bacilli had spores or not.

DR. ROCHESTER remarked that phthisical cases sometimes recur without any treatment whatever. He believed that specific treatment was out of place in the mixed infections which they generally present.

DR. HENRY D. HOLTON, of Vermont, stated that the serum of the ass would probably be superior to that of the horse, for there was very little fatality from phthisis in those countries where the milk of the former animal was used.

A CASE OF PULMONARY HYPERTROPHIC OSTEO-ARTHROPATHY,

by DR. N. S. DAVIS, JR., of Chicago.

As far as is known, but one other case of this nature has been reported in American literature,[1] but some forty cases had appeared in the European literature of the past five years. The condition was first described in 1890 by Marie, and the malady often goes by his name. Its essential forerunner is always a chronic multiple osteitis involving especially the terminal phalanges of the fingers and toes and the ends of the bones of the extremities. It has to be differentiated from acromegalia. The cause is supposed to be the absorption from the lungs or pleuræ of some chemical poison.

His own patient was a boy some six years old, with a cough and purulent sputa. He had had pneumonia in early life, and one year after the ends of the fingers and toes had begun to enlarge. The wrists were also increased in size. The skin and glands seemed normal, and the body well proportioned. There was slight kyphosis and scoliosis. Physical examination of the chest revealed an enlargement and immobility of the left side in respiration, with dulness and cardiac displacement. A diagnosis was made of lung compression from effusion probably, in view of the character of the sputa. Operation was advised, but thus far parental consent has been withheld. A noteworthy feature is the symmetry of the bone and joint lesions.

A differential diagnosis has to be made, as above stated, from acromegalia, where the fingers are uniformly enlarged, and the spinal lesion generally in the cervico-dorsal region, and a lesion of the pituitary body and surrounding brain tissue, with usually visual disturbances. In the arthropathy the spinal lesion is in the dorso-lumbar region.

DR. S. SOLIS-COHEN stated that he had seen two cases of this affection. In it the hands were generally lengthened, while in acromegalia they were broadened. Kyphosis was frequent in tubercular affections, and he was inclined to regard this arthropathy, with its attendant features, merely as an exaggeration of what we so often find in a lesser degree. The wrist and ankle joints were here involved, while in acromegalia they generally escaped. The trophic disturbance in these cases was a development of certain strictures at the expense of others, and was probably the result of a pus toxine.

DR. H. B. SEARS, of Beaver Dam, Wis., read

MEASURES CALCULATED TO MODIFY ACUTE INFLAMMATION OF THE RESPIRATORY TRACT.

DR. A. H. BURR of Chicago, read a paper on

HYDROTHERAPY IN FEVERS; ITS RATIONALE AND TECHNIQUE.

He gave a general description of the febrile state,

[1] Packard: American Journal of Medical Sciences, June, 1892.

claiming that the pyrexia results from the toxic derangement of neural resistance to and neural control of heat evolution. The coal-tar antipyretic craze was already on the wane. A general review of the history of the cold bath showed that its value depended first, on the physical effect of water as a neural stimulant, and, secondly, on the susceptibility of the sympathetic nervous system with its control over the glandular apparatus of the body, thirdly, on the reflex influence on the respirative circulation, metabolism, elimination and pyrexia.

Winternitz has already shown that the cold bath increases the number of leucocytes in the blood current, increases also hemoglobin and blood-gravity. Thayer's experiments on the blood from the ear gave identical results. Probably there is no actual increase in cell-formation, but the heightened activity of the circulation sweeps out into the stream the various cells which have lodged in the diverse corners of the vascular system.

The writer then described his apapratus for giving cold baths. It consists essentially of a rectangular frame which can be laid on the bed. To its sides are fastened tapes from a large rubber sheet, which is sloped down inside the frame and is under the patient. Thereby is formed an improvised tub which will easily hold twenty gallons and which can be syphoned out when the bath is ended. He bathes according to the full Brandt method.

The discussion was opened by DR. DAVIS, JR., of Chicago, who gave his adherence to all the views expressed in the paper. The bath did not shorten the duration of the disease, but it did lessen the danger and make the patient more comfortable.

DR. CHAS. G. STOCKTON of Buffalo made an earnest plea for the introduction of the Brandt method into small communities. He thought that the apparatus devised by Dr. Burr would contribute greatly to this end.

DR. COHEN thought that sponging on a rubber sheet had the disadvantage of merely collecting small pools of water about the patient. Immersion of the whole body is better. He would consider Dr. Burr's apparatus as next useful to a tub.

DR. ROCHESTER, of Buffalo, called attention to the friction-massage as an essential part of the Brandt method.

DR. JAMES TYSON, of Philadelphia, was an advocate of the bath. He had, however, lost some cases where it had been used, death resulting from hemorrhage and perforation.

DR. J. M. ANDERS, of Philadelphia, thought there were well-recognized limitations to the use of the bath. It was contraindicated where hemorrhages occurred. It ought then to be stopped for a while at least.

The closing paper of the session was read by DR. JAMES TYSON, of Philadelphia, on

THE SYMPTOMATOLOGY OF IRREGULAR OR ATYPICAL GOUT.

He alluded to the recent work of Roberts, who had shown that the uric acid circulated in the blood in the form of a quadriurate of soda. Local symptoms were probably produced by local deposits, though we might not be able to detect the latter.

The symptoms of irregular gout were of the most diverse variety. We might have dyspepsia, lithate deposits in the urine, eczema, muscular pains, deep-seated pains in the tongue, a feeling of crackling about the cervical spine, knotting about the small joints, pain in the back (especially the lumbar regions, in the femoral adductors and gastrocnemii), articular pains and nodosities; not uncommon also were headaches, pain in the palms of the hands, folliculitis about the nose, scleritis, corneitis and conjunctivitis, pharyngitis, tonsillitis, bronchitis and asthma, dryness of the tongue and skin; also hemorrhages into the bladder; in the nervous system were change of temper, capriciousness, melancholia and insomnia. He would lay special stress upon vesical hemorrhage, the frequent uric acid cause of which was not generally known.

He would lay down, therefore, the following rules to assist in diagnosis of atypical or irregular gout:

(1) Uric acidemia, though it was rarely possible to detect uric acid in the urine with the means at the disposal of the general practitioner.

(2) The supervention of an attack of typical gout on the subsidence of other ailments or in alternation therewith.

(3) The history of a previous regular attack.

(4) Heredity.

(5) History of exposure to lead-poisoning.

(6) History of the mode of life.

(7) High colored and scanty urine; the relation of gout to lithemia was a vexed question but there were no urinary deposits in pure lithemia.

(8) Glycosuria.

(9) Chronic interstitial nephritis, the unfortunate result toward which gouty tendencies inevitably lead.

(10) The results of therapeutics.

DR. STOCKTON remarked that gout did not necessarily lead to lithemia at all.

SECTION IN MEDICINE. — THIRD DAY.

DR. J. M. ANDERS, of Philadelphia, read the first paper, entitled

THE COMPLICATIONS OF MALARIA, WITH STATISTICS.

The cases studied were all taken from Philadelphia hospitals during the past twenty-one years, and numbered 2,122. Of this number only 1,780 were for various reasons available for study; and of the available number complications were noted in 189, or nearly 11 per cent. The types of malarias were as follows: Intermittent 1,434, remittent 75, malarial cachexia 27, chronic and irregular forms 22, unclassified 222. All doubtful cases were excluded. The relative frequency of complications is seen by the following statement: Heart disease 21, enteritic 21, neuralgia 18 (4 being supra-orbital), pleurisy 13, rheumatism 13, phthisis 12, typhoid fever 8, pneumonia 6, edema 7, jaundice 5, and nephritis 5. In addition some 30 other maladies were listed, each occurring from one to four times. Dr. Anders was inclined to believe that certain clinical states regarded as complicating malaria should be rather regarded as symptomatic of that condition.

With regard to some of the chronic complications, as heart disease, tuberculosis and nephritis, it might be said that they predisposed to miasmatic poisoning. He himself believed that malaria promoted phthisis. Pleurisy may occur in paludal cases, but is probably of secondary occurrence.

It has been a matter of dispute as to the relation of pneumonia to malaria. We do know, however, that there is an intermittent type of broncho-pulmonic symptoms influenced by quinine. Of the six pneumo-

nia cases mentioned by Dr. Anders only one died, and all were in connection with the intermittent type of the disease. Five were lobar and one lobular. This complication seemed to be less common in temperate climates than in the tropics.

As to typhoid fever, it was possible for both poisons to coexist in the system but this was rare. Nor was there probably such a thing as a compound causative agent.

The next paper, by DR. ROBERT H. BABCOCK, of Chicago, on

THE RELATIVE CONDITION OF THE TWO VENTRICLES WITH REFERENCE TO THE ADMINISTRATION OF DIGITALIS,

was read by Dr. Holliston.

The writer said that according to current text-books the indications for digitalis have been a weak and rapid heart; low vascular tension, with or without a mitral murmur; a dilated right ventricle, and dropsy. Cardiac dilatation implied more or less arterial anemia, with venous hyperemia. In many instances all the indications might exist for the use of foxglove, and yet the remedy did harm. Often far better results would be secured by the use of nitroglycerine and strychnine, the nitrate of the latter being in the writer's judgment the preferable salt. It was also necessary to distinguish between the action of digitalis on the two ventricles, and this divergence is probably produced by the varying conditions of the two coronary arteries.

Dr. Babcock did not believe that the remedy had much effect on the right heart. It was contraindicated in excessive dilatation of the heart. There the preferable thing to do was to first remove eight or ten ounces of blood from the circulation, though free purgation might answer.

DR. W. T. ENGLISH, of Pittsburg, Pa., read the next paper on

CARDIAC INSTABILITY DUE TO ACID AUTO-INTOXICATION.

An explanation of many of the so-called diathetic conditions is to be sought in abnormal chemical processes occurring in the body. Many abnormal heart phenomena were due to acid accumulation within the system and acid excretion was contemporaneous with cardiac irritability and vascular weakness because the heart grew weary from the effect of disturbed nutritive processes upon the myocardium. It became dilated, and thence ensued valvular incompetency.

In dyspepsia we saw an illustration of this fact in the effect of the acid blood on the heart, first on the myocardium and the nervous ganglia contained therein, and second through the coronary arteries on the myocardium and the deeper ganglia. As a result, the heart became temporarily exhilarated, so to speak; the systole shorter and less powerful; and finally the organ would stop in diastole; though it often happened that if the auto-intoxication was gradual and slight a marked degree of tolerance could be induced. Reduced alkalinity would lead to capillary spasm. These considerations were all proven by the effect of administering acid. The important deduction to be drawn from all these facts was that in conditions of heart debility, acid food should be carefully avoided.

DR. A. F. PATTEE, of Boston, followed with a paper on

THE THERAPEUTICS OF THE SENILE HEART.

In treating the cardiac condition of senility, reference must be had to the decrepitude of the individual rather than to the mere number of his years. Some men die of old age at forty-five while others may live on, and die from a mere accident at ninety. In infancy, the vessels are thin and elastic while in senility they have undergone morbid changes and are more or less rigid or unyielding, and the striated muscle of the heart itself fails to respond because of general malnutrition to the automatic demands made upon it.

In the treatment of this condition, reference must be had to three main indications — diet, rest and medicines. The amount of food consumed should be cut down after middle life. Stimulants ought to be omitted, and the amount of liquid ingesta carefully regulated. Most harm is done to senile hearts by allowing the patients to drink fluids *ad libitum*. Dinner must be taken at mid-day and longer intervals allowed to pass between meal times than in earlier years.

DR. STOCKTON did not believe that cardiac disease was often caused by acid auto-intoxication.

DR. G. W. WEBSTER, of Chicago, stated that in Dr. English's paper no distinction had been made between vegetable and mineral acids. The former are split up in the body and excreted as alkaline carbonates, and cannot, therefore, possibly increase systemic acidity.

DR. ALBERT E. STERNE, of Indianapolis, read a paper on the

TOXIC ORIGIN OF NERVOUS DISEASES.

The writer believed that inflammations of both the central and peripheral nervous organs were due in a great measure to the effect which certain discovered and undiscovered toxines exert upon them. In some the result is acute and speedy, as in anterior poliomyelitis; in some, the toxine is the product of micro-organisms as in diphtheria and typhoid affections, while in others the poison is of an inorganic character as in lead, arsenic, mercury and alcohol cases.

THE EFFECTS OF PURE OXYGEN INTRODUCED INTO THE BODY IN VARIOUS WAYS UPON THE HEMOGLOBIN,

by DR. GEORGE J. PRESTON, of Baltimore, Md., who first gave a *résumé* of the results of various experiments as to the effect of oxygen upon the body. It has been found that for the first few minutes there is but little rise in pulse-rate or vascular tension, but the respiration is lessened. It has been a mooted question as to whether inhalations of oxygen give more oxygen to the red cells than does ordinary air.

Dr. Preston has placed rabbits in glass jars into which the washed gas was led from a receiver. The results of four experiments are as follows, caustic potash being used in the chambers to absorb the expired $CO_2$:

| | | | |
|---|---|---|---|
| 1. Time, 5 min. | H. before, 58%. | Respiration before, 100 | |
| | after, 58%. | " | after, 200 |
| 2. Time, 15 min. | H. before, 52%. | " | before, 100 |
| | after, 80%. | " | after, 80 |
| 3. Time, 30 min. | H. before, 58%. | " | before, 100 |
| | after, 62%. | " | after, 60 |
| 4. Time, 60 min. | H. before, 52%. | " | before, 100 |
| | after, 67%. | " | after, 35 |

The rectal injections of the gas in dogs gave the same general results.

He has also noted the following results where men have been given oxygen inhalations:

1. Weight, 140 lbs. Time, 7 min. H. before, 82%; after, 92%
2. Weight, 160 lbs. Time, 5 min. H. before, 74%; after, 87%
3. Weight, 150 lbs. Time, 6 min. H. before, 76%; after, 85%
4. Weight, 190 lbs. Time, 5 min. H. before, 80%; after, 90%

No special symptoms of exhilaration or quickened pulse were noted. The inhalations do not increase the oxygen in the plasma but with it the red cells all get their normal complement of oxygen. It has also been found that in chloroform anesthesia the H runs down from 80 per cent. to 68 per cent. in the course of fifteen minutes. Da Costa has shown that the same thing is true in ether narcosis.

The final paper of the Session was read by DR. A. E. ROUSSEL, of Philadelphia, on

LEAD ENCEPHALOPATHY, WITH REPORT OF A CASE.

This patient was a male artist, about thirty-five, who gradually became anemic and debilitated. H. 85 per cent.; C. 2,500,000. The second sound of the heart was accentuated; and the urine concentrated, but free from albumin or sugar. Three days after being first seen he suffered from an excruciating attack of colic, with constipation; and lead was found in the urine. It was learned on inquiry that he was in the habit of washing his brushes in water and then wiping them on his lips. A lead line was found on the gums; and on the insides of the cheeks were bluish patches, which grew white on being washed with oxygenated water. After the colicky attack his general condition gradually grew worse until one day, while walking in the street, he felt a sudden malaise fell down, and developed violent convulsions and delirium. He was removed to the hospital, where the same symptoms persisted and the straight jacket became necessary. Temperature 101.6°. The convulsions were finally relieved by ether, and the patient fell into a deep sleep lasting seven hours, from which he awoke perfectly conscious and made a quick recovery.

The great indication in the cerebral cases is to induce sleep. In lead colic and constipation better results, in the writer's hands, have followed the use of large doses of olive oil than any other remedy both for the pain and the constipation.

*(To be continued.)*

## Recent Literature.

*Transactions of the American Orthopedic Association.* Eighth Session held at Washington, D. C., May 29, 30 and 31, 1894. Volume VII. Philadelphia: Published by the Association, 1895.

This handsomely bound volume of 358 pages contains a number of progressive articles of great interest to the specialists in the subject to which they relate as well as to general surgeons. Among them may be mentioned: "The Radical Treatment of Severe Talipes Equino-varus in Children," by Edmund Owen, M.B., F.R.C.P., London, England; "The Treatment of Congenital Dislocation of the Hip," by E. H. Bradford, M.D., Boston; "Tubercular Disease of the Shoulder-Joint," by W. R. Townsend, M.D., New York; "The Correction of the Deformity of Hip-Disease," by V. P. Gibney, M.D., New York.

THE BOSTON

# Medical and Surgical Journal.

THURSDAY, MAY 30, 1895.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

## THE KEELEY CURE *VERSUS* THE RATIONAL TREATMENT OF INEBRIETY.

THE superintendent of the Hartford Retreat for the Insane, Dr. Henry P. Stearns, in the seventy-first annual report of that institution, just received, makes public facts and statistics of the greatest interest in view of the recent attempts made in various States to influence legislation in favor of the Keeley Cure, with the object of making its use compulsory in public inebriate asylums.

Dr. Stearns has examined the records of the Retreat for the last twenty years, and finds that of 95 patients treated during that period for inebriety, 70 were discharged as "recovered." The word "cured" is not used, and the word recovered means simply recovered from the acute effects of alcohol, and free from any special craving for it. All the patients so classed, claimed that they had no desire for alcohol and were confident that they never should have such a desire. The superintendent justly states that a "cure" cannot be claimed from a treatment of a few weeks or months only, such as these patients had. If permanent cures are effected in such cases, they are secured after discharge, through the influence of a favorable environment, force of will, and a strong determination on the part of the patient, combined with such medicines and food as will conduce to secure this result. These favorable conditions must necessarily be continued for some length of time in order to restore the nutrition of the brain tissues, impaired by chronic alcoholism, and establish their normal action.

The theory upon which Keeleyism is founded, namely, that these elements of the nervous system can be suddenly forced back into normal action by the influence or shock of a violent stimulant or poison of another character, introduced into the system for a few days or weeks, is at variance with medical experience in this and all other forms of disease of long duration.

The claim of Dr. Keeley and the syndicate representing him that 90 or 95 per cent. of cases of inebriety

can be cured in a space of four weeks has not been substantiated by facts, and efforts to secure legislation making the employment of this treatment compulsory in State institutions — especially when we consider the fact that the nature of their remedies is kept secret — are as absurd as if the proprietors of any secret remedy should endeavor to compel the use of their nostrum in public hospitals.

The claim that the Keeley patients who have been discharged as cured are in reality so, is far from proven. There are no reliable statistics with regard to the percentage of cures in Keeley patients, as the patients are received and treated by thousands, and little or nothing is usually known of their subsequent history. A slight contribution to the record of these patients is made by Dr. Stearns, since of the 52 patients affected with toxic insanity admitted to the Retreat within the last four years, 18 have been graduates of Keeley institutes. Several of them have been suicidal when admitted, and two of them committed suicide after they were prematurely removed from the Retreat by their friends.

Dr. B. D. Evans, Medical Director of the Asylum at Morris Plains, N. J., in an article published in the *Medical News*, May 18, 1893, presented a table of 88 cases of insanity, all of which had been treated in Keeley institutes and graduated as cured.

Dr. R. M. Griswold, of Derby, Conn., in his statement before the committee of the present legislature of Connecticut on humane institutions, presented the following figures in reference to the results of "Keeley Cures": Of 34 cases from Danbury, Conn., which have been treated by Keeley methods within the last three years, he has found 13 relapses. Of 17 cases from the towns of Derby, Ansonia, and Seymour, he has found seven relapses. Of 94 cases from Norwich, New London, Rockville, Willimantic, Putnam, Windsor Locks, and Providence, R. I., he has found 42 relapses.

Several other reports of a similar nature from physicians who have had Keeley graduates under their treatment are presented.

The statement of Dr. B, who was a patient at the Retreat and a graduate of a Keeley institute is extremely interesting.

He says that during the four weeks while he was under treatment, there was no time when he could not take liquor, and that several of the 35 patients who received treatment with him did take liquor every day, procuring it in the village. Patients were marshaled together in a line and given the "shot" four times a day, and "a tonic mixture" every two hours, except at night. The physician who was in charge at the time was himself a graduate of one of the institutes. He afterwards abandoned the Keeley Cure business, and resumed the practice of general medicine, but within a year began again to take alcohol and became "a mental and physical wreck."

He further states that of 38 patients who were treated with him, 14 relapsed within a year, and of these three died of Bright's disease. He knows nothing of the subsequent history of the others, the larger portion of whom came from other sections of the country.

A letter from another physician who had also received the Keeley treatment is of similar tenor, and contains the statement that of the 33 patients whom he knew, and who were taking the cure when he did, 20 had relapsed into their old habits, some of them after taking the cure twice and even three times. The concluding paragraphs of the report contain a refutation of the Keeley methods and statistics so fair and forcible that we cannot refrain from quoting them in full.

"It should, however, be stated that the above statistics are of very little value as accurately presenting the whole per cent. of relapses of the so-called cures. The conditions are such that this cannot be ascertained. Neither those who have relapsed nor their friends are forward or, indeed, willing to advertise this fact. They rather desire as far as possible to conceal it, while only those cases which have become notorious are reported. Imperfect as they are, however, they serve to indicate that the claim that 90 per cent. of drunkards are cured by Keeley methods is without foundation; and also how preposterous is the petition that the legislature should become responsible for the treatment of inebriety by secret remedies.

"The course pursued by Dr. Keeley in keeping the nature of the supposed cure a secret, proves very conclusively that he has little confidence in it himself. He does not dare to make it public, but rather prefers to trade upon the desires and hopes of credulous families and legislatures and the unfortunate weaknesses of inebriate brains. If he or any other person should discover a remedy for chronic inebriety which would effect a cure in 90 per cent. of all cases in four weeks, and make its nature public for use by all physicians, he would be hailed by men everywhere as one of the great benefactors of the race, and both wealth and honors would be showered upon him."

## A DANGEROUS POPULAR ANTISEPTIC.

Ledermann publishes in the *New York Medical Journal* for May 18th, an account of a case of diffuse external otitis, of an extremely severe and resistant type, due to taking a friend's advice and treating a slight itching of the ears with carbolic acid. The strength employed is not known: "some pure carbolic acid was poured into a glass of water and syringed into the ears." Ocular symptoms and carboluria, showed the systemic poisoning, and the patient was in great danger of atresia of one of her auditory canals.

The popular knowledge that carbolic acid is an antiseptic is productive of a great deal of harm. The fact that it was the first antiseptic employed by Sir Joseph Lister in wound treatment, has been in many ways unfortunate for the human race. Surgeons have until recently regarded it as indispensable to have their instruments in a tray of carbolic solution, which if strong enough to sterilize the instruments, destroyed the surgeon's hands for practical purposes; and if, as was usually the case, it was so weak as not to actually burn the hands did no good as an antiseptic — circumstances which were bad for the patient, the surgeon, and all concerned. The disadvantages of carbolic acid, however, can be best seen in out-patient clinics, whither patients continually come with the skin of their hands parboiled and peeling off, exposing the raw subcutaneous tissue more or less eroded by the carbolic acid which a kind friend has advised them to use for a slight cut, or burn or abrasion. The desirability of ascertaining the strength of what they are using does not occur to them. They are the victims of popular "Listerism" in its most primitive

form. If the lay mind could only be made to appreciate that carbolic acid is always dangerous and seldom efficient as an antiseptic, a great deal of unnecessary suffering would be prevented.

## MEDICAL NOTES.

THE ILLNESS OF PROFESSOR HUXLEY. — The *British Medical Journal* reports that Professor Huxley's condition has of late markedly improved. His temperature is normal, and he is eating and sleeping well. We feel sure that our readers will be gratified to know of this improvement in his condition.

ALARMING SPREAD OF SYPHILIS IN RUSSIA. — Syphilis in Russia is reported to be rapidly on the increase. The great extent of the disease in 1890, when there were ascertained to be a million syphilitics in the various Russian hospitals, gives some slight idea of the prevalence of the disease in that country. Professor Pospeloff, of Moscow, has begun the organization of a section for the discussion of prophylactic measures against syphilis at the Twelfth International Medical Congress.

THE DUKE OF CAMBRIDGE AND THE INDIAN MEDICAL SERVICE. — The Duke of Cambridge is severely and justly criticised in an editorial in the *British Medical Journal* of May 11th for alluding in his response to the toast of "The Army" at the Royal Academy Dinner to Surgeon-Major Robertson as "that brave civilian." The military medical services of the crown are said to be already dissatisfied, and all ready to resent such a matter as their commander-in-chief forgetting to give them their titles. The English military medical service is apparently held under a ban in much the same way that the medical staff of the United States navy is held by the officers of the line — a state of things which renders it difficult to secure the better class of candidates for both services. The importance of securing first-rate men for military medical positions is not sufficiently recognized by the officers of the line here or in England. Within a very short period it has been found necessary to make certain changes in the examinations for the British army and Indian medical services, with a view to securing better candidates for the positions. The effect of such a slight from the commander-in-chief of the royal forces cannot help causing discontent in Indian medical service, and tending to lower the estimation in which the army medical service is held, and to keep off the better class of candidates for the service.

### BOSTON AND NEW ENGLAND.

ANNUAL MEETING OF THE AMERICAN NEUROLOGICAL ASSOCIATION. — The American Neurological Association will meet next week in Boston for the first time in its history. As will be seen in another column, the programme is full of interest. The Association is one of the oldest of the societies that go to make up the Congress of Physicians and Surgeons, having just completed its twentieth year of life. We can assure it a hearty welcome in Boston, and we hope that its meetings, which are open to the profession, will be fully attended.

THE ANTITOXIN SUPPLY FOR THE CITY OF BOSTON. — The Board of Health of the City of Boston is now able to supply antitoxin from the horses which have been undergoing immunization at Gallup's Island, under the care of Professor Ernst. The State Board of Health will thus be relieved of the tax upon its resources of furnishing a supply to the City Hospital, which has been found rather difficult owing to the extent of the demand from more remote parts of the Commonwealth. There are now four horses at the Bussey Institution, belonging to the State Board of Health, and four at Gallup's Island under the care of the City Board of Health, which are in condition to supply antitoxin.

THE MAINE GENERAL HOSPITAL. — Drs. S. C. Gordon, S. H. Weeks and L. W. Pendleton have resigned from the staff of the Maine General Hospital.

DR. COLVIN'S RECORD OUTDONE. — With regard to the JOURNAL note on May 9th on Dr. Colvin's having practised for fifty years in the same office, the *Newport Herald* of May 20th calls our attention to the fact that one of our own subscribers can present a record which is even better. "Newport can certainly beat this noble record by presenting our esteemed citizen Dr. Henry Edward Turner, the city physician, now in active practice, who graduated at the University of Pennsylvania, in March, 1836, and who has practised for fifty-nine years. He celebrated his golden wedding on July 18, 1894, having a reception in the same room in which his wedding reception was held, fifty years ago, and in the same house always occupied by the doctor and his wife during their married life. On May 18, 1895, he had been continuously a subscriber to the *Boston Medical and Surgical Journal* since he entered upon his professional life." It is a great satisfaction that this incident has called our attention to the fact that we have such constant and faithful readers, and we haven't the least doubt that the subscription to the JOURNAL has much to do with Dr. Turner's remarkable record.

### NEW YORK.

JANITOR'S CHILDREN AND DIPHTHERIA. — The evil effects of janitors having their residence in the public school buildings is again illustrated. The nine-year-old son of the janitor of School No. 89, at 134th Street and Lenox Avenue, has been attacked with diphtheria, the school building has been closed by order of the Board of Health, and as a result, 2,300 children will be deprived for some weeks of their school privileges.

DEATH OF DR. MORRIS HENRY. — Dr. Morris Henry, for many years prominent as a surgeon and dermatologist, died May 19th in the 60th year of his

age. He was born in London, England, and pursued his studies in London and at the Polytechnic at Brussels. He was graduated in medicine at the University of Vermont, and during the late war served as assistant surgeon in the navy. After the war he settled in New York and became a member of the Board of Police surgeons. For a number of years Dr. Henry was very active in society and literary work, and he originated and edited the *American Journal of Dermatology*.

DEATH OF COUNT VON KESSLER. — The death is announced in Paris of Count Adolph William von Kessler, who for some years past has resided principally in New York. At the time of the Franco-Prussian war he was living in a magnificent mansion in Paris. Herr von Kessler, as he was then known, was an officer of the Society of the Geneva Cross, which did such admirable work among the wounded of both armies, and when the Prussians entered Paris he turned his home into a hospital for the soldiers. For this act the Emperor Frederick gave him the patent of nobility. He also did material service in introducing the ambulance service in New York and several foreign capitals. Count von Kessler was born in Hamburg and was fifty-five years old at the time of his death.

DIPHTHERIA AND ANTITOXIN IN NEWARK, N. J. Dr. Herman C. Hale has been re-elected President of the Board of Health of Newark, N. J. On May 21st he made the first report of the bacteriological laboratory recently established under the auspices of the board. The laboratory was started in February and on March 25th the first of the horses purchased by the city was injected with diphtheria toxine. Since January 1st there have been reported 288 cases of diphtheria in Newark. Of these, 90 were treated with antitoxin and 198 were not. Of the former 23 died, and of the latter, 60; the percentage of deaths being respectively 25 and 32. The result, therefore, shows a decrease of 7 per cent. in the mortality under the use of antitoxin.

A BAD RECORD. — Frederick Waring, who was recently arrested on the charge of practising medicine without a license, preferred by the Health Board of the City of Yonkers, was found guilty before Judge J. X. Donohue in the City Court on May 25th. He was fined $50, and sentenced to six months' imprisonment in the Kings County Penitentiary. The man has a very bad record. He was sentenced to one year's imprisonment in the Kings County Penitentiary for practising without a license. Two years later he was again sentenced to five years' imprisonment in Sing Sing prison for the same offence. There are also two indictments pending against him in New York for manslaughter. He was twice placed on trial charged with causing the death of a woman named Clinton by criminal malpractice in 1886, but as both juries disagreed, he was paroled upon his own recognizance.

## Miscellany.

### TWENTY-FOURTH CONGRESS OF THE GERMAN SOCIETY OF SURGERY.

THE Twenty-fourth Annual Congress of the German Society of Surgery was held at Berlin, April 17–20, 1895. A large number of eminent representatives of German surgery were present.

Von Bergmann spoke of cerebral surgery, which, despite all the light brought by modern localization-doctrines and the aid of antisepsis, must always have a limited field, by reason of inherent difficulties, and especially the difficulty of diagnosis. Thus, of tumors of the brain, only twenty-nine per cent. of cases are suitable for operation, and surgical intervention is really practicable in a much smaller percentage. Progress in the future will be made in the attainment of certainty in diagnosis and in improvement in the technique of operations. Even now, the method of osteoplastic resections enables us to remove quite large growths. Bergmann exhibited to the Congress an instrument of his own invention, a small circular saw, made to work with great speed by means of an electric motor, which had enabled him to operate with great celerity; a large bone-flap is circumscribed, and the section begun with the saw is finished with fine scissors.

Attempts have been made to cure epilepsy by operation; success has attended only those cases where the epilepsy was due to motor-cortical lesion. Abscesses, though presenting great difficulties of diagnosis, have in many instances been opened after trephining. Surgeons have even dared to attack thrombosis of the sinuses. The transverse sinus has been reached through the mastoid bone, incised, and clots have been turned out; the patient has got well after antiseptic dressings, tamponading and ligature of the internal jugular vein. Out of thirteen cases, Bergmann has had six recoveries.

Von Bramann, of Halle, exhibited a patient from whom a voluminous sarcomatous tumor of the cerebrum had been extirpated. This tumor had caused a paralysis of the left arm. It was as large as the closed fist; occupied the motor region of the right hemisphere, and had invaded the dura mater and inner wall of the cranium. The gap in the bone resulting from the operation measured twelve centimetres. The patient made a good recovery, and though three years have elapsed, there has been no return of the sarcoma. The paralysis has completely disappeared, and the patient is able to work.

Mikulicz, of Breslau, spoke of the results of surgical intervention in Basedow's disease. He has operated eleven times; the characteristic symptoms, and especially the tachycardia were well marked in all; five patients presented a grave dyspnea. All the patients survived the operation which consisted twice in simple ligature of the thyroid arteries; in all the other cases the thyroid gland (hyperplastic or cystic) was extirpated. Six of these patients have got completely well; four have been considerably benefited; one has experienced but slight improvement. In the latter case, however, the operation consisted in tying the thyroid arteries on one side only.

In cases where the thyroid is removed, the cardiac troubles and the exophthalmia are long in disappearing. He would refer the pathogeny of the disease to

auto-intoxication by the products of the hypertrophied thyroid; the disease may, however, begin as a neurosis.

Kocher, of Berne, reported the results of one thousand thyroidectomies, a review of which was given in our editorial of last week.

Schuchardt, of Stetten, showed a patient, a young girl, on whom he had operated for suppurative peritonitis due to perforation of a round ulcer of the stomach. He did not excise the ulcer, but simply closed the perforation by buried sutures. Heusner, of Barmen, who was the first to save a patient by this operation (sixteen hours after the perforation and when the peritonitis was well advanced), stated at the meeting that he had lately had three unsuccessful operations.

Körte, of Berlin, reported the results of nine extirpations of tumors of the cecum. Four of these were carcinomatous, four tuberculous, and one was a case of actinomycosis. All these patients survived the operation, though the patient affected with actinomycosis died shortly after owing to the progress of the disease. After making these resections, Körte always practises the lateral implantation of the ileum in the colon, the end of which is invaginated and sutured.

Kölliker, of Leipzig, communicated an interesting case of rupture of the left kidney with hematuria, due to a fall. On the fourth day, the symptoms being alarming, he made a vertical incision in the left lumbar region; "the upper pole of the kidney was in great part detached from the rest of the organ by a laceration extending to the hilum." He put in a drainage-tube and plugged the wound. "The temperature became normal that day, the anuria disappeared, and the patient was well at the end of six weeks."

Mikulicz, of Breslau, made an interesting report on the "Surgery of the Stomach." He had performed 103 operations on the stomach; 23 were fatal. The most frequent causes of death were collapse and pneumonia. A preliminary exploratory incision in the middle line, above the umbilicus, should always be made for diagnostic purposes. It is then easy to tell if the case is suitable for operation. If the patient is very feeble, he should have the evening before the operation "a large subcutaneous injection of artificial serum." It is in gastrostomies, gastro-enterostomies, and resections for carcinomatous growths and their results that these operations have been attended with the greatest mortality; but even if a survival of only a few months can be hoped for, the operation should be performed.

Rydygier, of Hamburg, spoke of the treatment of intestinal invagination. The mortality of operations for the relief of this accident is still very high, because the operation is almost invariably done too late, the surgeon being called in only at the last extremity. In the acute forms, an early operation is just as imperatively demanded as in strangulated hernia. In all recent cases where the invaginated cylinder presents no signs of gangrene, it is to disinvagination that one should have recourse. Out of 24 cases which he has thus treated, eight have been saved. In all the other cases, where disinvagination is impossible or contraindicated, resection is the only procedure offering any chances of success. Of twelve patients thus operated on, three have survived. He advises König's operation which consists in resecting the invaginated cylinder after incision of the invaginating cylinder; however, the procedure in question is not applicable to cases of gangrene extending to this latter portion of intestine.

In the chronic forms of invagination, operative intervention is not so imperative as in the acute forms. Nevertheless it is important to interfere before a new aggravation of the symptoms renders the operation more difficult and more dangerous. The patient, as long as the invagination persists, is menaced with peritonitis by perforation. Disinvagination may be attempted with success several months after the onset, if there are no serious adhesions. If disinvagination is impossible, it is to resection that the surgeon should have recourse, and not to entero-anastomosis.

Alsberg, of Hamburg, stated that in three cases of acute invagination he had succeeded in obtaining disinvagination by laparotomy. In one of these cases, the operation was not performed till the sixteenth day. All three patients got well.

## Correspondence.

### A LONG PERIOD OF FECUNDITY.

PLATTSBURGH, N. Y., May 23, 1895.

MR. EDITOR: — Last evening I attended a woman in her thirteenth confinement. The child weighed four pounds when dressed. The mother is forty-six years old. Her oldest child is a little more than twenty-eight years of age. This makes a continuous period of actual child-bearing of about twenty-nine years, the mother having been married at the age of seventeen. The point of interest in this case is the long time of *actual* fecundity. Both father and mother seem to think this time may yet be extended.

D. S. KELLOGG, M.D.

### NEW SURGICAL SPLINTING.

SOUTH BOSTON, May 24, 1895.

MR. EDITOR: — Kindly permit me to correct an error which your correspondent apparently makes in his otherwise admirable report of the American Medical Association meeting in Baltimore. I refer to his report of my paper read there. He writes: "The edges of the splint must be covered with chamois skin." As a matter of fact, none of the splints shown there by me were so treated except one — my splint for hip-joint fixation; all the others, comprising splints moulded directly upon the patients, and employed to produce efficient fixation of the ankle, wrist, knee, elbow, shoulder, finger and toe joints, having no chamois skin, because in such splinting it is unnecessary.

I write this letter because I earnestly desire as accurate notions of my work in surgical splinting to prevail in Boston as elsewhere.

A matter of less importance is that the title of my Baltimore paper should have read, "The New Surgical Splinting: Report of Cases Exemplifying It."

Truly yours,

EDWARD A. TRACY, M.D.

### ANOTHER CASE OF "FRACTURE OF THE HUMERUS FROM AN UNUSUAL CAUSE."

PHILADELPHIA, May 25, 1895.

MR. EDITOR: — I note in your issue of March 21st, a case reported of fracture of the humerus from an unusual cause. Just such an one occurred to a friend of mine, himself a physician of very large reputation now and flourishing mightily, whose name I might quote, as he gave me

leave to report the matter fifteen years ago. At that time he was acting as surgeon to a trans-Atlantic liner, and was (and is) a man of great muscular strength, chiefly of a nervous explosive kind, however, but of great vitality and endurance. This accident resulted from the attempted feat of two men sitting opposite at a small table and each using the same hand, right to right or left to left, elbows resting on the table and thus trying who could push the opponent's hand backward till the knuckles touched the level. As in the case described by Dr. Monks, the break made so loud a noise that it was heard at a great distance, and was probably greatly assisted by the motion of the ship producing some collateral strain. This fracture was at the junction of the upper and mid thirds, and was followed by very little pain. He, being the only medical man on board, adjusted the parts himself and applied an original splint. The result was most satisfactory, except that a few days later a fall on the deck refractured the arm at the same place, yet the deformity was almost *nil*, attributable to his own skill or will or vigor.

It is of interest to mention also that a couple of months or so afterwards, while throwing an apple to a friend at a considerable distance, and presumably with his utmost force, the arm was broken again, but not in the same locality, about the junction of the lower and mid thirds, in no way disturbing the old seat of damage. The arm is now free from any recognizable deformity or lack of power or skill (as the statistics of one of the most celebrated gynecologists in the world will testify). Moreover, though subjected to many and various opportunities for damage in many lands and vicissitudes, he has enjoyed in the main excellent health and no evidence of fragilitas ossium other than those curious casualties within so brief a time, and while living a life of unusual healthfulness.

Very truly yours,
J. MADISON TAYLOR, M.D.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MAY 18, 1895.

| Cities. | Estimated population. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | |
|---|---|---|---|---|---|---|---|---|

| Amesbury | 10,920 | 2 | 0 | — | — | — | — | — |

Deaths reported 2,352; under five years of age 816; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 292, acute lung diseases 295, consumption 321, diphtheria and croup 97, diarrheal diseases 53, measles 37, scarlet fever 28, whooping-cough 17, typhoid fever 23, cerebro-spinal meningitis 20, erysipelas 9, malarial fever 7, small-pox 3.

From scarlet fever New York 13, Boston 3, Brooklyn and Pittsburg 2 each. Washington, Fall River, Lynn, Brockton, Quincy and Newburyport 1 each. From typhoid fever Philadelphia 8, Brooklyn and Washington 3 each. New York, Boston and Pittsburg 2 each. Providence, Nashville and Worcester 1 each. From cerebro-spinal meningitis Brooklyn 11, New York 3, Philadelphia, Boston, Chelsea, Quincy, North Adams and Pittsfield 1 each. From whooping-cough New York 7, Philadelphia and Brooklyn 4 each. Cincinnati and Brockton 1 each. From erysipelas New York, Brooklyn and Boston 1 each. From malarial fever Brooklyn 3, New York and Washington 2 each. From small-pox Cincinnati 3.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530 for the week ending May 11th, the death-rate was 17.7. Deaths reported 3,585; acute diseases of the respiratory organs (London) 247, whooping-cough 81, measles 83, diphtheria 65, diarrhea 60, fever 31, scarlet fever 31.

The death-rates ranged from 13.5 in Brighton to 25.8 in Plymouth, Birmingham 19.5, Bolton 22.7, Cardiff 14.4, Gateshead 14.1, Huddersfield 15.2, Leeds 18.1, Leicester 17.3, Liverpool 23.0, London 16.6, Manchester 22.3, Newcastle-on-Tyne 21.7, Nottingham 14.5, Sheffield 16.3, Sunderland 13.6.

## METEOROLOGICAL RECORD.

For the week ending May 18th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | Weather. | | Rainfall in inches. |

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MAY 18, 1895, TO MAY 24, 1895.

CAPTAIN ROBERT J. GIBSON, assistant surgeon, will be relieved from duty at Fort Sam. Houston, Texas, by the Commanding Officer of that post, and will report in person to the commanding officer Fort Thomas, Kentucky, for duty at that post.

MAJOR WILLIAM H. GARDNER, surgeon, is relieved from duty as attending surgeon and examiner of recruits at Headquarters Department of Dakota, and ordered to Fort Reno, Oklahoma Territory, for duty at that post, relieving MAJOR HENRY M. CRONKHITE, surgeon.

Leave of absence for four (4) months, on surgeon's certificate of disability, with permission to leave the Department of the Missouri, to take effect on being relieved from duty at Fort Reno, Oklahoma Territory, is granted MAJOR HENRY M. CRONKHITE, surgeon.

Leave of absence for ten days to take effect from the date of the conclusion of his examination for promotion, is granted CAPTAIN LOUIS W. CRAMPTON, assistant surgeon.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MAY 18, 1895.

L. L. YOUNG, assistant surgeon, to examination for promotion.

F. W. Olcott, passed assistant surgeon, from the "Constellation" and to the "Enterprise."

## MAINE MEDICAL ASSOCIATION.

The Forty-third Annual Meeting will be held in Common Council Chamber, City Building, Portland, Me., Wednesday, Thursday and Friday, June 5, 6 and 7, 1895.

### WEDNESDAY, JUNE 5th.

*Morning Session, at* 10 A. M. — Prayer. Reading of the Records of the last meeting. Business. Report of Treasurer. A Unique Case of Apoplexy, by R. D. Bibber, M.D., Bath. Cerebral Embolism, by John F. Hilton, M.D., Lewiston. Neurasthenia, by W. F. Hart, M.D., Camden. Report of Visitors to the Portland School for Medical Instruction. Report of Visitors to the Maine Insane Hospital. Report of Visitors to the Medical School of Maine. Voluntary Papers or Reports of Cases.

*Afternoon Session, at* 3 P. M. — Reception of Delegates from other Societies. President's Address. Business. White's Operation for Hypertrophied Prostate, by F. C. Thayer, M.D., of Waterville. Vaginal Hysterectomy, by W. K. Oakes, M.D., Auburn. Pyosalpinx, by J. F. Thompson, M.D., Portland. Voluntary Papers or Reports of Cases. Reports of Delegates to other Societies.

*Evening Session, at* 8 P. M. — Hennequin's Method of Treating Fractures of the Thigh and both Bones of the Leg, by Alfred King, M.D., Portland. A Case of Myxœdema Successfully Treated with Thyroid Extract, by J. K. F. Rogers, M.D., South Portland.

### THURSDAY, JUNE 6th.

*Morning Session, at* 10 A. M. — Business. Tuberculosis of the Knee-Joint, by S. H. Weeks, M.D., Portland. Report of the Committee on Revision of Code and By-Laws. Radical Cure of Inguinal Hernia, by C. E. Williams, M.D., Auburn.

*Afternoon Session, at* 3 P. M. — Reception of Delegates from other Societies. Election of Officers for the ensuing year. Treatment of Pulmonary Tuberculosis, by C. A. Peaslee, M.D., Wiscasset. Dietetic Treatment of the First Stages of Phthisis, by J. F. DeCosta, M.D., Buckfield. A Clinical Study in Typhoid Fever, by D. E. Parsons, M.D., Oakland.

*Evening Session, at* 8 P. M. — Annual Oration, by A. K. P. Meserve, M.D., Portland. Sequelæ of Diphtheria, by J. A. Spalding, M.D., Portland. Cases in Practice, by B. F. Bradbury, M.D., Norway.

### FRIDAY, JUNE 7th.

*Morning Session, at* 9 A. M. — Business. Reports of Delegates to other Medical Societies. Voluntary Papers or Reports of Cases. Report of the Board of Censors. Unfinished Business.

CHAS. D. SMITH, M.D., *Secretary.*

## AMERICAN NEUROLOGICAL ASSOCIATION.

### WEDNESDAY, JUNE 5th.

*Morning Session, at* 10 A. M. — Address by the President, Dr. Philip Coombs Knapp, of Boston. 1. Dr. J. A. Booth of New York, Hysterical Amblyopia and Amaurosis. Report of five Cases treated by Hypnotism. 2. Dr. George J. Preston, of Baltimore, A Case of Total Hysterical Anesthesia in the Male. 3. Dr. F. X. Dercum, of Philadelphia, Two Cases of Railway Spine, with Autopsy. 4. Dr. C. L. Dana, of New York, A Case of Hereditary Chorea, with Autopsy. 5. Dr. Chas. K. Mills, of Philadelphia, The Localization of Lesions in the Pons. 6. Dr. Geo. L. Walton, of Boston, Exhibition of a Specimen showing Fracture of the Cervical Vertebræ.

*Afternoon Session, at* 2 P. M., at the Harvard Medical School. 7. Dr. M. Allen Starr, of New York, A Lantern Exhibition of Photo-micrographs of Nervous Histology; Golgi Stains. 8. Dr. Edward Wyllys Taylor, of Boston, A Lantern Exhibition of the Medulla Oblongata of a Chimpanzee, with other Specimens. 9. Dr. William Townsend Porter, of Boston, The Part of Inhibition in the Physiology of Respiration. 10. Dr. Thomas Dwight, of Boston, Exhibition of the Brain of a Chimpanzee. 11. Dr. Burt G. Wilder, of Ithaca. Fissural Studies (*a*) Two Philosophers; (*b*) An Apparent Duplication of the Central Fissures. 12. Dr. Wm. N. Bullard, of Boston, The Diagnosis of Hemorrhagic Cerebral Pachymeningitis.

### THURSDAY, JUNE 6th.

*Morning Session, at* 9 A. M. — 13. Dr. James J. Putnam, of Boston, Hyperostosis Cranii, with Illustrations. 14. Dr. Charles K. Mills, of Philadelphia, Cortical Localization in the Light of Recent Investigations in Minute Anatomy. 15. Dr. C. E. Riggs, of St. Paul, Injury to the left Angular Gyrus. 16. Dr. E. D. Fisher, of New York. Report of a Case of Tumor of the Cerebellum, with Autopsy, Operation by Dr. John F. Erdmann. 17. Dr. Geo. J. Preston, of Baltimore, Cases of Brain Tumor. 18. Dr. Geo. L. Walton, of Boston, Presentation of a Brain Tumor.

*Afternoon Session, at* 2 P. M., at the new McLean Asylum, Waverley. — 19. Dr. H. A. Tomlinson, of St. Peter, Insanity and Phthisis, their Concurrency, Co-existence, and Transmutation. 20. Dr. Theodore Diller, of Pittsburg, The Association of Tabes and Paralytic Dementia. 21. Dr. Theodore H. Kellogg, of Willard, The Pulse in Insanity, Original Study of Cases. 22. Dr. H. M. Bannister, of Chicago, The Home Treatment of Insanity. 23. Dr. Wm. Noyes, of Foxboro, Must Acute Paranoia be admitted into our Nomenclature? 24. Dr. C. E. Riggs, of St. Paul, The Criminal Insane Abroad. 25. Dr. Irving C. Rosse, of Washington, The Conservative Value of the Play Impulse.

### FRIDAY, JUNE 7th.

*Morning Session, at* 10 A. M. — 26. Dr. Joseph Collins, of New York, a Contribution to the Pathology and Morbid Anatomy of Amyotrophic Lateral Sclerosis. 27. Dr. Wm. C. Krauss, of Buffalo, Report of a Case of Peroneal Muscular Atrophy, with Autopsy. 28. Dr. James Hendrie Lloyd, of Philadelphia, Telegrapher's Paralysis. 29. Dr. James Wright Putnam, of Buffalo, Writer's Cramp. 30. Dr. G. M. Hammond, of New York, Report of a Case of Multiple Neuritis in an Infant. 31. Dr. Geo. L. Walton, of Boston, The Etiology of Obstetrical Paralysis.

*Afternoon Session, at* 2 P. M. — 32. Dr. Smith Baker, of Utica, Auto-mimesis. 33. Dr. Morton Prince, of Boston, Pseudo-neurasthenia. 34. Dr. C. H. Hughes, of St. Louis, Adianoia, the true Paranoia. 25. Dr. J. T. Eskridge, of Denver, Subject to be announced.

DR. G. M. HAMMOND, *Secretary.*

The profession are cordially invited to attend the meetings of the Association, which, with the exceptions above noted, will be held in the hall of the Boston Society of Natural History.

## THE ASSOCIATION OF AMERICAN PHYSICIANS.

The Tenth Annual Meeting will be held in Washington, D.C., May 30th and 31st, and June 1st, Dr. William Osler, Baltimore, President.

The programme presents the following papers: The President's Address, by Dr. William Osler, Baltimore; Leucomaine Poisoning, Dr. B. K. Rachford, Cincinnati; Some Toxicogenic Germs found in Poisonous Foods, Dr. V. C. Vaughan and Dr. George D. Perkins, Ann Arbor; Effects of the Gaseous Products of Decomposition upon the Health of Animals that are Compelled to Respire them, Dr. A. C. Abbott, Philadelphia; Renal Affections following Influenza, by Dr. G. Baumgarten, St. Louis; A Contribution to the Study of Thoracic Tumors, Drs. William Pepper and Alfred Stengel, Philadelphia; The Etiology of Idiopathic Hypertrophy of the Heart, Dr. James T. Whitaker, Cincinnati; The Transmission of Mitral Diastolic Murmurs, Dr. J. P. C. Griffith, Philadelphia; The Use of the Differential Stethoscope in the Study of Cardiac Murmurs, Dr. A. H. Smith, New York; The Cause of the Exaggeration of Sounds over the Right Upper Chest, both in Health and Disease, Dr. Charles Cary, Buffalo; The Preparation of Antitoxin, Dr. H. C. Ernst, Jamaica Plain, Mass.; A Case of Madura Foot (Mycetoma Pedis), Dr. J. G. Adami, Montreal; Gonorrheal Arthritis — Clinical Observations, Dr. W. P. Northrup, New York; Hyperthermy up to 66.5° C. (148° F.), Dr. A. Jacobi, New York; A Comfortable Way of Using Cold in Fevers, Dr. F. H. Williams, Boston; Some Observations on the Spleen and Marrow in Leucemia, Dr. J. Guitéras, Philadelphia; Goitre in Michigan, Dr. George Dock, Ann Arbor; Displacements of the Liver, Dr. J. E. Graham, Toronto; Carcinoma of the Liver with Cirrhosis, Dr. M. H. Fussell, Philadelphia; Epidemics of Typhoid Fever, Scarlet Fever, and Diphtheria Due to Milk Infection, Dr. S. C. Busey, Washington; Forcible Artificial Respiration — the Fell-O'Dwyer Apparatus — Cases, Dr. W. P. Northup, New York; Carosso's Treatment of Pulmonary Tuberculosis, Dr. H. C. Ernst, Jamaica Plain, Mass.; On the Direct Faradization of the Mucous Membranes of the Stomach and the Intestines of Animals (Dogs, Cats, and Rabbits), Dr. S. J. Meltzer, New York; Two Cases of Fat Necrosis, Dr. C. G. Stockton, Buffalo.

## RECENT DEATHS.

PROF. CARL VOGT, the distinguished German biologist, died at Geneva on May 6th, at the age of seventy-eight years.

J. D. ROBINSON, M.D., of Wooster, O., died May 9th, aged seventy-five. He is said to have performed the first amputation in the War of the Rebellion.

## BOOKS AND PAMPHLETS RECEIVED.

Nouvelle Méthode de Traitement de la Tuberculose Pulmonaire, du Lieutenant Colonel G. M. Carasso, Docteur en médecine, Directeur de l'Hôpital Militaire de Gênes.

List of Surgical Splints Exhibited at the Columbian Exposition, Chicago, 1893. By Edward A. Tracy, M.D., Boston, Fellow of the Massachusetts Medical Society. 1894.

Report of a Surgical Clinic (Illustrated), Complimentary to the Visiting Members of the Mississippi Valley Medical Association. By Prof. Augustus C. Bernays, M.D. 1895.

# Address.

## PRESIDENT'S ADDRESS,

DELIVERED AT THE TWENTY-FIRST ANNUAL MEETING OF THE AMERICAN NEUROLOGICAL ASSOCIATION, BOSTON, JUNE 5, 1895.

BY PHILIP COOMBS KNAPP, A.M., M.D., BOSTON.

GENTLEMEN: — Our programme is long, and contains much that is more interesting than anything I can offer. One or two duties, however, must be performed before I can invite you to listen to it. First of all, I must thank you for the honor conferred upon me in choosing me to preside on this occasion; next, I must offer to you, in the name of the medical profession of Boston, a most hearty welcome on this your first visit as an Association to our city, with a wish that you may pay us many more such visits; and, finally, I must present to you greetings and regrets from our honorary and associate members abroad, Erb, Hughlings Jackson, Ferrier, Horsley, and others, whose letters will be read later. Having done this, it might be more fitting to begin upon our programme without delay; but, in view of the fact that the Association has just completed its twentieth year of life, I may perhaps be pardoned for detaining you for a few words of retrospection and of suggestion for the future.

On the fifteenth of December, 1874, a letter was sent out, signed by seven men, three of whom are still active members of this society. Its opening sentence was as follows: "It is contemplated to institute a Society, to be called The American Neurological Association, to be devoted, as its name imports, to the cultivation of Neurological Science, in its normal and pathological relations." Five and thirty men, including the signers, accepted the invitation, and on the 2d, 3d and 4th of June, 1875, the first meeting of the new Association was held in New York. Twenty members were present, and Dr. Weir Mitchell was elected as the first president, but, on his withdrawal, the late Dr. Jewell was chosen to fill his place. The new society was something of an experiment; there were but two similar associations in this country, the Ophthalmological and the Otological, where there are to-day thirteen or more. Few neurological societies existed abroad, and it was not until eleven years later that the Neurological Society of London was organized. Up to that time, in most parts of the world, the neurologist had had to content himself with the crumbs that fell from the alienist's table, and those, apparently, had been so scanty that at first we declined to share our own feasts with the alienists. We have grown more liberal with years, so that we have even offered them of our abundance of late, although the food was not wholly to their relishing. With that exception, which was but temporary, we have pursued no exclusive policy. Although dealing with the highest and most difficult problem of medicine, the study of the brain of man, ours is not the specialty of a single organ; we must search every part of the body to make our diagnosis, and be general physicians first and neurologists afterwards. We went out with our first invitation into ophthalmological highways and hedges, and we have ever welcomed the physiologist, the general physician, and the surgeon into our ranks.

I must leave it for others to speak of those early and, if tradition be correct, somewhat stormy days of the Association's life. A number of the founders of the society are happily with us, who have taken honorable part in the transactions during the whole twenty years; we regret the absence of the rest who are still on our rolls — Bartholow, Bannister, Mitchell and Seguin. Others, too, can speak from better knowledge of those who met twenty years ago and who have now finished their work: Jewell, Hun, Clarke, McBride and Van Bibber. A word of tribute, however, is due to one of our late members who has died this year, that genial comrade Matthew Dudley Field, who sent, only a week before his death, a cheering message, full of hope that with restored health he might be here to-day.

Of the work which we have done during the last twenty years little need be said. We have flourished as a society, our membership has increased from thirty-five to eighty-five, our meetings have steadily grown in interest and in profit, and we have done our share in the establishment and the success of the most important medical body in this country, the Congress of Physicians and Surgeons. Of the scientific work which has been done under the auspices of the Association it can honestly be said that if, both in neurology and psychiatry, the work done by our members in the last twenty years were to be deducted, America's claim to consideration in the scientific world in those branches would be poor indeed. We have done something to add to the enormous mass of knowledge concerning the nervous system that has been accumulated during the last twenty years. What the advance in that knowledge has been we all know, and time is lacking to review it here.

Although on such an occasion as this a little self-gratulation is pardonable, it is the part of wise men not to indulge in the vain-glorious boastings of the Fourth of July orator, but to ask ourselves not what we have done, but rather what we have left undone. As we look over not only the more complete bibliographies, but also the various references in the works of our colleagues abroad, — where, by the way, we find much more frequent notice of American work than there was twenty years ago, — we may observe that American names are far less frequently quoted in the sections on anatomy and experimental physiology than in those on symptomatology, pathology and therapeutics. Our programme to-day shows that we are doing some work in these directions, but the amount that has been done is still below the mark. We have as yet produced no work on anatomy to set beside even the elemental work of Edinger, much less the exhaustive treatise of Dejerine, to cite only one or two examples; nor have we produced any work on the experimental physiology of the nervous system to rank with those of Munk, Ferrier, Luciani or Goltz. In these branches we have done too little, but, in extenuation, it must be said that it is only within a few years that the facilities for experimental research have been at all adequate, even in our larger cities, and we are still in great need of endowments sufficient to carry on such research. The beginnings that we have now made show that when it shall become possible for a young man to make a living, though but a plain one, from purely scientific work in the field of neurology, we may expect results which will put us more nearly on an equality with our foreign brethren.

We need make less apology for the clinical and pathological work that we have done in the last

twenty years. It has perhaps been given to but few of us to attain the grisly immortality which links our names to some new form of disease, but we have added a few new titles to the list of diseases and their symptoms, and we have done much to define more accurately and to describe more in detail the affections discovered by others. As might be expected from the eminently practical nature of the American mind, our greatest additions to the world's knowledge have been made in the domain of therapeutics. The contributions of American neurologists and surgeons have done much to teach us the all too narrow limitations of the operative therapeutics of the nervous system. But for an oversight, we should have been first in the field in the operative treatment of cerebral tumors, and we can claim second place on account of the character and amount of the work that has been done in that field in this country. We have done something, perhaps enough, to prove that neither hypnotism nor treatment by the animal extracts is likely to prove a panacea for the affections of the nervous system. Important, too, as it may be to discover a new stain or to define a new tract of fibres in the pons, our chief aim, after all, is to heal the sick, and, in spite of the promise or lack of promise of brain surgery, animal extracts, electricity and hypnotism, there has been no discovery as yet in these twenty years in the domain of the nervous system, that has brought comfort and healing to so many people as that of the rest cure by one of our active, and soon, I hope, to be honorary, members, Dr. Weir Mitchell, of Philadelphia.

So much for our past. We need in the future a journal of neurology under our own control, with a sufficient financial support to enable us to publish fitting illustrations with the reports of our anatomical and pathological work. We need, too, in most of our cities, that recognition in our large hospitals which our President urged last year, a recognition which will come when we have taught the public the necessity and importance of our special field of work. While we are teaching, too, let us do something toward making the general physician realize that the ignorance of neurology, which he too often professes, is far from creditable, and that it would render him ridiculous in any country but this.

The problems before us which demand our attention are too numerous to be rehearsed. Much of the brain cortex still resembles the map of Africa as it used to be in our boyhood — an unexplored blank. We must apply the Golgi methods in disease, and define, if possible, the pathology of the neuron. We must banish the word functional, by demonstrating the pathology of the so-called functional diseases. We must study still more precisely the symptoms of disease, and put our knowledge of electrical diagnosis and the sensory disturbances on a more exact basis. We must differentiate the various clinical forms of insanity, and bring some order out of the chaos labelled neurasthenia. Above all we must remember, as has just been said, that our chief aim is to heal the sick. What shall it profit our patients, if we know the course of the axis cylinder of every neuron in their spinal cords, and the exact percentage which each factor has in the etiology of tabes or general paresis, or the finest points in differential diagnosis, or the minutest pathological changes, if the end of it all is to be a Weigert stain?

It is too much to hope that in the future we can remove sclerosed tissue and substitute healthy nerve cells or fibres in its place, or that we can do more than alleviate for a time the symptoms which such sclerosis causes. Our hope, therefore, must be in prevention.

The discussion which we held last year at the Congress in Washington indicated the importance of infection in the etiology of many disorders of the nervous system. In the work of the bacteriologist and the boards of public health lies much hope for the future. When we can deal with syphilis and tuberculosis as we can with small-pox, and as we seem likely to do with diphtheria, we shall have done much toward the prevention of some of the most hopeless affections of the nervous system.

For those affections dependent upon a defective nervous organization, an unstable and invalid brain, much has already been done and still more can be done in the future when the public is ready to admit the unpleasant fact that such persons are mental cripples, and must have their lives ordered for them as the surgeon now orders life for the hunchback or the cripple. They need a definitely prescribed existence, as to their food and drink, their stimulants and sedatives, their work and play, their study and exercise, their reading and society. This is done now in a few cases, but we see daily many other cases where it is in some degree advisable, and where, if it were done, many morbid nervous and mental conditions might be prevented, or at least materially benefited. For such people and for many who call themselves well, the conditions of our social life are injurious, but we are none of us young enough to hope to change the entire social fabric. There is very much in the world that does no harm to a well man, which these people cannot bear; we cannot alter the world to suit them, but, when we are permitted, we can shield them from the special things of the world that prove injurious.

In yet another way we can protect the unstable and those who are not sufficiently developed mentally to act absolutely as their own rulers, and thus we can prevent a certain amount of nervous disease. As our boards of health strive to protect the public from infection by specific germs, so it should become our province to guard the public against mental contamination from the degenerates of whom we are just now hearing so much. We restrain the lunatic who has homicidal impulses; we should also strive to counteract the evil influences of the fanatical, neurotic and degenerate, in the fields of sociology, politics, morals, religion, art and literature, and point out their morbid tendencies.

We have heard something too much for a number of years of the increased nervousness of our age. The neurotic and the degenerate, like Job, speak in the anguish of their spirit, and complain in the bitterness of their souls. They tell us that the world is sick with their disease, and with damnable iteration, they analyze, not only for their physicians but for the public at large, all the mental, moral, physical and sexual aberrations of their diseased minds. It is a matter of doubt, however, how much harm has been done to the nervous system of the healthy man by the penny-post, or the telegraph, or the railway train, or even the daily paper. Let us admit, however, that in the struggle for existence as manifest in our day, the weaker brain must succumb, that social and mental unrest are great; yet, if we look back a little, we find throughout history the same struggle, perhaps under different conditions, the same unrest, the same doubt,

the same *tædium vitæ*. The Preacher, two thousand years ago, held that all was vanity and vexation of spirit, yet, even then, he found no new thing under the sun. With the diminution of infectious diseases, better food, more rational standards of living, and greater security for life and property, it is more than probable that there has been an actual diminution in the total amount of nervous disease, even though greater knowledge permits us to detect the less marked manifestations of such disease. Greater or less though the amount may be, there is still much that is distinctly preventable; let it be our aim in the future to aid in its prevention.

## Original Articles.

### AN EXAMINATION OF SOME RECENT STATISTICS IN REGARD TO ETHER, AND A CONSIDERATION OF SOME PRESENT METHODS OF ITS ADMINISTRATION.[1]

BY JOHN B. BLAKE, M.D.,
*Surgeon to Out-Patients, Boston City Hospital; Physician to Genito-Urinary Department, Boston Dispensary.*

ONE of the most astonishing facts in the history of anesthesia, is the rapidity and completeness with which chloroform supplanted ether throughout the whole of Europe and a considerable portion of the United States. Within ten months after its first public administration in the Massachusetts General Hospital, ether was being used throughout almost the entire civilized world. Within two and one-half years after its discovery, there were not more than half-a-dozen large clinics on the Continent which had not discarded ether for its rival, chloroform. For so general an action as this, there must have been reasons, and reasons readily apparent; and if there were arguments against such action, they must either have been disregarded or else were essentially less apparent upon a short examination of the qualities of both anesthetics, and until a sufficient number of reliable statistics were collected upon which a final judgment might be based.

The advantages which chloroform possessed over ether and which were immediately apparent to the surgeons using anesthetics were in effect:

(*a*) The smaller amount of chloroform necessary to produce complete anesthesia;

(*b*) The fact that the patient becomes unconscious under the influence of chloroform more quickly, and perhaps, more quietly;

(*c*) That chloroform is non-inflammatory and non-explosive;

(*d*) That there is less irritation of the respiratory tract with chloroform;

(*e*) That the recovery from chloroform is more prompt and the after-effects less marked.

That these advantages were at once obvious to the observers of that time, and that in a considerable measure they hold good to the present day, must be admitted by any impartial investigator.

They were naturally just that class of phenomena which would be demonstrable upon a short and rather superficial examination. That they were not the most essential attributes of anesthesia required time to prove.

The one final and absolutely decisive test by which any anesthetic is to be judged, must be, of course, its effect on human life. Compared to this, all other inconveniences or discomforts are of small moment. The ideal anesthetic and the ideal method of its administration must be, first, that which while producing complete anesthesia, in no degree imperils life; second, that which is rapid and effectual in its action, and which in its careful administration is not unpleasant to the patient; and third, which is free from undesirable after-effects, and from the accidents of inflammability, explosiveness, or great bulk. That we shall ever possess such an agent is very doubtful, but that we shall always try to discover it, is simple duty.

Since the final test, therefore, which is to decide the choice of an anesthetic is the safety of its action, a large amount of trustworthy and accurate statistics bearing upon this point must be gathered as a basis for such a choice. Statistics have been at hand for many years, but for some reason have failed until recently to convince many of the European surgeons. Perhaps the wide-spread belief that disasters following chloroform were exaggerated, and those following ether overlooked, may in part account for this. At all events, the writer has been unable to discover any other sufficient reason; and it seems hardly fair to believe for a moment that eminent disciples of the English, German, French, Italian and other European schools, should so unanimously favor the use of chloroform, unless upon firm conviction after thorough examination.

A student who attended the Harvard Medical School a half-a-dozen or more years ago was told that statistics showed one death in 20,000 ether cases, and one death in 2,000 chloroform cases; and accepting these statistics as the average of those attainable at that time, it was beyond the comprehension of the average student that chloroform could be used in any civilized country, except perhaps in those rare cases in which all authorities agree that ether is contraindicated. And yet, even at that time, Boston, Lyons (France), and to a lesser extent Geneva and New York, Berne, and perhaps Dresden, were the only great cities of the world in which ether was being used to the complete or even comparative exclusion of chloroform.

The crusade which some of the English medical journals, notably the *Lancet*, began some half-dozen years ago against the indiscriminate use of chloroform, is well known.

About four years ago, Juillard in Geneva, and Gurlt in Berlin, offered almost simultaneously fresh statistics upon this subject, which had been almost overlooked for many years. These statistics, collected in different countries, but mainly Continental, agree on the whole so nearly, and emphasize so strongly the greater safety of ether, that they have seemed worthy of close examination. They are characterized by the same modern scientific spirit that is manifest in other branches of learning; they come from different races and from various countries; they are rich in details. Besides those of Juillard and Gurlt, several other extensive articles have appeared within the past two years, notably the papers of Vallas of Lyons, Garre of Tübingen, and Vogel of Berlin. Finally, one noteworthy and very interesting communication has been published by Professor Miculicz, of Breslau, which though shorter than some of the others, attracts attention to itself as being one of the very few which does not accept the superiority of ether as proven.

[1] Being one of two papers receiving the second Lyman Prize for 1894.

For four years past, Gurlt has presented at the annual meeting of the Deutschen Gesellschaft für Chirurgie the statistics of chloroform and ether narcosis which he has been able to collect in each preceding year. From the first these figures have shown a decisive and unvarying proportion in favor of ether. As a result, the number of etherizations in Germany for 1893–94 was practically double that of the previous year, while the number of chloroform cases was diminished; a pleasant comment upon the confidence of the German surgeons in the investigator, and upon the spirit which prompts them to use the method which careful statistics and practice proves to be the best, even though to them personally the less attractive — though it must be confessed that it has taken several years for the spirit to move them in the latter direction.

Gurlt's final statistics, given to the Gesellschaft für Chirurgie at Berlin in April, 1894, included the observations for four years. The figures are:

| | |
|---|---|
| 166,812 chloroform cases . . . | 63 deaths, or 1- 2,647 |
| 26,320 ether cases . . . . | 2 deaths, or 1-13,160 |
| 8,011 ether and chloroform cases . | 1 death, or 1- 8,014 |

All observers report increased secretion, saliva and mucus, and the occasional development of bronchitis and pneumonia after the use of ether.

Other German observers are:

| | | |
|---|---|---|
| Zeigler, | 600 ether cases . | no deaths |
| Vogel, | 1,200 ether cases . | no deaths or serious complications |
| Körte, | 600 ether cases . | no deaths or serious complications |
| Tschmarke, | 500 ether cases . | no deaths or serious complications |

Some late French statistics are as follows:

Vallas recalls the fact that in 1867 a commission at Lyons, appointed to investigate the question of anesthesia, reported that "in twenty years there were but six deaths from all ether cases, and that though ether certainly may kill, it is much less dangerous than chloroform."

Ollier recorded 40,000 ether cases without a single death; and no death ensued in 730 recorded by Chalot, in 6,500 recorded by Tillier, or in 15,000 recorded by Poucet.

The writer has not been able to collect many statistics of English surgeons. Those found, are given here, together with the comparative French figures.

Williams (English), 14,581 ether, 3 deaths, 1 to 4,860; 12,368 chloroform, 10 deaths, 1 to 1,236.

Middlesex (see Vallas), 1,050 ether, 1 death; 208 chloroform, 1 death.

Juillard, 314,738 ether, 21 deaths, 1 to 14,987; 524,507 chloroform, 161 deaths, 1 to 3,258.

Attention is called, not only to the enormous figures of Juillard, but to the large number of observers who offer statistics upon small numbers of cases, in which all essential and controvertial points have been carefully noted. Such statistics necessarily must be most valuable and the desirability of obtaining them from all parts of the world is too obvious to need more than a passing comment. It is precisely this class of statistics which is most difficult to find in the United States.

According to these observers, vomiting would seem to be less frequent on the Continent than in America. The estimates of the various writers vary from "vomiting slight and rarely observed," to "vomiting present in about half the cases." Subcutaneous injections of morphine, before the ether, is the means most widely suggested as a preventive. Occasionally a small amount of atropine is combined with the morphine. Irritation of the lungs and trachea, secretion of mucus, cough, and an initial period of excitement are unanimously declared to be more frequent with ether than with chloroform. The German authorities believe that chloroform irritates the kidneys more than ether, and agree that ether, rather than chloroform, is unquestionably indicated when it becomes necessary to anesthetize old persons, young persons, very weak persons, and those suffering from heart disease. There is a marked difference of opinion as to the preferable anesthetic for brain surgery. Narcosis with the A C E mixture is universally regarded as dangerous, though it was used by Billroth as late as 1892. It seems to be a fact that the so-called ether nephritis was first described by American writers, and has never been found to exist in any considerable degree, except by Americans (see Garre). This is rather remarkable, when we compare it with other statistics in regard to ether.

Fueter and Roux report that they did not find a single instance of albuminuria among several hundred ether cases which they investigated.

Bütter discovered albumin once, after ether, in 500 cases.

Körte found it in 600 ether cases; seven contained albumin before ether, not increased after it; six had albumin after ether, which was absent before it.

Wunderlich finds six cases out of 72 etherizations in which albumin was found after and not before; six cases in 52 chloroform anesthesia, with albumin after, not before; nine cases of albuminuria, five increased, four not increased.

The writer has examined 50 cases, before and after ether. (Urine filtered and nitric acid test applied; the presence of a whitish precipitate or cloud at junction of acid and urine, visible against a dark background, was considered to be evidence of an appreciable and abnormal amount of albumin.)

Of these 50 cases, 33 did not contain albumin before ether; eight of these did not contain albumin after ether; 25 of these did contain albumin after ether. Seventeen contained albumin before ether; in 11 of these 17, albumin was increased after ether; in four it was not increased after ether; and in two it diminished after ether.

In 36 cases out of 50, ether either produced albumin, or increased that already existing.

In 25 cases which contained albumin after ether and none before, two presented a moderate amount (large trace), four a slight amount (trace), and 19 an extremely slight amount (slightest possible trace).

In 11 cases in which pre-existing albuminuria was increased after the ether, it was moderately increased in five cases, and very slightly increased in six cases.

No explanation was found in the two cases in which pre existing albuminuria was decreased considerably after ether.

Attention is called to the extremely slight amount of albumin found in the majority of the cases. No thorough examination was undertaken in regard to the duration of the albuminuria. From occasional detached observations, it seemed, as would naturally be expected, to be of very short duration. Examination for casts was not made.

The striking contrast which these figures present to those of Wunderlich and the other writers cited above, is, of course, immediately apparent. The writer realizes that these results must be confirmed by careful and more extended observations before they can be ac-

cepted as final. No fixed relation between the amount of ether and the amount of albumin was observed. In some cases where the patient was under ether an hour or more, but a very slight trace of albumin was found; and in one or two, in which the amount of ether given was small, the albumin was found in moderately large quantities. The urine examined was that passed on the night following the operation. The condition of the kidneys occasioning such an albuminuria, would probably be simply a slight congestion. In this connection, it is interesting to note the temporary albuminuria found by MacFarlane in the urine of healthy young men, after severe football games. Further investigations, it is hoped, will shed more light upon this question, and perhaps explain the ether nephritis of the early American observers on anesthesia. The results, however, would suggest a contraindication to ether in advanced renal disease, especially when accompanied by pulmonary complications.

Before leaving the subject of renal complications, it must be mentioned that Becker, in 188 cases, found acetonuria in about two-thirds; the anesthetic and the duration of anesthesia apparently did not bear any fixed relation to it. Baxer reports a case in which a diabetic patient sank steadily, and died after a short chloroform anesthesia.

The foregoing authors and statistics are all manifestly in favor of ether. The single article which the writer has been able to find which does not champion ether is that of Miculicz, mentioned above, a careful operator and a good observer; it demands closer scrutiny. Like many others, Miculicz abandoned chloroform for ether, at least partially, in 1893, as a result of Gurlt's statistics. In 1894, after less than 100 etherizations (the actual number was about 65), he abandoned ether and returned to chloroform. The mask of Juillard, to be described later, was used in administering the ether, and possibly accounts for the result obtained. Miculicz points out that anesthesia, of whatever origin, is more dangerous than had formerly been believed, and protests strongly against its indiscriminate use, when it can be avoided; especially in cases for diagnosis only, or where local anesthesia is possible, it should not be induced. He goes so far as to doubt that it is an important aid in making a diagnosis. He then mentions the undoubted fact that chloroform is very often of poor quantity and poorly given, and finally, that other conditions complicate or actually cause many cases of so-called chloroform death. He calls attention to the cyanotic redness of face and neck and the impossibility of judging the depth of the narcosis from the eyes or expression; and finally, among his 65 cases, he found three cases of collapse during ether, two cases of collapse after ether, four cases of acute bronchitis, and two cases of edema and pneumonia.

The cyanosis of face and neck, and the impossibility of seeing the eyes (which seems to be what Miculicz means), American surgeons would unquestionably attribute to the ether mask employed — a tight, hemispherical basket, covered with material impervious to air, and held down snugly over the face during the whole period of anesthesia, save for the very short period it is lifted to receive more ether. And indeed one cannot help thinking that the slight temporary collapse which occurred in three cases during the ether, and perhaps also the more serious collapse in two cases after the ether, were also due to this most undesirable method of combining $CO_2$ with ether to produce unconsciousness. Whether or not ether can produce true pneumonia, properly so-called, is a very doubtful question. Prescott believes that it cannot; and the fact that it once appeared after ether in a case of Miculicz, does not by any means prove that it was anything more than a coincidence. It is certainly possible for the fumes of ether to cause a slight bronchitis, and not only possible, but probable, when the Juillard mask is used. And, finally, until another method of producing anesthesia is tried, and upon a much larger number of patients, the overwhelming statistics of so many other trustworthy observers pointing to the undoubted greater degree of safety to life under ether than under chloroform narcosis, must be accepted as proving that ether is, as Vallas concludes, just as effective and certain in its action as chloroform, and that it is less fatal.

The suggestion which Miculicz makes in regard to careful notes to be recorded, both of the anesthesia itself, and the conduct of the patient after it, is certainly most appropriate, and will undoubtedly coincide with the wishes of most surgeons; and if an examination of the statistics leads him to think that too many deaths have been attributed to chloroform, when really arising from other causes[2] surely a similar examination of so-called ether deaths would reveal the same thing, and in at least an equal degree.

Several deaths have occurred, either during ether or shortly after it, in Boston, within the past twenty years. In every case, one or more disturbing influences have existed, in the presence of which it is not possible to say that ether has caused death. They have all been, apparently, deaths during ether, not deaths due to ether. If they emphasize anything, however, it is that ether is dangerous in all cases of operation on the trachea or larynx, particularly when there is coexisting acute inflammation of the air passages, or the immediately surrounding tissues. This is a fact which Dr. Gay of Boston has repeatedly emphasized. One of these cases, which occurred under the observation of the writer, is described in some detail in the following pages.

The writer has given ether, to primary or complete anesthesia, between 300 and 400 times. In these cases there has never been a death traceable to the ether alone. In two cases there have been alarming symptoms apparently due to the ether, one of which required immediate tracheotomy. This case was one of deep cellulities of the neck in a man who was a steady drinker. Induration and swelling of the brawny cervical tissues increased gradually for two days, and the temperature rose steadily. There was no indication of the location of the pus. The swelling finally encroached upon the esophagus, preventing the ingestion of everything except small quantities of liquids, and began to cause embarrassment of respiration. The patient was carefully etherized by the writer, the attending surgeon having resolved to make multiple incisions in the neck. Patient took the ether fairly easily, though the mucus in mouth and throat immediately began to increase. After a very short period of moderate excitement, the breathing became stertorous, and suddenly stopped — face cyanotic, pulse not affected; ether was taken off immediately, and patient pushed directly into adjacent operating-room. As respiration did not recommence, surgeon did im-

[2] See Casale, Centralblatt für Chirugie, No. 22, 1894.

mediate tracheotomy, and, the tube being in position, with a little artificial respiration, breathing began again. Patient rallied well and seemed on a fair way to recovery; but temperature rose again on third day, and he died with symptoms of septic poisoning. It is possible that if chloroform had been used, tracheotomy might not have been necessary; it is probable that the patient would have died in any event. This cannot be considered a death due directly to ether, though it compares rather closely to those cases which Miculicz calls "late collapse," and which he would cite as a form of ether death. In a similar case, chloroform would be the anesthetic of choice.

The second case was a serious operation for a presumable malignant growth near the spine. The patient, a man of forty years and of excellent habits, had some years previously contracted a double pleurisy, as a result of which, his attending physician declared, his respiration had since been more or less diaphragmatic. He took the ether easily, pulse and respiration being good, though there was a slight sighing noise at the end of each expiration; in seven minutes the anesthesia was complete; but before the end of this time, the color began to darken and the respiration became labored and almost entirely diaphragmatic. When removed to the operating-table, the color was livid, and soon became a very deep slaty blue (the heart was normal). The rate of respiration was very low, about ten to the minute, but the pulse remained fairly good. There was a considerable secretion of mucus in mouth and throat. The patient was placed in the Sims position to facilitate the operation, and in this position the breathing became still worse, and the color darker, if possible; ether removed, and upper shoulder lifted, and breathing became rather better. The operation was commenced with the understanding that if the etherizer thought the condition of patient demanded it, he should request the surgeon to discontinue. Early in the operation, it was found that the position and extent of the growth rendered relief by operative means impossible, and the operation was abandoned. With the removal of the ether, color at once improved, and was normal before patient regained consciousness. Time from beginning of anesthesia, forty minutes; amount of ether used, six ounces. Before ether, one-sixteenth of a grain of atropia by stomach. In spite of various gloomy prophesies at the time of operation, there was, as a sequel, neither vomiting, edema of lungs, bronchitis nor pneumonia; the patient never developed a symptom traceable to or explanatory of his unusual condition under ether. Whether the old pleurisy had caused adhesions of both lungs, which prevented a proper action of the lungs and oxidation of the blood, or whether the malignant growth had involved the pneumogastric, or perforated the chest wall or whether all of these conditions combined to produce the result, is impossible to decide with certainty. In external appearances, the case was undoubtedly the worst that has ever come under the writer's observation. In a similar case, the choice of anesthetic might still be open.

It is, of course, undeniable that the shock produced by etherization sometimes adds the straw necessary to turn the scale in the wrong direction. In these cases, however, it is impossible to say how much is due to the operation, how much to the hemorrhage and how much to the ether; and the result would perhaps be worse with chloroform. In any event, with the present absence of notes or statistics on these points, reliable conclusions are impossible. It may be well to recall the fact, however, that laparotomies and external urethrotomies, as well as lesser operations, may be done under cocaine, and that thus the shock of general anesthesia may be avoided in just those cases where it is particularly unwelcome.

There are certain contraindications to ether upon which all authorities agree, and which, though they do not absolutely forbid ether, make chloroform the anesthetic of choice.

(1) Operations within the mouth, and upon or close to the air-passages, particularly if there be accompanying inflammations, or conditions causing irritation of the air-passages, such as foreign bodies, tumors exerting pressure, etc.

(2) Certain conditions of the lungs, particularly acute bronchitis, asthma, double empyema.

(3) Advanced renal disease, and diabetes.

(4) Operations demanding the use of the actual or thermocautery upon or close to the face.

The third indication is sometimes omitted; but the writer is convinced that it is real enough to be insisted upon with equal emphasis with the others.

Beyond the above, there are no considerable contraindications to the use of ether as an anesthetic.

*(To be continued.)*

## THE EDUCATIONAL ASPECTS OF PHYSICAL TRAINING.[1]

BY W. A. BROOKS, JR., M.D.

MANY of the best minds of the intellectual world are devoting their energies to promoting the advancement of educational demands. It might well be asked, what bearing has this upon the subject of physical training? The answer to that question is embodied in another: What is going to determine the limit of educational demands? Obviously they are limited by the ability of the individual to grasp and to understand, and the amount of time which can be devoted to study. Ability is a personal equation. Time is limited by the duration of life.

What is it which enables a man to do his work properly if it is not physical condition? And what is it, barring accidents, which determines whether a man lives to be seventy or dies at forty, if it is not his surroundings and the care which he takes of himself? The standard of higher education can be raised until the limit of mental and physical endurance is reached. As a greater demand is made, it can only be met by carrying with it a provision for the building up of endurance.

But as yet, physical training, the only means of building up endurance, has never received more than a passing notice from the majority of the learned men who stand at the head of our institutions, and who map out and direct the work of those who are under their immediate control. While they carefully direct mental exercises, they utterly ignore physical demands. They compel students to come up to a certain intellectual standard, taking it for granted that they are in a sufficiently good physical condition and know how to keep so. To be sure they may provide a gymnasium and instructors in physical culture, but whether the in-

[1] Read before the Boston Society for Medical Improvement, March 18, 1895.

dividual takes advantage of these opportunities concerns them little and interests them less.

At the expense of the government a chosen few are educated to fill positions in the army and navy. The government does not propose to have its money wasted, and so in order that the students at these institutions may be physically able to do their work, both before and after graduation, there is a fixed standard of physical condition and an ample provision made for physical training.

At some other institutions of learning, the students upon entering are required to bring a certificate of good health. After entering there are generally no further requirements either as to conditlon or training, except that by some means or other they must be able to do the work given them. The institutions are generally in need of funds. It would never do to demand too perfect an individual. On the standard of health too many might be debarred.

Granting that physical training is an important adjunct to mental work, the question arises, to whom must students of health turn for instruction in this branch. Obviously the men who should be best fitted to direct such work are the men who are devoting their lives to the welfare of mankind — the medical profession. But while they devote years of study to pathological conditions and their relief, very few hours are devoted to the consideration of the healthy body and how to keep it so.

It is not that its importance is underestimated, but rather because, through tradition, physical training in the minds of most physicians is associated with athletes and athletic sports.

Physical training has not yet acquired the dignity of being incorporated in the curriculum of medical study, but is supposed to lie within the province of the gymnasium instructor or the professional athlete. And yet it is to the physician that the man worn out with business cares, the student nervously exhausted, the parent anxious that his children should grow up strong and healthy, all come and demand relief and advice, for he is supposed to as thoroughly understand the laws of health as he does the symptoms and treatment of disease. And he should. Why then, is not more attention paid to the subject of physical training in our medical schools? Is it not because a physician's reputation is made not from his attempts to keep his patients in good health, but from his success in treating them after they are ill?

Unless a physician has of his own accord looked into the subject and carefully considered it, he is apt to do as much harm as good when he recommends exercise to a patient. For exercise, to the average practitioner, simply means something, anything, which calls for muscular exertion. It is not necessary that a graduate in medicine should be a skilled gymnast or a competent instructor in gymnastics, but he most certainly should have some idea of the amount of exercise which an individual needs, the best means of his obtaining it, and the proper manner of beginning it.

I take the liberty, therefore, of presenting to you this evening, a few ideas upon the subject of physical training.

The healthy, vigorous boys or girls need no special instruction in this branch. Their natural instinct is is to romp, to enjoy life and to join in various sports and pastimes. They simply need a word of caution against too severe or too prolonged exertion, and a few directions how to guard against getting chilled or overheated.

But it is different with the children of delicate physique. Their natural instinct is to stay within doors. The pleasantest day seldom tempts them into the open air; and even when they do go, the inherent sense of their own weakness keeps them from joining in the sports of their playmates. Their parents generally help them in this tendency. Because they are known to be delicate they are kept from the very things which might enable them to grow strong. The majority of them could be greatly helped by being made to join in certain games and forced to follow a systematic course of training. Through the lack of systematic and regular exercise, many a child has been prevented from growing strong and healthy.

As most of what I have to say can be applied to both sexes, I shall for the sake of simplicity, confine my remarks to the male sex.

The line between health and disease is never widely separated, but the change from one to the other is in the inverse ratio, for it is much easier to lose one's health than it is to regain it. There is no system of training which can prevent a child from becoming ill, but a systematic life will strengthen a child's power of resistance. You cannot by exercise, remove from a child his inherited weakness; but you can build him up and give him greater power, so as to establish a balance of health in his favor. According to the age and natural strength of the child you should map out the line of his early life. If he is strong, see that he does not develop one portion of his body at the expense of another. If his chest is weak, encourage him in those games which call for lung power and good chest muscles. Have him taught to stand and sit properly and to use his lungs voluntarily, by breathing slowly and deeply.

You cannot apply one system to all, for each individual body has its own peculiar characteristics.

When the boy becomes a youth, he becomes more of a creature of impulse. If he enjoys exercise he takes it. If he is fonder of his studies he abandons it. The one needs restraint, the other encouragement. An excess in either direction leads to permanent injury: either to too great muscular development or to a loss of physical condition.

Accordingly, when the youth takes up his life's work, he brings into it either the energy of good health or the millstone of an impaired constitution.

Proper food, good air, sufficient rest and exercise, are the demands for physical training.

The laws of physiology tell a man when he must eat, and what the character of his food must be. It is not within the means of every man to always get what is best for him, but it is within his power to learn how to breathe properly and to take a sufficient amount of exercise.

The natural tendency of most men is to breathe superficially; for as breathing is largely an involuntary action, it is only when the will power is invoked, that men slowly and thoroughly inflate their lungs. By muscular exertion the same object can be attained. Accordingly it becomes necessary that, during exercise, a proper attention should be paid to the manner of breathing. When you advise a man to exercise, call his attention to the value of his holding himself erect with chin, chest and toes in nearly the same line as possible; with shoulders well settled, not falling

forward, and with the mouth closed. Tell him to breathe as slowly and deeply as possible, but to avoid straining his lungs by too full or too forcible inspiration.

In regard to the amount of exercise which he should take, that must depend upon his strength. The question of how his exercise is to be taken, largely depends upon his occupation, and the amount of time which he can devote to it.

Certain points must be remembered. He should begin gently, increase gradually, exercise with regularity, and always avoid too excessive or too prolonged exertion.

The men who most need exercise are those whose occupations keep them within doors, and who labor especially with their brains. This is the class which finds difficulty in getting what they need, for their time is limited and their work never finished. They can, however, always take a sufficient amount, if they feel so disposed. For instance, if a man lives in town, he can take a fifteen or twenty minutes walk to and from his business. Upon rising in the morning he can devote the same length of time to exercising in his room, either with chest-weights or dumb-bells, or by going through exercises and motions without any apparatus. These exercises he can repeat at night, either just before dinner or before retiring. It is surprising how much benefit can be obtained from two short walks in the open air and a half-hour's exercise during each day.

If he goes to a gymnasium, he should thoroughly understand how to begin his exercise. The latter part of the afternoon is the best time. He should wear the proper amount of clothing, and do his work quickly and systematically. The work at first should be light, and never carried to the point of fatigue. He can begin with the chest-weights. With a light weight in each hand he should go through the various movements, ten times for the first day is sufficient. Then a few moments with the wooden dumb-bells, a dip or two between the slanting parallel bars, a short exercise of throwing the so-called medicine ball (a large leather ball stuffed with hair or tow), ending up with a slow run around the track, for a distance equal to a quarter of a mile. This will be found to be enough and not too much for most beginners, and there will be no resulting stiffness or soreness the next day.

After this exercise he should take a moderately cool bath, a brisk rub, and then dress slowly. On each succeeding day he should increase by one the number of times which he performs each movement, and perhaps add a lap to the length of his run.

By the end of three weeks he is doing each movement twenty-five or thirty times, he moves more quickly, and already the effect is seen and appreciated. He is now in a condition to bring more variety into his work, and can either join one of the regular classes or with a friend indulge in a game of hand-ball, court-tennis or rackets. He has not made the mistake of beginning his exercise too violently, and there is no reason why he should ever have felt the slightest lameness.

A man who has once got himself into fairly good physical condition is ready, whenever the opportunity offers, to indulge in any of the out-door sports. He can row, play tennis or golf, or enjoy a bicycle ride. There is one chief objection to the bicycle. As yet I have not seen what I consider a proper saddle. Nature intends when we are in a sitting position that the tuberosities of the ischii should receive the weight. The modern bicycle saddle allows the greater part of the weight to fall upon the perineum. This is especially disadvantageous for lady riders. The ease with which a bicycle can be driven tempts one to ride too fast and too recklessly. Steep hills should be avoided as they call for too great a strain upon the heart.

Whatever the form in which exercise is taken, over-exertion should always be avoided. But over-exertion should not be confounded with the natural fatigue which one feels after a long walk, row or ride. That is but the natural result of a well-regulated and healthy exercise, and it demands but one treatment, namely, rest.

Rest is one of the important parts of physical training. The hard-working man, who can or will take his hour's rest at noon, does better and more satisfactory work during the remainder of the day. The man who gets his seven or eight hours of sleep during the night, wakes up ready and eager for his day's work to begin.

But in the face of all these facts and suggestions, one is constantly confronted by the statement that there is Mr. "So and So," who is perfectly healthy, and yet he has never taken any exercise in his life. All that can be said in reply is that a man who has been blessed with a good constitution can apparently abuse it with impunity. The effect of his life, however, can generally be seen in the constitution of his children.

Looking at physical training from a selfish standpoint, it does not always appear to be a necessity to an individual blessed by nature with a good constitution; but looking at it from the stand-point for the welfare of mankind, it becomes not only a necessity, but also an obligation.

I have purposely omitted the consideration of the practical application of physical training to the students in our schools and colleges, for I consider it of too great importance to be hurriedly passed over in a general paper of this kind.

In conclusion, allow me to add that while I know that physical training cannot do everything for the human body, I do believe that it will greatly assist in youth the acquirement of health, and later in life will so aid the preservation of strength as to give greater power for the postponement of the inevitable end, which according to the laws of nature must sooner or later come to us all.

## Clinical Department.

### A REPORT OF CASES IN WHICH THERE WAS OBLITERATION OF THE ANTERIOR TRANSVERSE ARCH OF THE FOOT.[1]

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

ONE year ago the writer presented a paper to the Society for Medical Observation, upon the subject of the anterior transverse arch of the foot and the relation of the obliteration of this arch to certain conditions and symptoms which had previously received very little if any attention. Particular emphasis was put upon its relation to that condition which is known

[1] Read before the Boston Society for Medical Improvement, March 18, 1895.

by the name of metatarsalgia. This paper was afterwards presented at the meeting of the American Orthopedic Association, which was held in Washington in May of last year, and was published in the *Boston Medical and Surgical Journal*, September 6, 1894.

The presence of this arch was proven anatomically by a series of dissections and frozen sections, which were made through the kindness of Professor Dwight of the Harvard Medical School, and clinically by the study of impressions of normal and abnormal feet.

The variations and changes which occur in the transverse arch and the symptoms which are associated with these changes were described at some length, but because of the limited number of cases which had been studied and from which the deductions were made, the conclusions were in part theoretical. It is partly for this latter reason, and also with the desire to give added emphasis to the opinions which were offered at that time that this series of cases is reported.

In all there are 14 cases, most of which have been seen by the writer during the past year. In each of the cases the anterior arch was obliterated, and the symptoms were entirely relieved (and that almost immediately) by restoring the normal relations of the bones which form this arch. Four of the cases were men, while the remaining ten were women. In eight of the cases the anterior arch alone was affected, while in the other six there was flattening of the longitudinal arch as well. In ten cases the chief symptom was pain referred to the anterior portion of the foot. In about half of this number the pain was of the sharp paroxysmal type, while in the remainder it was less acute, but as a rule more constant. The paroxysmal pain was usually developed by walking or standing, and was at times so severe as to prevent locomotion. In one case the pain was worse when the foot was at rest, relief being obtained by motion. The seat of the pain varied considerably; but in the majority of the cases it was located about the head of the second or third metatarsal bones. In two cases it was referred to the toe; in one to the extreme end of the toe, at the corner of the nail. In but one case was the pain assigned to the head of the fourth metatarsal bone.

In six of the cases a well-marked callus had formed in the middle of the ball of the foot, due to the increased pressure at that point; and it was chiefly because of the difficulty in walking due to the sensitiveness of this callus that these patients desired treatment.

In two cases the foot had become so wide from the giving way of this anterior arch that the pressure of the shoe against the first and fifth metatarso-phalangeal articulations had caused marked redness and sensitiveness at these points.

The age of the patients has no special significance, other than showing that it is essentially a disease of adult life. The youngest patient was about twenty years of age, while the oldest was nearly seventy.

The treatment of this condition has been most satisfactory; and the relief that is obtained, at times almost instantaneous, has been as much of a surprise to the physician as to the patient. The treatment naturally consists in restoring the bones to their normal relations, that is, the re-formation of the arch. This has been accomplished in several ways; the simplest method, and that which has been adequate in the majority of the cases, is the use of a felt pad that is incorporated into a leather inner sole and which can easily be slipped in or out of the shoe. The position of the pad varies but little, and it should be placed under the second and third metatarsal bones just back of their articulation with the phalanges. The thickness of the pad, however, does vary; and it may have to be changed several times before the correct thickness is determined. A very thin piece of felt should be used at first, to which more can be added from time to time if necessary. In placing the pad care should be taken to avoid pressure directly upon the heads of the metatarsal bones, as the discomfort in walking with the pad in this position is very great; and if the callus is present, the pain will be aggravated.

This simple procedure has proved to be enough in the majority of the cases; the pain is relieved and the callus, from the change in the point of pressure, rapidly disappears.

Occasionally some lateral support is needed, particularly in the cases in which there is irritation or sensitiveness about the great or small toe joint. For this purpose a circular bandage applied very tightly so that the pressure comes wholly behind these joints has given the greatest satisfaction. At times the pad and bandage have been used together.

Besides this mechanical treatment special attention should be given to the muscular development of the part affected. Exercises should be given to strengthen practically all of the muscles of the feet, more special attention being paid to those which have to do with the maintenance of the tranverse arch. Beside this, stimulating bathing and massage are of value, not so much with reference to the immediate as to the permanent relief of the condition.

If with the obliteration of the tranverse arch the longitudinal arch also has given way, this should be corrected, the plate being attached to the same inner sole with the anterior pad.

The diagnosis, to briefly recapitulate from the paper of a year ago, is to be made from the subjective symptoms; pain in the anterior portion of the foot, with the callus under the centre of the ball of the foot; from the tracings which are more or less characteristic; and from the widening of the anterior portion of the foot.

## Medical Progress.

### RECENT PROGRESS IN SURGERY.

BY H. L. BURRELL, M.D., AND H. W. CUSHING, M.D.

(Concluded from No. 22, p. 541.)

#### LAMINECTOMY FOR THE RELIEF OF PARAPLEGIA.

J. A. Wyeth,[12] reports six cases, all of which recovered from the operation. The technique he prefers is a free incision just over the spines, division of the attachments close to the bones with dull scissors or the elevator, strong retraction, and iodoform-gauze packing to control and arrest bleeding. When well exposed, the laminæ are gnawed away in bits first by the round rongeur, and when an opening is effected, by the more rapid cutting fenestrated rongeur. When exposed in full length of the injured region, and all bleeding stopped, the dura is carefully punctured with a scalpel, and as the first few drops of

[12] Annals of Surgery, August, 1894.

cerebro-spinal fluid escape, the grooved director is inserted and the dura split open in the middle line. This membrane should be closed by a careful continuous catgut suture. The muscles are sutured by subcutaneous catgut sutures, and the skin incision closed by silkworm, leaving a wick of iodoform gauze running from the dura out of the lower angle of the wound for drainage. Dry dressing over all. Each of his cases healed without suppuration. The outflow of cerebro-spinal fluid continued from two to four days in all but one case, in which it leaked out for several weeks. From his experience he concludes:

(1) The operation offers no great difficulty or danger.

(2) Paraplegia justifies exploration, and this should be done early in all cases where no improvement is marked. The degenerative changes, which occur from compression which has not divided the cord, add to the urgency of early interference.

### SACRAL OPERATION TECHNIQUE.

Borelius has by clinical experience formulated the conclusion that the Rydygier method requires modification on account of its interference with the innervation of the bladder.[16] Incidentally he found it difficult to remove the upper part of the vagina when involved by carcinomatous infiltration by extension from the uterus. He devised a modified operation — a posterior sacral operation for exposure and resection of high-seated rectal growths, and an anterior sacral or para-rectal operation for exposure of the female genital organs.

The posterior operation consists of a skin incision in the median line from the middle of the sacrum to the tip of the coccyx and obliquely outward, to the right, along the border of the gluteus maximus muscle. The tendinous origin of this muscle is divided, and this skin-muscle flap reflected to the right. The left side of the sacrum is now exposed, and with a broad chisel is cut through obliquely from the fourth sacral foramen on the right to the third sacral foramen on the left. The right border of the coccyx and this bony flap are reflected to the left with the whole anal area. Then the rectal resection and suture is made in the usual way. The wound cavity is tamponed with gauze. The bone flap is replaced and fastened by a few sutures through the periosteum. The upper part of the skin wound is sutured; the lower, along the edge of the gluteus, is left open for the end of the gauze tampon. By this method the paralysis of the bladder which occurred when the third and fourth sacral nerves on both sides were cut was avoided. In three patients the Borelius method resulted in immediate union of the bone flap. In no case did paralysis of the sphincter ani or bladder occur. The great ligaments of the sacrum are preserved on both sides. In two cases a fecal fistula remained.

The anterior sacral or para-sacral operation consists of a skin incision from a point in the median line about two centimetres above the sacro-coccygeal articulation, forward and somewhat to the left, past the tip of the coccyx, and across the ischio-rectal fossa to a point three to four centimetres anterior to the anterior margin of the anus; then towards the median line near the posterior vaginal commissure. The left border of the coccyx is exposed. The sacro-coccygeal joint is cut or chiselled through. The anterior part of the incision is deepened into the ischio-rectal fossa till the flap with the coccyx and anus can be reflected to the right. The vagina is now separated from the rectum and opened. It is divided horizontally below the tumor which with the uterus is freed from below upward in the usual way, and removed. The peritoneum is sutured and the remaining portion of the vagina. The wound cavity is tamponed (iodoform gauze), and the coccyx sutured in position; the tampon is brought out behind for drainage, and the rest of the wound closed by deep and superficial sutures.

The above method has been used in four cases. The coccyx has always united. The preservation of the coccyx preserves the muscular attachment between it and the anus in which this method is superior to the latest Hochenegg method. There has been no death.

A ureter was once included in a suture, but it was noticed and freed. Borelius, on account of the sacral nerves, would never resect the sacrum higher than the lower border of the third foramen on one side and the fourth on the other.

[16] Centbl. f. Chir., 1895, Bd. xxii, 57.

### INFLUENCE OF CICATRIX IN THE PRODUCTION OF ATROPHY, AND ITS UTILITY IN SURGERY.

In an opening address to the Nottingham Medico-Chirurgical Society, T. Pridgin Teale,[17] reiterates a proposition that he made some years ago, which is of interest. It is, "that tissues which depend for their nutrition upon vessels passing through a cicatrix have a tendency to waste, a tendency which often does not become evident until some time has elapsed from the completion of cicatrization, and may continue for months, or even years, until in some instances the dependent tissue fades away completely."

He illustrates this proposition by a number of cases, and speaks of the influences of cicatrices upon nevi, thyroids and prostates. It is a suggestive address.

### THE TREATMENT OF IMPACTED EXTRA-CAPSULAR FRACTURE OF THE NECK OF THE FEMUR.

F. A. Southam,[18] in an interesting article, states that the treatment usually adopted in cases of impacted extra-capsular fracture of the neck of the femur consists in simply keeping the leg at rest, without making any attempt to overcome the characteristic deformity, namely, the shortening and eversion of the limb, always present in a greater or less degree. As might be expected, the result in most cases is very unsatisfactory, for the leg remains permanently more or less shortened and everted.

With a view to preventing, if possible, this result in a case recently under his care in the Manchester Royal Infirmary, the impaction was at once broken down under anesthesia, and, the eversion and shortening by this means having been overcome, the fracture was then treated in the ordinary way, extension being maintained by means of a weight attached to the leg, a long straight splint being applied to the outside of the limb. The consequence was that the fracture readily united with the limb in the corrected position, no deformity remaining.

The satisfactory result obtained by Southam by breaking down the impaction, would lead him to again adopt this treatment under similar circumstances, provided that the patient was of good constitution and not advanced in years.

[17] Lancet, October 27, 1894.
[18] Ibid., November 17, 1894.

STERILIZATION OF CATGUT BY BOILING IN OLIVE OIL.

B. L. Eastman,[19] of Kansas, U. S. A., has tested the above method, and states that as the result of his investigation catgut can be rendered sterile by heating in olive oil at 212° F. for three hours. The method is cheap, reliable and rapid. The quality of the gut is not impaired. For some reason the oil thus boiled becomes turbid, but is clear again after two or three days. The boiling is done over a water bath. The gut is wound on a glass spool which is placed in a bottle containing the oil. The bottle is sealed and placed in a water bath, which is then covered. It is exposed to the temperature of the boiling water in this way for three hours. The boiling point of the oil is stated as about 400° F.

THE USE OF SULPHUR IN SURGERY.

Mr. W. Arbuthot Lane[20] summarizes a year's experience, and comes to the following conclusions: (1) Neither sulphur nor the products generated by its decomposition acted prejudicially upon the life or health of the individual into whose body it was introduced. (2) If placed in contact with recently incised healthy tissues, twenty-four hours sufficed to render the parts sterile as far as organisms are concerned. (3) If the recently incised or scraped surface were but poorly supplied with blood, as, for example, the brawny edge of a carbuncle or a spreading gangrene of a limb, sulphur might be left in contact with the tissues advantageously for a considerably longer period. This also applies to a granulating surface. (4) The entry of other organisms into a tuberculous cavity did not influence the action of the drug, since it destroyed all organisms, whether free in the cavity or intruding into the surrounding living tissues forming its wall.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. G. MUMFORD, M.D., SECRETARY.

Regular Meeting, Monday, March 18, 1895, Dr. C. J. Blake in the chair.

Dr. W. A. Brooks, Jr., read a paper on

THE EDUCATIONAL ASPECTS OF PHYSICAL TRAINING.[1]

Dr. E. N. Hartwell: I have been very much interested in Dr. Brooks's paper. He has pointed out some things with regard to what seem to me the privileges of the medical profession that may help the cause of physical training very much. It is to the physicians rather than the school committees and legislatures, it seems to me, that we should look to instruct the public as to their duties in this matter of physical training. I should not include under the term physical training quite so much as I understand Dr. Brooks to do. It seems to me that many of the procedures of which he speaks are only indirectly connected with physical training in its proper sense and would be more properly classed under the head which the "Index Medicus" terms personal hygiene or individual hygiene. I should not quarrel with him on that ground. It does seem to me though that the conception of physical training which has been borne in upon me is sufficiently inclusive. I should prefer to define physical training as the more or less systematized employment of muscular exercise for general or special ends. If we appreciate what that includes, we see that physical training enters not only into what may be called the two great departments of physical education, athletics and gymnastics, but also into all technical training, like the training of the hand, training of the body in the military drill, training of the hand in violin playing, writing, etc., the use of the vocal organs and so on. The teachers and exponents of such specialties might well understand the physical training element in them and the means by which they can best secure their particular ends.

It seems to me rather desirable, in the interests of the more formal physical training which Dr. Brooks especially disclaims the intention of covering by his paper, that those who are most especially interested in

[1] See page 562 of the Journal.

having the legitimate claims of physical training recognized and its spurious claims disallowed — I mean those of us who are called upon to teach and apply the principles of physical training in general education — should strive to have it kept separate in thought and practice from particular forms like vocal culture, military drill, Sloyd, and the like. It would be hard to estimate the loss which physical training has undergone in this community from the fact that the school committee after it established physical training in the early sixties combined it with vocal culture, and placed it under the control of a man who was a very successful voice-trainer, but not in any proper sense a physical educator. The department fell to pieces, expeditiously and naturally. We have not yet recovered from the ill effects of that ill-advised experiment, it seems to me.

Again, it is better to confine it in this way, because then those who are the practitioners of it, the drill-sergeants and leaders of companies and regiments, can be the more readily and distinctly kept within the limits of their special and particular province. It is not the province of gymnasts properly speaking, Swedish or other, laymen or laywomen, to practise medicine in the way that many of them strive to undertake it now. To a certain extent I think that is due to the fact that their field has not been sufficiently mapped out and control over it assumed by the medical profession.

So far as I can learn, in the earliest expression of an interest in physical education made by a Bostonian the term was used in a very broad sense, broader than I should say that Dr. Brooks would be willing to attribute to it. The expression occurs in "A Discourse on Cold and Warm Bathing," by Dr. J. G. Coffin, published in 1818. "Let us remember," he says, "that the great purposes of physical education are to superintend the infant body, to favour its development and progress in childhood and youth, till it is completed in the man,— and then to preserve in health this complicated machine fitted and prepared for all the duties, labours and enjoyments of the animal, intellectual, and moral life." In the *Boston Medical Intelligencer*, which was devoted expressly to "The Cause of Physical Education and the Means of Preventing and Curing Disease," and belonged to Dr. Coffin, the nature of the baby's bath, whether or not pins should be used in the baby's shifts and such matters were discussed by Dr. Coffin under the head of physical education. His journal started in 1826, I think. In two or three years it was combined with another medical journal, resulting in the establishment of the *Boston Medical and Surgical Journal*, by which title it has been known ever since.

Some of the colleges have a professorship of Hygiene and Physical Education. Dr. E. Hitchcock has served Amherst in that capacity since 1860. He has charge of the gymnasium and lectures to the Freshman class upon the general rules of right living. This is supplemented later on by lessons in physiology and hygiene; and practical and pointed talks in regard to various departments of life, including the married and unmarried states, are given to the students in the Senior year. Since the establishment of departments of physical training (so-called) in many of the colleges under the charge of physicians, customs similar to the Amherst custom have doubtless increased. For instance at the Leland Stanford University, the head of this department is a regularly constituted member of the faculty, and has charge of a rather enlarged department of general hygiene. But so far as I know, the kind of course which Dr. Brooks favors in medical schools has not been provided in that class of institutions. I think we have but one hygienic institute worthy of the name connected with a medical school. It is in Philadelphia, and it is devoted to general hygiene. A thorough-going and genuine course in school hygiene or in personal hygiene is nowhere provided, I believe. Indeed, I do not know that there is a professorship of personal hygiene in any of the European medical schools.

The health of the school population seems to me to be worth considering from Dr. Brooks's point of view. According to Dr. Harris, the United States Commissioner of Education, in 1890 about 23.5 per cent. of the total population of the United States was found in schools of some sort; 96.5 per cent. of the school population was in elementary schools, only 2.5 per cent. was in secondary schools, and less than one per cent. was in institutions of superior instruction, including professional schools, colleges and the universities. Now to this great mass of children who never reach the secondary schools, who terminate their school life before established adolescence has set in, we, as believers in preventive medicine and general hygiene, ought to pay more attention than we do, it seems to me.

Not many years ago after some wrestling with certain legal questions, an instructor of hygiene was appointed for the Boston schools. It was the opinion of the law officers of the city that a sanitary inspector could not be employed except by the City Board of Health. It seems to me that the experiment was a very instructive one. The duties of the instructor in hygiene were laid down in a way; at the same time they were quite mixed and indefinite. He was practically tied hand and foot as to power and initiative. The result was that there arose a gust of the odium theologicum, and the office was abolished.

Owing to the impression made by an extensive epidemic of diphtheria, Dr. Durgin, President of the Board of Health, has been enabled to appoint fifty medical inspectors to visit the schools daily. It seems to me that this is a move in the right direction. No one man picked out of the ranks of the medical profession can oversee and attend to the multifarious and diverse duties of a medical, sanitary and hygienic Poobah. We have in the first place this enormous mass of population which constitutes the largest contingent of the industrial army of the United States. Schooling is certainly sedentary in its nature, and it lasts so many years that you may call it a sedentary occupation. The State owes it to itself that this population shall not constitute a menace to the public health. If the public health is to be properly guarded, we should have public health officers rather than State police to see that school-house sites are well chosen, that drainage is all right, that heating, ventilating and other apparatus is of a proper sort, and properly used. No ordinary physician is competent, as a rule, to pass upon questions of sanitary engineering which come up in planning, erection and furnishing of school-houses; hence, I think, that public health officers and sanitary and architectural experts have their duties to perform in the matter of preserving the health of the children after they are in

the schools. Even then there is room for a special inspector or director of school hygiene — call him what you choose — whose business it should be to see that the teachers carry out such reasonable rules as may be laid down by the public health officers, sanitary experts and school officials acting together; because the practices and procedures of the school-room which affect the eyes, ears, brains and muscles of the pupils, constitute a special branch of school-hygiene and should be recognized as such. These three classes of experts working together could regulate the gymnastics, the plays, the games and the school-life of the children in the interest of public health and their own health, and in the interest of school-work at the same time.

Opportunities for the thorough training of such experts are not easy to find. I do not think they are found anywhere in the United States at present.

I have had the curiosity this afternoon to look through the "Zeitschrift für Schulgesundheitspflege" to see how far this matter of hygiene and school hygiene plays a part in the training of European teachers, and to see how far, if at all, the universities have taken measures to provide genuine and adequate facilities for instruction in this branch. I have been rather surprised to find that a good deal has been undertaken in this direction. In 1888, in the hygienic institute in Berlin the head of which is Dr. Koch, two courses were given in hygiene, one for government officials and another for school officers; and Dr. Koch, Dr. Esmarch and others took part in the instruction given in that year, and the courses have been pretty regularly repeated since then, I think. The university of Bern, in Switzerland, instituted a special extraordinary professorship in school hygiene alone in 1890. The Hygienic Institute at Naples, a government affair, in 1889 was resorted to by 34 physicians, 8 apothecaries and 4 engineers. A notable requirement regarding the study of hygiene is that which was ordained in Sweden in 1889, to the effect that after April, 1890, all aspirants for a licentiate's diploma, with which most Swedish medical men are content, would be required to take a two months' course at the Caroline Institute at Stockholm. It became an obligatory part of the State examination requisite to the practice of medicine, and to make room for it the clinical courses on the diseases of the nervous system and the eye were cut down from eight to six months.

Within the last few years much activity has been shown in improving the opportunities for teaching teachers the principles of hygiene in general, and of school hygiene in particular, in various parts of Europe. For instance, in Austria in 1891 and 1892 instruction in hygiene, in the training-schools for teachers, was authoritatively and definitely put in the hands of educated physicians, instead of being left to the ordinary teachers. These are some of the subjects included in the line of study laid down for normal pupils: air, earth, water, food, clothing, explanation of the structure and functions of the human and animal body, infectious diseases, disinfection, first aid to the injured. The following special topics indicate the meaning given to school hygiene: the school-house and the school-room, school-desk and school-table, faulty methods of sitting, the duration of instruction, intermissions, school games, various school diseases, their causes and remedies. In 1893 the Prussian Minister of Education issued certain regulations with regard to the conduct of courses in hygiene for public officials of various sorts, whose duties would be better performed if they were well informed in that subject; these regulations relate to the course given in the hygienic institutions of the universities of Berlin, Kiel, Königsberg and Marburg. In Bern, Giersen and Leipsig university courses were delivered, and in other places lectures were given, to the candidates for teachers' positions in 1893.

It seems to me vain to look for very much help at present from the purely philosophical faculties of our universities and the colleges. Such faculties have been so taken up and overcome by the rank growth of certain branches of physical training, notably in the athletic field that they are rather paralyzed even were they quick and willing to see what should and might be done both in the way of providing scientific instruction in the different branches of hygiene of which we have spoken and towards regulating and improving the departments of athletics and of gymnastics. It would seem that our humanists and classicists have scarcely apprehended the old Roman notion which underlaid the custom of placing S.V.B.E. "if you are well, it is well" at the beginning of every letter. If those who control our colleges would take to heart the meaning of the saying of Seneca, "Non est vivere, sed valere vita," we might look to them in a way we may not now to help forward this cause of personal hygiene and physical training. As one generation after another of athletes leaves college and enters adult life, they should be clear-sighted enough to see how much needs to be done and how much can be done for the health and strength of the rising generation. Their help is needed. I welcome Dr. Brooks's contribution very much because of his standing as an athlete. Hitherto those who have been most interested in school hygiene and in the work of the directors of physical training in such colleges as have attempted to organize such departments have not received much sympathy or aid from athletes as a class. I have thought sometimes they have not received nearly all the help they were entitled to from those who devote themselves so vigorously to boating and baseball and football. I venture to hope that Dr. Brooks will have many followers.

DR. H. P. BOWDITCH: Dr. Brooks in his paper has emphasized particularly one side of the question of physical training, namely, the importance of the training of the individual, which Dr. Hartwell calls the question of personal hygiene, and there is no doubt that every one who has listened to him has felt convinced that a course of exercises such as he has described would be a very desirable thing for almost all of us, and yet I should like to ask whether he does not think that sometimes there are cases in which those forms of gymnastic training are objectionable on account of the lack of interest which the individual takes in them. I have had persons say to me: "I do not doubt I should be better, in a way, for going to the gymnasium and taking physical exercise, but it is so repulsive, I bore myself so for the sake of the exercise, that I find it very difficult to overcome that feeling." In such a case a brisk walk in the open air is perhaps quite as good for the general health.

Another question is: How are we going to limit the amount of exercise which may be profitably taken? Is it possible in any way to lay down a rule for different people to follow? It seems to me that we all of

us have got to be more or less a law unto ourselves in that respect. A certain amount of development of the physique is, of course, essential to every well-regulated body. There is no question that the mind works better in a vigorous body. The close relation of the development of the physique and the development of the mind has been proved in many ways, perhaps in no way more clearly than by Dr. Porter's investigations in the St. Louis schools, where he showed clearly that the children best developed physically were also more advanced in their school work. There was a parallelism in the mental and physical development evident in that way. But at the same time what is a reasonable development for one person would be an excessive development for another, and the question of early habit becomes very important in this respect. I should like to ask Dr. Brooks if he does not feel it is quite possible in early youth to devote so much time to athletic training that much of the subsequent life has to be spent in keeping up the physique one has built, whereas the general health and capacity for doing work might be as good with less physical development, and this large physique secured by training may be a source, not of weakness, but of loss of time which could be better spent in some other way.

There is another subdivision of the subject which has attracted my attention perhaps more than any other, and that is the duties of those who have charge of universities and schools with regard to securing proper training and development of the classes which come under their control. Here certain rules must be established. The children are in classes. Certain definite rules must be laid down, and the responsibility becomes very great upon the officers of instruction. They cannot afford to neglect the physical training of their pupils, and the question is, What general rules can be adopted to enable them to be developed in the proper manner. And here it seems to me the first thing to be borne in mind is that in the healthy child the opportunity for exercise is about all he needs. If you give him a chance to exercise his body, he will exercise it as much as is good for him, and he only needs to be restrained. This fact has been lost sight of in a nation which has set us an example in so many branches of education, namely, the German. I have spent a number of years in Germany and have had occasion to observe the school children in that country; and if you examine the children between eight and twelve, they are very far from presenting that degree of physical development which the children of a corresponding age have in this country or in England. It has seemed to me that, in consequence of the demands of the school curriculum, most of the German children have very little vitality left after those demands are satisfied. When the school hours are over they wander home listlessly with none of that freedom and desire to exercise their bodies which is so conspicuous in school children let out from school with us. This impressed me so much that I spoke of it to a German friend, and asked him whether I was wrong in thinking that the curriculum made too much demand upon the German school children. He said: "No; you are right, I have young children of my own now, and I am looking round for a school where they teach just as little as possible." When I hear the German schools lauded and held up for examples for us to follow, I say to myself: There is no question that these schools have carried book-learning to a much greater extent than we have: a German child at fourteen knows a great deal more that is contained in books than our children do, but he has lost something which our children have — that vigor of physique which comes from the opportunity to exercise, and furthermore with it has come a capacity for applying knowledge, I think, in a way which the German child does not possess. A German well-trained school boy will know a great deal more that his books have told him, but will not compare with the American school boy in power to apply his knowledge in unforeseen circumstances. I think that knowledge of life in the child of fourteen is vastly greater in the case of the American child; and this is largely due in my opinion to the fact that our school-children's brains are not overtaxed. No doubt they might do more than they do, but we must beware of pushing the requirements of the preparatory schools too far. The Germans are becoming conscious of this defect themselves, for the opinion of my German friend was not an isolated one; and now it is not an uncommon thing to see the German school children marched out twice a week in the afternoon to a field in the neighborhood of the city where they live and allowed several hours for play, but all is done as part of the school curriculum. They do not know how to play. It is rather pitiable to see the little children take off their eyeglasses and wipe them and wonder what they shall do next. We can learn a lesson of how not to do it, I think, from our German friends.

When we come to the higher schools and universities, it seems to me that there we should take for our guide the fundamental fact that the training of the body is just as important and should be placed upon the same basis as the training of the mind. If we recognize as part of the university education the proper training of the body, the teacher in that department should be a member of the faculty, should have his work recognized as part of the curriculum, and should be able to encourage pupils to come to him with the idea that their attendance upon his instruction will be regarded just as much to their credit as time spent with any other instructor in the university. It might not be possible to shape a series of required courses and electives and honors in gymnastics as in mathematics and the classics; but something of that sort should be attempted. There is no question that if a boy who comes to college with a poor physique, perhaps with some defect in his physical development, goes through college and by strict attention to the rules laid down by his teacher in gymnastics develops into a strong man, he deserves credit for the good qualities he shows just as much as the boy who obtains honors in mathematics. He must show fine moral traits, determination, self-sacrifice and persistency in accomplishing his object to attain this. If we get physical training put on that basis we shall be in a fair way to solve the problem, which each year presents itself with more and more force, controlling the growing tendency of students to devote too much attention to athletics. From the point of view of the university authorities, success in athletics ought to be a matter of absolute indifference. There is no reason why the university authorities should care whether Harvard or Yale wins: it is their business to give their pupils as good physical development as is desirable to enable them to accomplish the results for

which they come to the university, namely, the development of the mind in the best possible way, not training their physique to an excessive point, for we must remember that we have only one nervous system and if we devote all our nervous energy to the development of the muscles we shall not have it to develop the brain: When the authorities recognize this, and put the matter of gymnastics on a level with the other branches of the curriculum, it seems to me we shall be in a fair way to answer a great many of the questions which now present themselves with very little hope of a speedy solution.

Dr. Sargent: I have been greatly interested in listening to Dr. Brooks's paper, also the discussions that have followed it. Dr. Brooks took me back to the time when I had to decide in my own mind whether to engage in the practice of medicine or to take my studies in medicine preliminary to the work to which I have devoted my life; and it is certainly gratifying to me, in recalling the experiences which I have undergone in the last fifteen years, fighting the questionable tendencies of athletics at first almost single-handed, to hear the comments I have listened to this evening. For a long time I have thought the medical profession was a little bit benighted on this question. To me physical training is nothing but applied physical hygiene. I have given suggestions and hints to that end to the young men who have come under my observation. Unfortunately for the cause of physical training, this subject of athletics has assumed undue importance. No doubt our colleges have allowed this subject to assume a bias in the wrong direction. They have encouraged the spectacular and sporting side of the subject and almost ignored the hygienic and educational aspect. They have nursed and fostered the highest grade of scholarship and extreme athleticism. These are incompatible in the same individuals; therefore the athletes and scholars are contending for fame in opposite directions, one class is striving for distinction by the supreme efforts of the mind and the other class by the supreme efforts of the body; and in my opinion neither class is doing what it ought for the advancement of education in its broadest and noblest sense.

It seems to me time to return to the old Greek idea of unity in development, unity in education, and to take a rational view of the claims of both body and mind, and educate them both together. I see no way of doing this but by recognizing physical training, and putting it on the same footing as any other department in college. When we consider one or two phases of this whole movement, to me it is simply shameful. Harvard and Yale to-day are each spending over $50,000 a year, and employing thirty men, to bring fifty stalwart fellows into condition to meet their foremost rival. On the other hand, the departments of physical training in each institution are spending one-fifth of that sum, and have one-fifth that number of men, to look after the physical training of the remaining students — 98 per cent., or about 3,000, at Harvard University. Now the absurdity of this position is only paralleled by assuming that some few well-chosen speakers should be selected and trained for the rhetorical contests, and the rest of the students be excused in order that they might attend the rehearsals and applaud the progress of their companions. It seems to me that this is radically wrong. In making this assertion I want to remove from your minds, however, the idea that there is any institution in this country that is carrying physical training to excess. If you could have an opportunity of meeting all of these men as they come to the college from the preparatory schools, see them in a state of nature, how impoverished they are — with poorly developed chests, crooked spines and emaciated limbs — you certainly would not consider that physical training was being carried to excess. In fact, I invite you to come to Harvard and look over the photographs of these men, and I think you will be prepared to meet the argument that physical training is being carried to excess in any of our institutions. On the other hand, our scholarly men are suffering for the need of systematic physical exercises, and the majority of our students at the present time do not show permanent signs of gain. Until our scholarly men are encouraged to attend the gymnasium in view of aiding their mental development, and not consider it, as many do, something detrimental to the best intellectual efforts, and when the majority of students can show improvement in their physique, it seems to me it will be time to talk about an excess of physical training. It is a misfortune to have an athletic question and a physical-training question coupled together in the minds of our people. It seems to me the thing for us to do who are interested in the physical welfare of students is to use our utmost effort in the direction of staying the tide of this concentrated athleticism, and try to give to the masses something of the time and the energy now devoted to the special training of the favored few.

Dr. Channing: In regard to the amount of physical training in the female colleges; at Wellesley there are 800 girls, and out of that number about 250 in the Freshman class, and for those girls physical training is compulsory. This year a movement has been made to have the training continued into the Sophomore class; but that is at present all the compulsory physical training that there is at Wellesley. The girl has a start, and then it is stopped and the balance of the time is passed without anything done in that direction. At another college in this State where there are 200 girls, practically nothing whatever is done. There is such a tremendous difference in the amount of attention that is paid to the girls in their colleges and to young men in theirs, very little or nothing being done in some of the former. I am told that in the English colleges for women they spend on the average about five hours a day on their studies; the rest of their time they can devote to out-of-door sports, recreation and exercise, whereas in one of these colleges here in our State the girls devote nine hours a day to their studies, and practically have very little or no time for out-of-door exercise or sports or gymnastics. It seems to me the subject in the end is very much broader than perhaps we usually consider it. Physical training is simply a means to an end and such discussions as these are an assistance in helping to illustrate what can be done; but the great difficulty is that we are constantly talking about it, but do not know how to practically apply it. That is the case in these colleges for girls. I recently talked with the head of one of them where nothing is done, and she asked what should be the first step. Everything must eventually go back to the physical education of the child. That has got to be the starting-point of our efforts. The child starts in a fairly healthy way in the beginning of life, and we must incorporate into our system of education some

plan by which the child can be continued along the course in which he begins. After he gets to be two or three years of age, he is put under intellectual pressure which he is unable to bear, and then he begins to show signs of possible degeneracy; and although we are told that nervous diseases are not practically increasing much at the present time, yet we have this tendency that I speak of in children. The lesson for us to learn is that they are made of plastic material, and are not pieces of machinery. Let our physical training be used to develop this material along simple and natural lines.

DR. WHITE: It seems to me the medical profession can do something in this direction. I do not think we have done our duty by any means. We are constantly in our daily practice making inquiries of individuals as to how much exercise they take, and find how little they do take. Both the university, which is nearest to us, and the school committees which govern our children here, have very slight professional representation upon them. It seems to me the medical profession should attempt in some systematic way to exercise an advisory influence upon these non-professional persons who control the minds and bodies of growing children and younger adults of both sexes. I asked the president of our university not long ago why it was that proper physical training could not be made a part of the regular required routine at Cambridge. He could not give an answer satisfactory to me or, I think, to himself, and he said he did not see how it was possible to do it. Why is it not possible? When I was in college I was aroused at 6 o'clock for six months in the year and at 6.30 the other six months, and taken into a stone building and there spent twenty minutes. That was repeated in the afternoon. They have learned to abolish that requisite, but I think if they had required twenty minutes morning and evening of proper physical training of every student up to the present time there would be better persons living in this community now. I know if I do not give one half-hour of sharp exercise to myself twice a day I am not in proper condition to do my work, nor do I believe any one is. I do not see why the medical profession cannot insist on the governing bodies of our universities putting such a compulsory plan in operation. I do not see the slightest reason why it cannot be introduced into the training of Harvard College next year. I hope some time to see that done.

DR. HARTWELL: I would like to call attention to the Woman's College of Baltimore, which since its opening in 1890 has made it obligatory on all its students to practise daily in the gymnasium under proper supervision and instruction throughout their course. This they must do in order to get their degrees. A word upon the organization of the department may be in place. It was put in charge of a competent woman physician who had studied the best systems of European gymnastics. Her assistants in conducting the department have always been well-trained Swedish women, because the gymnasium was originally fitted with Swedish apparatus.

As to what the medical profession might do in aid of school hygiene I should like to allude to another point. It may not be generally known that it is practically a rule in the Boston schools, laid down by the department of public buildings, that the school-rooms shall not be washed, the reason being that it injures the life of the floors. There are many school-houses in the city of Boston that have not been washed in twenty years. We have had many doctors on the committee, but they have done but little and that unsuccessfully towards changing this. I hope Dr. Durgin will take the matter up, and that the members of this and other societies will back him if he does. It seems to me that having saved the sum necessary to keep the floors clean for so many years, we can afford to keep them clean for the next five, at least.

DR. BROOKS: Dr. Bowditch makes the statement that some object to going through these exercises. All I can say in reply is, that many people object to taking any drug or following any course of treatment, notwithstanding the fact that that they may be benefited by it. All that the physician can do in such cases is to try to prescribe his medicine in as pleasant a form as possible. His exercise must be arranged with the same object. If the patient then refuses to follow his advise the responsibility of his health rests with himself.

Dr. Bowditch asked if I did not think the time devoted to exercise might be more profitably spent? In my opinion one hour a day devoted to exercise which makes a man feel better and gives him greater energy, could not possibly be spent more profitably. In regard to the early great development I think Dr. Bowditch is perfectly right, but I did not touch, as I remember, upon the subject of over-development among athletic young men. I do not think a moderate amount of early development compels a man to take any more exercise in the latter part of his life.

DR. BOWDITCH: I think I did not make my meaning quite understood. Dr. Brooks's last remark has partly answered the first question. The question was whether it was not possible for a man to develop himself so much in his early life that he will require, in order to feel in good condition during the rest of his life, to take an amount of physical exercise which does not do him any harm, of course, but might, perhaps, if he did not have this big physique to take care of, be spent more profitably in other ways. I did not mean that any amount of time could be better spent than in securing one's healthful condition, but whether it was not possible to have a physique which required an undue amount of time, and in that way might involve themselves by a great development of the physique in youth in the employment of their time the rest of their life which might better be put in some other way.

DR. BROOKS: I can only reply to that from my own experience. I played football eight years and rowed seven years, and it was pretty heavy exercise. Two years after I left the medical school I took practically no exercise, and I think I suffered accordingly. During the past year I have taken exercise of a very light character, and I find that it requires a very slight amount to keep me in fairly good condition.

DR. VICKERY: Mayor Bancroft of Cambridge, a prominent athlete, said his exercise seems to keep him going now that he cannot take any.

DR. J. E. GOLDTHWAIT read a

## REPORT OF CASES IN WHICH THERE WAS OBLITERATION OF THE TRANSVERSE ARCH OF THE FOOT.[1]

DR. BRADFORD: When Dr. Goldthwait a year ago called attention to this subject, I think he added more than he realized, more certainly than I did, to

[1] See page 564 of the Journal.

what is an important subject. Since his paper I have had my attention called to a number of cases; and I think any one who has examined the matter will say that he is not only correct in his generalizations, but will recognize the value of this contribution to orthopedic surgery. I have here some impressions of feet from patients whom I have examined for various reasons, and these have been taken with the feet resting without pressure. I have also taken casts where the full pressure has been on, and it is evident that the transverse arch is practically a spring; when much weight is thrown the transverse arch is obliterated. These casts will show that the transverse arch varies in different feet. This one may be considered a normal foot. The other three are pathological, all showing the obliteration of the transverse arch. Now as to symptoms I should agree entirely with what Dr. Goldthwait has said, but I think I would take exception to his statement that the pain is so rarely over the fourth metatarsal. It seems to me he has confounded in his last two cases two affections, one the obliteration of the transverse arch, and the other Morton's affection, which is the pinching of the nerve through the dropping of the fourth metatarsal. The head of the fifth metatarsal being shorter than the fourth, when the fourth drops the head of the fifth pinches the nerve causing an intense pain. It has been my fortune to see ten of these cases besides cases where the pain was not localized but was more in the middle of the foot. To demonstrate this still more clearly I will pass around this specimen comparing it with this. Here is a case with a normal transverse arch. Here is a case where the head of the fourth metatarsal has dropped down and there is intense spasmodic neuralgic pain. Furthermore I cannot force the head of the fourth metatarsal up by pads or whatever means, and I am preparing to do Morton's operation of removing the head of the fourth metatarsal. If we compare this case with that case, and then compare this where there is dropping of the second metatarsal, I think you will see that although they can all be placed under the head of obliteration of the transverse arch, yet at the same time it is a different affection from the wedging of the fourth metatarsal downwards. Here is another specimen where the third and fourth are both lower.

Dr. Lovett: I have been very much interested in the question of the transverse arch since Dr. Goldthwait's paper, and I looked through a day or two ago some fifty or sixty tracings I have had taken of some nurses, and I found that the presence of the transverse arch could not be shown in more than one-fourth or one-third of the cases, and in the majority of the cases where it was absent, it did not give rise to any especial symptoms of discomfort. I presume that an abnormal foot exists in a larger proportion among nurses than among almost any other class in the community; and certainly the longitudinal arch in many of the cases was broken down, too, but the common absence of a transverse arch was very noticeable. With regard to Morton's disease, I could not help feeling as Dr. Bradford did, that that was perfectly well characterized by a definite pain located at the end of the fourth metatarsal; nor do I believe that in all cases it is caused by any breaking down of the transverse arch. The last two cases I have seen have had contraction of the plantar fascia and abnormally high transverse arch. A tracing I meant to bring showed a very well-marked transverse arch in a perfectly typical case of the disease.

The cases of painful affection of the foot where the pain is wandering round in various places associated with breaking down of the transverse arch, have seemed to me more akin to the condition of flat-foot than to Morton's disease proper, which it seems to me has a perfectly definite symptomatology and which is associated with two definite conditions, as I have seen it aside from any change in the transverse arch — one, contraction of the plantar fascia, the other, breaking down of the longitudinal arch of the foot; and it seems to me the term Morton's disease should be confined definitely to cases showing pain at that one place at the end of the fourth metatarsal, because the pathology, as he described it, rested on that, as Dr. Bradford has explained, and in a certain number of those cases I feel sure that the pain is entirely independent of any breaking down of the transverse arch.

Dr. Dane: I have been interested in Dr. Lovett's speaking of the cases in which the pain was located sharply at the point Morton had spoken of and yet showed a distinct transverse arch. Last winter I had two cases, both of women about forty, in which there was very excruciating pain, so much so, that one was obliged to sit down on the steps of a public building and remove the shoe. The treatment for broken-down transverse arch relieved the pain entirely, so that the woman has not had any since; and yet tracing showed almost an abnormally high transverse arch. Blocking it up with a pad in that way completely and immediately relieved the pain.

The method of taking the tracing which I employed was this: I smoked a sheet of paper with camphor, had the patient step on it with the entire weight. Another method was to smear the surface of the foot with Day & Martin's blacking, and have them bear the weight again.

Dr. Goldthwait: Dr. Dane's case is, I think, similar to the cases of so-called acute flat-foot, in which the arch is still present, but with whom the pain is relieved by some support. I do not think the tracings of the transverse arch are invariably satisfactory. They are very suggestive, and to be developed most satisfactorily by having the foot rest lightly upon the paper. I have a series of tracings in which different degrees of weight were borne, which show the transverse arch gradually becoming obliterated as the weight was increased.

I seem to have caused some misunderstanding in using the term metatarsalgia. If Morton's disease is confined purely to the localization of neuralgic pain over the head of the fourth metatarsal bone, no one would take exception, but the term metatarsalgia has been used to describe neuralgic pain in the front part of the foot without more definite localization, for that reason I used the term. The one case in which the pain was located at the head of the fourth metatarsal bone, was entirely relieved and on the first application of the pad, similar to the one passed around; and the patient who had suffered a great many years and to whom the breaking in of a new pair of shoes was perfect torture, and dreaded as much as anything could be dreaded, is entirely relieved and has had no further trouble. I have no doubt there is a certain number of cases in which the nerve is pinched between the heads of the fourth and fifth metatarsal bones which may require operation.

## AMERICAN MEDICAL ASSOCIATION.

FORTY-SIXTH ANNUAL MEETING, BALTIMORE, MD., MAY 7–10, 1895.

(Concluded from No. 22, p. 550.)

SECTION IN MEDICINE. — THIRD DAY (CONTINUED).

A PAPER having the title of

REPORTS ON TYPHOID FEVER — CONTINUED,

was presented by DR. J. E. WOODBRIDGE, Youngstown, O.

The writer has previously expressed his views as to this disease in the *Journal of the American Medical Association*, March 20, 1894, and there gives in full the remedies employed by him and their mode of application. He believes it is possible to avert death in every case and that if the treatment is commenced before the eighth day, the disease can surely be aborted. He does not believe there is in the cases he has reported any doubt as to the correctness of diagnosis, and he has the recorded testimony of a large number of physicians who have adopted his views. Out of 600 cases so treated by others nine have died; and of all the others the average duration of the disease has been only twelve days. He believes that the plan of intestinal antisepsis which he advocates eliminates the danger of perforation and hemorrhage and removes all the other dangers of the later stages of the disease. He believes that the latter results from a specific poison which may possibly be of a microbic origin.

As is known, his initial remedy is a combination of small doses of calomel, podophyllin, carbonate of guaiacol, eucalyptus and menthol in capsule. These he gives frequently so as to produce five or six characteristic passages in the first twenty-four hours. Diarrhea does not contraindicate their use. After the fever curve is brought down, the guaiacol is increased in amount and thymol added. Later the calomel and podophyllin are discontinued and the guaiacol still further increased. Full details are given in the article above referred to.

Several participated in the discussion, the general trend of which was one of scepticism as to the correctness of Dr. Woodbridge's views. Some had tried his remedies with good results, and noted that where the typhoid fever did not abort, it seemed to change its type to a purely intermittent or remittent form.

DR. W. E. QUINE, of Chicago, made the special point that in the light of our present knowledge no diagnosis could be regarded as accurate which was not guarded by the results of the examination of the blood and urine.

DR. WOODBRIDGE, in closing, made the still more remarkable statement that he did not confine his patients to bed but allowed them to walk about and come to his office for treatment (?). He allowed them steak and beef if they desired it.

The next paper was by DR. GEO. W. WEBSTER, of Chicago, on

THE DIFFERENTIAL DIAGNOSIS OF CHOLELITHIASIS.

Ten per cent. of all men, twenty-five per cent. of all women, and thirty-six per cent. of all the insane have gall-stones, but of all those so affected but one per cent. have any symptoms therefrom. Medicines are absolutely useless to dissolve these stones, and the early diagnosis is a necessity as the cases should be sent to a surgical clinic rather than to Carlsbad.

All cases practically fall into two classes, first, those with the stone in the cystic duct, and second those with the stone in the common bile duct. Jaundice is the invariable accompaniment of the latter variety, and may or may not be present in the former.

In the first variety colic is the initial symptom. It is referred to the duodenal region, is sudden, of varying intensity, accompanied by nausea, vomiting, chill, fever, sweating and rarely convulsions. The pulse is frequent, small and soft. Collapse often ensues, with cramps in the voluntary muscles. Physical examination reveals a dilated gall-bladder, while in the second variety we regularly have an atrophy of this organ. The tumor dulness is continuous with that of the liver, and the mass moves with respiration. On auscultation the sound of the stones moving on each other can be heard.

Differential diagnosis of the variety lies between gall-stone, lead colic, malarial poisoning, renal colic, peritonitis, gastralgia and other abdominal tumors. The only positive evidence of gall-stones is to find them in the feces; but it must be remembered that after leaving the biliary passages they may dissolve in the bowel.

In the second variety, operation is more dangerous, though the reasons for the removal of the stones are more imperative. Persistent jaundice of varying severity signifies a movable stone. We have, as before, colic; bile in the urine, with evidences of cholemia due to the degeneration of the hepatic cells; diminution of urine and of urea; slight albuminuria; melancholia. The stools are scanty and clay-colored. The pulse is slow. We may have septic endocarditis, with blood disintegration. Vascular tension is low. The appetite poor and the tongue coated.

It is useless to make an anastomosis between the gall-bladder and the gut, leaving the stones *in situ* in the common duct. Moreover, the irritation from the latter may lead to malignant disease of the head of the pancreas.

DR. J. H. MUSSER, of Philadelphia, said he could not rely on the statements of the text-books as to the age at which cholelithiatic symptoms manifested themselves. While they were rare before thirty, he believed that they might occur as early as the fifteenth year, and related the clinical history of a case to substantiate this view. Attacks of abdominal pain coming on in early life were often misunderstood, but their continuance in later years, with additional symptoms, might show their real nature as to their origin from biliary disturbances. It should be remembered that pain was not constant in biliary obstruction. As to gastralgia, he believed that many cases supposed to be such were really of hepatic origin, though, of course, there could be a true gastralgia in neuropathic persons and in the form of a crisis in certain nervous diseases, as tabes.

The indications for operation he would find in renal inadequacy and the state of the red cells of the blood. After the latter had once fallen below 3,000,000 per cubic millimetre, subsequent disappearance was startlingly rapid. In one instance under his observation, the fall from 2,500,000 to 800,000 had occurred in a very few days. Cases of pneumonia and biliary colic were often confounded in their incipiency; and in the latter the fever often assumed an intermittent type.

SECTION IN MEDICINE. — FOURTH DAY.

The session opened with the reading of a paper on

NEW METHODS OF PRECISION IN THE INVESTIGATION OF FUNCTIONAL DISORDERS OF DIGESTION,

by DR. J. H. KELLOGG, Battle Creek, Mich.

In his methods, the writer follows the general rules laid down by Hayem and Winter, but has modified them in certain respects. The main problem is to estimate the abnormal conditions of the stomach. In the study of over four thousand stomach fluids he has found it possible to include all cases of disorder of the chemico vital processes of the stomach as regards proteid digestions into four general classes, hyperpepsia, hypopepsia, apepsia and dyspepsia. In hyperpepsia, the calculated acidity is above the normal. The significance of this is that the free HCl and combined chlorine are found in quantities sufficient to produce normal hyperacidity, there being excess of stomach work not regarding quality.

In hypopepsia free HCl and combined chlorides are not found in sufficient quantities to produce a normal degree of acidity. Here we may have a typical condition, or H without deficiency of HCl. In either the proteid digestion may be normal in quality or neutral chlor-organic compounds may be present and each of the latter types may or may not show fermentation.

In apepsia there is no normal proteid digestion. The characteristics are a neutral or a very slightly acid stomach fluid with or without fermentation.

In dyspepsia HCl and combined chlorides are present in sufficient quantities to produce a normal degree of acidity, with the same subdivisions as the foregoing.

Some curious results have come to light in the course of his study of stomach fluids. The old teaching of the physiologists is that not much sugar is present in the stomach during gastric digestion but he has found it present in the proportion of seven or eight grammes to one hundred cubic centimetres of stomach fluid. Soluble and unconverted starch often accounts for fermentation where there is hyperacidity.

DR. WEBSTER opened the discussion by stating that there was a want of knowledge as to what occurs in health and that in any given case we should try to determine first, the locality and second, the extent of the departure from health.

DR. KELLOGG stated, in closing, that he had found the chewing of dry food the best method of promoting the salivary flow. Stimulants of all kinds, however, would after awhile lose their power. A 1–4,000 strength of HCl would greatly lessen the salivary digestion in the stomach, would in fact practically stop it.

DR. I. E. ATKINSON, of Baltimore, Md., followed with a paper on

A CASE OF SUPPURATIVE PANCREATITIS, WITH NECROPSY.

The patient was a woman aged thirty-five, the mother of two children, the one twelve years and the other six months old. She was first seen on December 2, 1894. Though still quite stout she had lost over forty pounds. Fifteen months previously she had an attack of hepatic colic with a secondary jaundice lasting over three weeks. No stones were found in the stools, the pain was constant but ceased abruptly. In September, another attack of colic occurred with secondary jaundice. The urine was dark and the stools clay-colored. The pain gradually wore away and the jaundice also, but she gradually grew weaker and finally took to bed. Pain returned, though milder in character, with jaundice and the vomiting of stomach contents occasionally streaked with blood.

She was examined on the sixty-second day of her confinement to bed. She had vomited several days, almost without nausea, a greenish fluid and the bowels were slightly loose. Singultus was annoying. In the epigastrium was an area of induration not movable or fluctuating. Its diameter was three inches in the median line and four-and-one-half laterally toward the left mammary line. Percussion gave a relatively dull note but it was not tympanitic in character. The lower abdomen was normal. The urine showed a gravity of 1.020 and a little sugar, but no albumin. Severe lancinating pains were felt with a point of greatest intensity under the xiphoid cartilage extending in the back between the shoulders. Respiration was rapid and of a purely costal type. There was a slight febrile movement but no chill and no sweating except about the head. All evidence of intestinal obstruction was wanting, in fact the bowels were rather loose.

A diagnosis was made of hepatic colic with impaction of the stone at the orifice of the common duct and pancreatic duct, producing incomplete obstruction, inflammation and hyperemia.

She grew steadily worse and the indurated area extended down to the navel. Diarrhea continued but there was no free fat in the stools. Vomiting of green mucus with blood and ingesta was persistent. All treatment was useless and in view of her low condition, surgical interference was deemed out of the question. Crepitation became evident over the lobar lungs posteriorly. A discharge of bloody pus from the bowels occurred, the mass grew smaller and the patient died in collapse.

The autopsy revealed considerable foul gas in the abdomen which escaped with an explosive sound; multiple peritoneal adhesions easily broken up; no fluid in cavity; areas of fat necrosis in omentum on left side over abscess cavity; obliteration of the head of the pancreas, the remainder of which formed the posterior wall of the abscess cavity, the walls of which extended up behind the stomach. The pus collection seemed to have occupied the usual site of the pancreas and of the lesser omental cavity. A small bit of pancreas tissue attached by a sort of pedicle lay free in the abscess cavity. The opening of the cavity into the bowel was at the normal site of the entrance of the pancreatic duct. The source of the gas could not be learned.

Dr. Atkinson said that with the light thrown on diseases of the pancreas by the classical writings of Fitz, we ought to be able to recognize these cases. Fitz has divided them into three classes: the hemorrhagic, gangrenous and suppurative. The first variety is to be recognized by its sudden onset and the presence of a tumor, tympanitic from the superjacent bowel. It proves fatal in a very few days or may pass into the gangrenous form and last from a few days to six or eight weeks. The patients die from asthenia or from sepsis. The suppurative variety may extend even over one year. As a rule, there is no fat necrosis. Dr. Atkinson believes that this case was undoubtedly originally one of the hemorrhagic variety.

The paper was discussed by DR. STOCKTON, who said he had never seen a suppurative case, and he regarded it difficult to diagnosticate this class of maladies. The case reported showed less depression and shock than usual. He had never seen free fat in the stools in these malignant cases under his observation. In one instance the pancreas had been large and hard, like the condition found in an interstitial nephritis. This case did not appear to be one of malignant growth and there had been no hemorrhage or evidence of previous trouble. He would ask Dr. Atkinson if he had found fat necrosis more common in the interstitial forms of the disease.

The latter, in reply, stated that no gall-stones had been found at autopsy. As to fat in the stools, he believed it to be the rule except in acute cases. Sugar in the urine was by no means common, and when it occurred, it generally came late. If we found on abdominal section at autopsy fat necrosis, it was at once an indication of the nature of the trouble.

The closing paper of the session was read by DR. T. O. SUMMERS, of New York, on

LEUCOCYTES AND PROTONUCLEIN.

After stating certain general propositions with reference to the successive steps taken towards the establishment of protonuclein as a therapeutic agent, and its method of preparation, the writer concluded with the following statements as to its administration and the indications for its use:

Protonuclein is prepared in tablets, powders, and may be used hypodermically. It is a powerful prophylactic as well as a direct antitoxic, the latter effect extending to all zymotic diseases. It will keep indefinitely, being enveloped in benzoin and milk-sugar which preserve its potential activity just as a grain of corn is preserved by its environment.

Protonuclein is indicated in any form of the disease where the organism is in a low asthenic condition, and in all zymotic or inflammatory conditions or whenever there are toxic germs to be destroyed.

The following papers were read by title: "The Conservative Use of Lavage in Diseases of the Stomach," by Dr. J. M. G. Carter, Waukegan, Ill. "Constipation and Faulty Elimination as a Factor in Disease," by Dr. F. S. Thomas, Council Bluffs, Iowa. "The Physician," by Dr. Julius Kohl, Belleville, Ill.

The following were elected officers of the Section for the ensuing year: Chairman, Wm. E. Quine, Chicago, Ill.; Secretary, DeLancy Rochester, Buffalo, N. Y.

## Recent Literature.

*Clinical Gynæcology, Medical and Surgical.* For Students and Practitioners. By eminent American teachers. Edited by JOHN M. KEATING, M.D., LL.D., and by HENRY C. COE, M.D., M.R.C.S., Professor of Gynæcology, New York Polyclinic. Illustrated. Philadelphia: J. P. Lippincott Company. 1895.

The extended works in conjoint authorship which are so prominent a feature in the medical literature of the present day, offer an especially hard task to the reviewer, since each one of the component parts is necessarily an entity in itself, and it is manifestly impossible to criticise each successive article in a full and satisfactory manner within the limits of a single review.

These works usually fail in comprehensiveness and are marred by frequent repetitions. These failures are in part inherent in the system; in part are usually the result of an attempt to arrange the book after the method which would be followed by a single author, and to distribute to each of the contributors a portion which is expected to be in direct continuity with those which precede and follow it.

In the present volume the editorial work has been admirably done, in that the subject has been divided into broad general topics in such a way that each author's sub-subject is, so far as possible, independent of the others, and capable of standing by itself. The book is then a series of clinical essays on gynecological subjects, which are so arranged that between them they cover the whole field of the specialty very admirably.

Among the twenty articles which comprise the book, it is only possible for us to pick out for remark a few which are distinguished by especial excellence.

The introductory chapter is written in the well-known flowing and eloquent style of the late William Goodell, and is a mournful reminder of the loss which the profession has so lately sustained.

The eighty-two pages on gynecological technique by Hunter Robb, will perhaps be as valuable to the general practitioner as any portion of the book. The subject is one in which Dr. Robb has done perhaps more extensive and exact work than has ever been done by any other gynecologist. The article is most clearly and practically written. Every page teems with facts which are essential to operative success, and it will be read with interest by experts as well as by beginners.

The chapter on Anomalies of Development in the Genital Tract, by Barton C. Hirst, M.D., is an admirable one. That on Traumatic Lesions of the Vulva, Vagina, and Cervix, by Matthew D. Mann, M.D., is admirable in the clearness with which the author describes the procedures for the repair of these lesions, and the decision with which he adheres to the descriptions of those which are of acknowledged worth, without complicating his article by long-drawn-out descriptions of others which he does not wish to recommend.

The chapter on Inflammation of the Female Genital Organs is fully up to the standard which would have been expected from its distinguished author, Dr. William M. Polk, whose name has been so closely identified with recent progress in this subject.

In these days when the interest in everything gynecological tends so strongly to become wholly surgical, the editors are to be congratulated on having been able to place the article on Displacements of the Uterus, by Dr. Paul F. Mundé, in the hands of a contributor who is still an active advocate of the use of minor measures of treatment, and is not disposed to pass over the pessary with a perfunctory notice for the sake of having the more space to devote to hysterorrhaphy, the Alexander-Adams, and other similar operations.

Drs. Hermann J. Boldt and Henry C. Coe furnish most exhaustive and valuable articles on the Neoplasms of the Female Genital Tract. Both of these articles give to the work a value to the specialist as a book of reference which it could not otherwise have had.

The article on the Diseases of the Urethra, Bladder,

and Ureters, by Charles Jewett, M.D., and John Polak, M.D., has the advantage of dealing with a field which is at this moment in the process of active development. It is fully up to the standard of the day, and is of especial interest in its suggestion of the extent to which recently discovered methods of exploration are curtailing the number of so-called functional ailments, and furnish us instead with a pathologically accurate diagnosis upon which to found our treatment.

We are very glad to see that the volume includes an article on Diseases of the Rectum and Anus by the able pen of Dr. Edward E. Montgomery. This subject is one which the gynecologist can never afford to neglect, but which is too often omitted from text-books on the subject.

The book as a whole is to be cordially recommended.

*Twenty-sixth Annual Report relating to the Registry and Return of Births, Marriages and Deaths in Michigan, for the year* 1892. Pp. 375. Lansing, Mich., 1894.

The Registration Reports of Michigan are in many respects, among the best reports of the kind in the United States, so far as thoroughness of compilation of the material presented is concerned.

The returns of births and deaths are, as the compiler states, "deficient to such a degree that they would require to be increased by at least 60 per cent. to correctly represent the actual numbers of births and deaths that occurred." This deficiency, however, is in no way to be charged to the compiler but to the existing statutes relating to registration in Michigan. The defects of these statutes are fully pointed out in this report.

It is evident that the compiler has made the best possible use of the deficient data in hand, and is entitled to much credit for so fully and thoroughly presenting the subject. Intelligent comparisons are made with the statistics of other States and countries.

The marriage, birth, and death rates for 1892, and for the five years (1886–90), as presented in Table 5, were as follows:

| | 1886–1890. | 1892. |
|---|---|---|
| Marriage-rate per 1,000 | 17.1 | 18.4 |
| Birth-rate " | 23.8 | 21.2 |
| Death-rate " | 10.1 | 9.9 |

From this it would appear that the returns of deaths were considerably more deficient than those of births.

Of the total mortality reported:

| | | |
|---|---|---|
| Deaths from consumption caused | 11.8 | per cent. |
| " diphtheria and croup caused | 7.5 | " |
| " typhoid fever caused | 3.6 | " |
| " scarlet fever caused | 2.5 | " |
| " whooping-cough caused | 0.8 | " |
| " cancer caused | 3.2 | " |
| " pneumonia caused | 7.4 | " |
| " brain diseases caused | 8.7 | " |
| " heart diseases caused | 5.5 | " |

The compiler recognizes the importance of a revision of the old system of classification and nosology which has been in use for a very long period (Dr. Farr's), and boldly strikes out in a new line, with a provisional classification, which he recommends and employs as a practical system adapted to modern requirements. His reasons for the changes are fully discussed in this report. One of the chief changes in this system is the transfer of tuberculosis to the class of specific infectious diseases.

In the Twenty-fifth Annual Registration Report of Michigan a review of the results of registration in that State for a quarter of a century was presented as fully as the imperfect data collected would admit.

On the other hand, the Fiftieth Annual Registration Report of Massachusetts might have presented a half-century's work of extremely valuable character, since the registration of this State is far more thorough and complete than that of Michigan; but when the report was issued, it was found, to the shame of Massachusetts, to contain no reference whatever to the fifty years' work, and was generally condemned by experts as the most worthless report of the series. Its successors, the reports of 1892 and 1893, are quite as deficient and useless, so far as any "practical utility" is concerned, as that of 1891.

The State of Michigan may be congratulated on the fact that this important department of public work has been intrusted to a competent medical authority, who fully appreciates the value of the work of his department.

*Die Bekämpfung der Infectionskrankheiten: Hygienischer Theil.* Von Oberingenieur J. BRIX PROF. DR. E. PFUHL, und Hafenarzt DR. NOCHT, Herausgegeben von Stabsarzt PROF. DR. BEHRING. Pp. 493. Leipsig: Georg Thieme. 1894.

It would be impossible, within the limits of a book-notice to give a complete *résumé* of the contents of this extremely valuable work published under the direction of a most progressive author, who has called to his aid the best experts in the subjects treated.

The first portion of the work, by Chief Engineer Brix, of Wiesbaden, treats of the sanitary measures for the prevention of those infectious diseases which stand in relation to water, and the soil. In this portion of the work all questions relating to water-supplies, both public and private, and to sewerage and refuse disposal of towns and dwellings, are treated in the most thorough and systematic manner. The purification of water and of sewage occupy an important share of the work.

It is a satisfaction to find, in a work of this character, that the principles of water and sewage purification are laid down in an exceedingly clear and concise manner, and with no uncertain sound: For example, "By no method of purification can the sewage of cities be so thoroughly accomplished, as by means of irrigation."

Drs. Pfuhl, of Berlin, and Nocht, of Hamburg, contribute the portion upon disinfection of clothing, linen, beds, houses and ship-utensils. This chapter is fully illustrated with cuts and plans of disinfecting stations and apparatus.

The final chapter is contributed by Port-Physician Nocht, of Hamburg, and treats of the disinfection of ships. Prominence is given to the use of lime (in the form of whitewash and of the consistency of cream) and of steam. Bilge-water and the disinfection of the bilge receive due attention, and the results of analysis of the bilge-water of eleven ships are given.

The work is very properly dedicated to Dr. R. Koch, whose teachings and influence the authors gratefully acknowledge.

It deserves a good English translation and will serve as an excellent text-book for the higher technical schools. Its very elaborate table of contents, comprising twenty-five pages, should be alphabetically arranged in a second edition, or possibly at the close of a therapeutic volume which may soon follow

THE BOSTON

# Medical and Surgical Journal.

## EXPERIMENTAL MYELITIS.

THE action of bacteria or their products on the central nervous system is a subject which for a number of years has been exciting a large amount of speculation. Clinical evidence has not been lacking to show the probable infectious nature of certain lesions, notably those included under the general head of myelitis. Putnam's exhaustive review of the part infection plays in nervous disease, published in a recent number of the *American Journal of Medical Sciences* (March, 1895), gives one a conception of the great amount of work which had been done upon the subject up to that time. In view of the extensive literature which has appeared, and the wide interest which the whole subject has aroused from a clinical point of view, it is rather remarkable that attempts at experimental verification have been comparatively few. It is, therefore, with great satisfaction that we call attention in some detail to an article in the February number of the *Annales de l'Institut Pasteur*, the result of the work of Vidal and Bezançon, from the laboratory of Professor Cornil. The object of this investigation was the production of myelitis by means of streptococcus injections.

After discussing briefly the work of an experimental nature hitherto done on the subject, with references, the writers go on to the details of their own experiments. The animal used for inoculation was the rabbit, the aim being to reproduce in it as closely as possible the conditions which are observed clinically in man. To accomplish this end they inoculated a large number of animals, 116 in all, with streptococci taken from 89 different sources, and endowed with varying degrees of virulence. An enumeration of the origin of the streptococci cultures is as follows: 20 from normal mouths; 49 from the mouths of patients suffering from erysipelas, scarlatina, measles, small-pox, sore throats of various sorts, typhoid fever, influenza, pneumonia, etc.; the bacteria were also taken from a normal duodenum, from puerperal infection, lymphangitis, erysipelatous patches, appendicitis, purpura, and abscess of breast.

Of the 116 inoculations, but seven animals, or six per cent., later developed paralytic symptoms, which appeared at intervals between the seventh day and the second month, and ran a different clinical course. The streptococci which led to the paralysis were derived, in one case, from an erysipelatous mouth, once from the mouth of a small-pox patient, once from the uterus of a puerperally-infected woman, twice from the same normal mouth, the virulence, however, of the streptococcus in these two latter cases being increased by association with the colon bacillus. In the remaining cases, the inoculation was made from a culture taken from a pseudo-diphtheritic membrane. The animals were inoculated, for the most part, in the cellular tissue of the ear. A rise of temperature followed in most of the cases, with various local disturbances about the seat of inoculation. The advent of paralytic symptoms bore no relation to the supposed virulence of the organism injected. In the seven cases death resulted 13, 15, 25, 32, 37, 45 and 70 days after inoculation.

The advent of myelitis appeared in some cases as a sequel of the disturbance caused by inoculation; in others the animals had apparently completely recovered when the paralysis set in; in still others the spinal cord lesion was the first clinical manifestation of the infection. As a rule, the spinal symptoms appeared quickly, without appreciable cause. In others an exciting cause could be assigned, as in the following case: A male rabbit, inoculated two months before, had been perfectly well until in attempting copulation, he became suddenly paralyzed. Such a case bears a striking analogy to the sudden onset of myelitis in persons to all appearances previously healthy — not an infrequent clinical observation. The symptoms on the part of the affected animals varied widely: the paraplegia was in some cases flaccid in character, in others associated with contractures. In two rabbits the contractures were general, affecting all the extremities and the muscles of the trunk and head. One animal was hemiplegic; all presented considerable muscular atrophy, and nearly all had diarrhea, fecal incontinence and retention of urine.

Of the seven animals that died the spinal cord was examined in four cases. There was no macroscopic lesion, neither meningeal changes nor areas of softening. In one case, after two months' hardening in Müller's fluid, certain changes could be discerned with the naked eye, which later found an histological explanation.

After hardening, the cords were cut and stained in various ways, the bacteriological examinations for streptococci being made by Weigert's method. In every case histological examination showed changes of a diffuse nature, degenerative in character, and of varying intensity, affecting both gray and white matter. The lesions were most marked in the cord whose macroscopic appearance was pathological after hardening in Müller's fluid.

The gray matter throughout the cords was more or less affected, but especially in the lumbar enlargement. The ganglion cells of the anterior horns showed marked degenerative changes up to complete destruction. The neuroglia of the gray matter was but slightly affected; especially was there absolutely no trace of an inflammatory process to be observed. Occasional large granular cells were noted in the neighborhood of degenerating ganglion cells. There was only slight alteration of nerve fibres, merely hypertrophy of certain axis-cylinder processes.

The vascular changes were extreme, especially in the capillaries of the anterior horns and the commissures. The vessels appeared engorged with blood, particularly at the level of the lumbar enlargement; the walls at places were ruptured and the blood extravasated into the surrounding tissue even to the extent of producing infarcts. There was, however, absolutely no indication of inflammatory change, no thickening of capillary walls nor leucocyte infiltration.

The lesions of the white matter were not less interesting, and were identical in the four cases examined, differing only in their intensity. The degenerative changes observed were irregular in distribution, affecting both myeline sheaths and axis-cylinder processes, in the usual way. The neuroglia, as in the gray matter, showed only slight alterations. Large numbers of compound granule cells were visible in the degenerating white matter and especially about its periphery. The ganglia, nerve roots, peripheral nerves and muscles were found to be normal.

The conclusions which the writers reach from their observations, in connection with those made by other investigators are, that in the rabbit the cord lesions produced by streptococcus inoculations may show themselves symptomatically either by progressive muscular atrophy, or by flaccid paraplegia of subacute course, or by paralyses with more or less generalized contractures.

Such experimental myelitides reproduce for the most part the lesions observed in man described as acute myelitis. There are, however, two peculiarities of the human form which are not reproduced experimentally, namely, the perivascular extravasation of leucocytes, and the hypertrophy of neuroglia. Bacteriological examination of the rabbits' cords did not demonstrate the presence of streptococci, whereas they were at times found in the viscera and blood, whence the legitimate conclusion is reached that the observed lesion is produced by soluble toxines and not by actual bacterial action.

The importance of the work, whose substance we have attempted to give in the foregoing abstract, is certainly very great, both from a scientific and a practical point of view. Those who have the progress of scientific neurology at heart will most heartily welcome any painstaking attempt to establish its etiological problems on a basis of demonstrated fact. Practically, too, there is much to be gained from any knowledge of the causation of disease, which is definite and exact. The time has long since past for the old reproach to be raised that the efforts of the theorist in medicine have no definite bearing on the everyday work of his more practical brother. It must be through the establishment of etiological relationships, which alone can be worked out by means of laborious scientific methods, that the ultimate good of the community at large may best be subserved.

## EXCISION OF THE STERNO-MASTOID MUSCLE FOR WRY-NECK.

Mikulicz, of Breslau, has published an interesting article[1] in which he discusses the various methods of treatment for wry-neck, and its pathology. He considers that open incision of the muscles (Volkmann) has no special advantage over a thorough subcutaneous operation. He advocates in severe cases a complete extirpation of the muscle. He claims that the muscle is completely degenerated and shows no faradic reaction; that it has no functional value; and that any disfigurement of the neck resulting from its loss is more than compensated by the rapid relief from the torticollis. He states that, contrary to the general impression, the fibrous degeneration rarely affects the muscle transversely, but rather longitudinally along the fibres. In rare cases the lower half was found affected.

Mikulicz thus describes his operation: A skin incision, three to four centimetres long, between the sternal and clavicular ends of the muscle; skin and platysma divided; with blunt instruments the sternal and clavicular insertions are exposed and undermined; the deeper structures are protected by an elevator; the muscular insertions are separated from the bones; the cut ends are seized with forceps and strongly drawn out of the wound. As the muscle is pulled down, it is freed from its sheath. The head is at the same time held so as to relax the muscle. In this way the muscle can be exposed nearly to the mastoid process. When the limit of the diseased portion is reached, it is divided with scissors. The portion connected with the spinal accessory nerve is left undisturbed. After extirpation of the muscle the wound is sutured without drainage and the head bandaged in a corrected position.

Since April, 1891, this surgeon has treated 25 cases of torticollis: 22 congenital, three acquired. Of these, three yielded easily to orthopedic treatment; five were treated by subcutaneous tenotomy; 17 by extirpation (eight partial, nine total) of the muscle, and in the whole 17 the result was satisfactory. Where no secondary changes in the vertebræ existed, the restoration of the normal position of the head was rapid. A flattening of the side of the neck resulted from the removal of the muscle. The muscle removed was found in all cases to be diffusely diseased, always along the course of the fibre.

Mikulicz regards the process as a variety of myositis

[1] Centralblatt. f. Chir., 1895, xxii, 1.

fibrosa — a peculiar chronic inflammatory process; and thinks that those swellings of new-born children, called hematoma, which result in muscular contraction, are inflammatory processes from the beginning. The evidence in favor of this opinion is stated, and is quite interesting.

The article is somewhat startling on account of the method of treatment proposed, and will not be accepted as conclusive without discussion, at least as far as treatment is concerned. It has already elicited a reply from Lorenz, of Vienna, who considers that the after-treatment is as important in these cases as in those of club-foot; that the bony changes must be treated as well as the muscular contraction; that there coexists in these cases a cervical scoliosis which must be corrected before a perfect result is obtained, and that this is true whether the sterno-mastoid muscle is divided transversely by tenotomy or the open method, or extirpated entirely.

Lorenz claims, and justly too, that if proper treatment is directed to the spinal changes there will be very few cases which will require so extreme a procedure as total extirpation of the muscle.[2] After open or subcutaneous section of the contracted sterno-mastoid, he practises "plastic correction" of the deformity. After dressing the wound aseptically, the narcosis is continued, the forehead and occiput are grasped between the hands, and the head bent in a sagittal plane toward the side formerly convex. All violent movements must be avoided, and the amount of force used be carefully estimated. In order to accomplish this properly, considerable time is often required. When the head has been well carried down to the desired side, it is grasped by applying the fingers of each hand to the skull on the convex side, while the thumbs are placed on each side of the ear on the concave side, and the head carried by forcible and repeated efforts so far toward the side formerly convex, that the ear touches the shoulder. The correction must be made complete and forcible, according as the preceding deformity was severe. In less than half an hour the most obstinate forms may be thus corrected. The operation is a trying one for the surgeon, and care must be taken that the trachea is not compressed during the manipulations. The ends of the divided muscle are so far separated by this manœuvre, that there is no danger of cicatricial contraction bringing them together again. The head is held from ten to fourteen days in the corrected position by a suitable bandage, and after the removal of the bandage, active movements are practised; no mechanical treatment is required.

Lorenz contends that better results will be attained, and with less deformity, by this method than by Mikulicz's total extirpation of the sterno-mastoid. Inasmuch as the defect left by division would certainly be less than by excision of the muscle, his contention is probably right, at least in reference to the deformity.

[2] Centralblatt. f. Chir., 1895, xxii, 105.

## MEDICAL NOTES.

THE EIGHTIETH BIRTHDAY OF PROFESSOR VON DITTEL. — Prof. L. von Dittel, of Vienna, celebrated his eightieth birthday on May 15th.

THE CHAIR OF HYGIENE AT MARBURG. — Professor Behring has been nominated for the chair of hygiene at Marburg, as successor to Prof. C. Fraenkel, who has been called to the chair of hygiene at Halle.

DR. BARNES HONORED. — The Society of Obstetrics and Gynecology of Bordeaux, in organizing a Congress for August 8th, on the occasion of the Exposition, has elected Dr. Robert Barnes *Président d'Honneur*.

PROPOSED MEDICAL LEGISLATION IN WISCONSIN. — Attempts are being made by Wisconsin physicians to secure the enactment by the Legislature of a law for the regulation of the practice of medicine.

THE MISSISSIPPI VALLEY MEDICAL ASSOCIATION. — The twenty-first annual meeting will be held in Detroit on September 3d, 4th, 5th and 6th. Dr. William Pepper, of Philadelphia, is to deliver the annual address in medicine.

A CAMPHOR FAMINE. — According to reports from London, a camphor famine is now threatened as one of the results of the China-Japanese war. Cholera mixtures and smokeless powder will be expensive luxuries during the summer.

A QUARANTINE AGAINST THE PLAGUE. — Under the last regulations of the United States Treasury Department, the plague has been declared quarantinable, along with cholera, yellow-fever, typhus, variola and leprosy. The plague is now raging at Amoy, China, at the rate of fifteen deaths a day.

STRYCHNINE IN SNAKEBITE. — Dr. T. A. Manikam Pillay, in medical charge of the hospital at Ulunderpet, South Ascot, India, reports in the *India Medical Record* of December 16, 1894, three cases of snakebite successfully treated with hypodermic injections of strychuine, according to Dr. Mueller's method.

THE DECORATION OF M. PASTEUR. — The recent statement in *Figaro* that M. Pasteur had refused a decoration offered him by the Kaiser in recognition of his services to humanity, because the memory of 1870 was too strong to allow him to accept it, has been authoritatively denied in Germany. It is stated that no decoration was offered him, and therefore he had no opportunity to refuse.

RETIREMENT OF JOHN S. BILLINGS. — Dr. John S. Billings announces his intention of retiring from his position in the army next October. He hopes before that time to have completed the Surgeon-General's Catalogue, a work which will always remain a monument to his executive ability, learning and perseverance. Its importance to the workers in medicine and medical literature can hardly be overestimated. Dr. Billings retires in order to accept the chair of hygiene at the University of Pennsylvania.

AN ORDER OF THE COURT OF INTEREST TO DR. KEELEY. — According to the *Chicago Herald* of May 2d, Judge Myers of the United States District Court, in session at Leavenworth, Kan., has made a very important order affecting the rights of Dr. Leslie E. Keeley. W. F. Johnson, of Topeka, sues Dr. Keeley for $100,000 damages, the petition reciting that plaintiff has been made a physical wreck because of the gold cure. Judge Myers, in granting the prisoner's request, rules that Dr. Keeley must make known the ingredients of his bichloride of gold compound. The court holds that the cure is not a property right nor trade secret. Inasmuch as it is unprotected by patent and has been in use more than two years, there is nothing to prevent Dr. Keeley's testifying as to its composition, and the court orders him to do so.

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, May 29, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 55, scarlet fever 32, measles 87, typhoid fever 8. During the week ending June 5th, the report was as follows: diphtheria 70, scarlet fever 28, measles 66, typhoid fever 15.

APPOINTMENTS AT THE HARVARD MEDICAL SCHOOL. — Dr. Harold C. Ernst has been appointed Professor of Bacteriology in the Harvard Medical School, and Dr. Francis H. Davenport Assistant Professor of Gynecology at the Harvard Medical School.

PROF. THEOBALD SMITH, M.D. — Dr. Theobald Smith, formerly chief of the Division of Animal Pathology in the United States Bureau of Agriculture, at Washington, has been appointed Bacteriologist of the Massachusetts State Board of Health, and Professor of Applied Zoölogy in the Bussey Institute of Harvard University.

THE ANNUAL DINNER OF THE MASSACHUSETTS MEDICAL SOCIETY. — At the Annual Dinner of the Massachusetts Medical Society on June 12th, His Excellency, Frederic T. Greenhalge, Governor of Massachusetts, Prof. Charles Eliot Norton, of Harvard University, the Rev. James B. Doonan, of Boston College, and Sir William H. Hingston, of Montreal, will be the after-dinner speakers.

BEQUESTS TO HOSPITALS. — By the will of the late Joseph B. Lefavour, of Beverly, Mass., $5,000 is bequeathed to the Beverly Hospital, and $5,000 to the Free Hospital for Women in Boston.

MEDICAL LEGISLATION IN RHODE ISLAND. — The Legislature of the State of Rhode Island has recently passed an act for the regulation of the practice of medicine.

THE KEELEY BILL DEFEATED. — The bill to render the employment of the Keeley treatment compulsory at the Massachusetts Hospital for Dipsomaniacs and Inebriates has been again defeated in the Massachusetts House of Representatives.

ADAMS NERVINE ASYLUM. — The Adams Nervine Asylum at Jamaica Plain is about to open a building with twelve beds for the reception of male patients, inhabitants of Massachusetts. Insane persons cannot be received, and a certificate from the attending physician that the patient has disease of the nervous system will be required. Hitherto the benefits of this charity have been confined to women.

THE INCREASE OF CREMATION. — At a public meeting of the New England Cremation Society held in Boston on May 31st, an interesting history of Cremation in the United States was given by the president, Mr. John Storer Cobb, in his annual address. During the ten years in which this method has been used for the disposal of the dead 17 crematories have been established. The following figures show the number of bodies cremated throughout the country in each of the 10 years: In 1885, 36; 1886, 119; 1887, 125; 1888, 199; 1889, 262; 1890, 362; 1891, 464; 1892, 576; 1893, 677; 1894, 876. These figures are interesting in showing a steady and rapid increase, from 36 in 1885 to 876 in 1894.

### NEW YORK.

YELLOW FEVER IN HAVANA. — Reports from Havana show that yellow fever has increased very notably of late in that city. Health-Officer Doty, appreciating the danger of the disease arriving in New York, on June 2d started for Cuba in order to familiarize himself with the methods of discharging and lading cargoes at the Cuban ports. At Havana he will consult with Dr. Burgess, the United States Medical Inspector, and will examine the system of the Spanish officials for preventing the spread of yellow fever in Cuba. His trip will include visits to Matanzas, Cardenas and Calbarien, and on his way home Dr. Doty will inspect the new quarantine station at New Orleans.

THE NEW YORK STATE MEDICAL ASSOCIATION. — The Eleventh Annual Meeting of the Fifth District Branch of the New York State Medical Association was held in Brooklyn on May 28th. There was a morning and an afternoon session, and during the recess a luncheon was provided by the Branch. The meeting was presided over by Dr. Austin Flint, of New York, who made an address at the morning session. He also opened the discussion on a paper by Dr. H. A. Hanbold, of New York, on "The Propriety of Administering Digestive Ferments," in which the author argued, on physiological grounds, against the use of such ferments. Professor Flint in his remarks also took the same position. Nearly all the cases of dyspepsia which he had seen, he said, had been old cases which had been under the care of other physicians, and most of them had been treated unsuccessfully with pepsin, pancreatin, etc. A careful study of all these cases failed to show that any one of the patients had received the slightest benefit from this class of remedies. He would not say that some of the cases had not improved while digestive ferments were

being given, but whatever improvement was seen was due, not to them, but to the judicious regulation of the diet. A change of food was often of the greatest possible service in restoring the patients' digestive powers to their normal condition.

Among the other papers were "Living Bacteria in the Bladder," by Dr. X. T. Bates, of Dutchess County; "The Advocacy of a New Method of Operation for Marked Deflection of the Nasal Septum," by Dr. S. Oppenheimer, of New York; "The Abuse of Medical Charities," by Dr. Frank van Fleet, of New York; "Overfeeding," by Dr. T. J. Barton, of Dutchess County; "Chronic Catarrhal Laryngitis, with special reference to its Etiology," by Dr. Dwight L. Hubbard, of New York; and "Clinical Notes on a Recent Series of Operations," by Dr. Thomas H. Manley, of New York.

THE UNIVERSITY OF THE CITY OF NEW YORK.— The death of Dr. Alfred L. Loomis has led to a number of changes in the Faculty of the Medical Department of the University of the City of New York. Dr. Wm. H. Thomson, is now Professor of Medicine; Dr. W. Gilman Thompson, Professor of Materia Medica, Therapeutics and Clinical Medicine; Dr. Charles L. Bristol, Lecturer on Physiology; Dr. Henry P. Loomis, Professor of Pathology, and Dr. Charles E. Quimby, Adjunct Professor of Practise of Medicine.

DR. ALLAN MCLANE HAMILTON.— It is announced that Dr. Allan McLane Hamilton, the well-known neurologist, has leased a house in London, and that hereafter he will practise for a portion of each year in that city; returning to New York in the autumn.

REGULATION OF THE MEAT MARKET.— At a meeting of the Board of Health held May 27th, the following resolution, proposed by Dr. Cyrus Edson, was adopted: "That no meat or dead animal above the size of a rabbit shall be taken to any public or private market for food until the same shall have fully cooled after killing, nor until the entrails, head and feet, (except of poultry and game, the head and feet of swine,) shall have been removed; nor shall the body or any part thereof of an animal which is to be used as food be carted or carried through the streets except it be covered, so as to protect it from dust, dirt or cold, and no meat or poultry shall be hung or exposed for sale outside of any shop or store in this city."

MAYOR STRONG VETOES THE BILL TO TRANSFER THE INDIGENT INSANE.—The bill which recently passed both houses of the Legislature transferring the maintenance of the indigent insane of New York County to the State, has failed to become a law owing to the fact that Mayor Strong did not give it his approval. It is stated that his opposition to the measure was to the clause which stipulated that before the transfer could be made the city would have to pay the $1,000,000 back taxes due to the State on account of the former State-care Act. Much regret has been expressed by Dr. Carlos F. MacDonald, the President of the State Commission in Lunacy, at the Mayor's failure to approve, as he believes it will be very difficult to carry a similar bill through another Legislature.

A LIBRARY FOR THE BLIND.— A free circulating library for the blind has just been incorporated in New York.

## Miscellany.

### AMBULANT TREATMENT OF FRACTURES OF THE LOWER EXTREMITIES.

AT the German Surgical Congress, von Bardeleben gave the results of the treatment of fractures of the leg at the Charité in Berlin since his last report, made in 1894. Since that time 74 cases of fracture of the lower extremity had been treated. Of the 46 fractures of the leg 39 were treated with the *Gehverband*. Of four fractures of the patella, two were treated with and two without walking apparatus. Of 23 fractures of the thigh, 16 received the ambulant treatment. In all, then, 181 fractures of the lower extremity have received the ambulant treatment at the Charité: 135 fractures of the leg, 7 fractures of the patella, 38 fractures of the thigh, and one compound fracture of the thigh and leg on the same side.

This method of treatment has a most favorable influence on the general condition of the patients. The time required for consolidation varies between 38 and 19 days, according to the nature of the fracture; in a single case of compound fracture 78 days were necessary to complete consolidation. The ambulant treatment, according to von Bardeleben, is a distinct advance, provided careful supervision is given to the cases while it is in progress.

### ANOTHER CASE OF COCAINE POISONING.

SCHEDE[1] has reported at a recent meeting of the Hamburg Medical Society a case of cocaine poisoning by the injection of two grammes of a ten-per-cent.-solution of this drug into the urethra. Cyanosis, dilatation of the pupils, and deep coma supervened, followed by trismus and tetanus-like convulsions. Artificial respiration was begun, and the subcutaneous injection of ether and camphor, and the inhalation of nitrite of amyl did not affect the symptoms. After twenty-five minutes, Cheyne-Stokes respiration supervened, and the cyanosis increased. Venesection produced no improvement. The inhalation of oxygen and intravenous injection of 650 grammes of salt solution finally brought the patient round, the recovery being attended by transitory convulsions, and three hours elapsing before complete recovery of consciousness. The lesson of this rather severe experience is the same as that of the case noted in the JOURNAL of April 18th, in which death resulted from a urethral injection, of six grammes of a five-per-cent. solution, namely, to employ weaker solutions, and exercise greater care as to the amount employed, above all in urethral injections. Although the amount of the solution employed in this last case was not excessive, the strength was certainly unnecessarily great. A peculiar susceptibility to the effects of cocaine may

[1] Munchner med. Wochenschrift, May 7, 1895.

exist when least expected, and the knowledge that it may exist should keep us always on our guard in the use of this excellent but poisonous drug.

## Correspondence.

### END OF A VACCINE VIRUS CONTROVERSY.

BROOKLINE STATION, BOSTON, June 1, 1895.

MR. EDITOR: — Under other circumstances, I would dislike very much to call your readers' attention to a matter concerning which so much legal controversy has arisen: but as it is important that they should not be deceived regarding the question of the legal successor of Dr. Henry A. Martin & Son, I am obliged at this time, to respectfully ask you to allow me to dispel any doubts on this point by printing the following decree:

FULL BENCH, SUPREME COURT OF MASSACHUSETTS.

FRANCES C. MARTIN, *Administratrix of the Estate of Henry A. Martin, vs.* EVERETT M. BOWKER. HOLMES, *Judge.*

This is a bill seeking to enjoin the defendant from using the name of Henry A. Martin in connection with the business of producing and selling animal Vaccine Virus.

The only use of the name which the defendant has made or threatened to make is to describe himself as "Dr. Everett M. Bowker, Successor to Dr. Henry A. Martin & Son."

The plaintiff relies chiefly on P. S. C. 76, Sec. 6, forbidding any person to "assume or continue to use in his business the name of a person formerly connected with him in partnership, or the name of any other person," without written consent, but we are of the opinion that the statute does not apply to advertising oneself as "formerly with" or "successor to" another. The word "assume" in the statute means use for the first time in the same way that is contemplated in the other branch, "continue to use in his business." This latter plainly means to use as part or all of the partnership name so as to indicate that the person named is a member of the firm.

Apart from the statute the plaintiff shows no ground for an injunction. The defendant is a successor to Dr. Henry A. Martin & Son. The history of the business is this:

Originally it was carried on by Dr. Henry A. Martin, and afterwards by him and his son, Stephen C. Martin, under the name of Dr. Henry A. Martin & Son. In 1876 the father retired, and the son became sole owner of the business by purchase and carried it on under the same name until his own death in 1893. By his will he left it, including the good-will as well as the apparatus and other assets, to his wife, after a life estate which has lapsed. The wife sold it to the defendant, and so far as she had power, gave him the right to use the style and description complained of.

Taking the strictest view of what is necessary to make a successor, there is no doubt that the defendant is one, and thus being so, he has the right to advertise the fact to the world.

Bill dismissed, May 21st, 1895.

Any breach of the above decree will be vigorously prosecuted.

Very respectfully,
EVERETT M. BOWKER, M.D.

### METEOROLOGICAL RECORD,

For the week ending May 25th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | We'th'r.* | | Rainfall in inches. |

Deaths reported 1,501; under five years of age 438; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 165, acute lung diseases 203, consumption 201, diphtheria and croup 67, diarrheal diseases 18, measles 21, scarlet fever 16, whooping-cough 10, typhoid fever 24, cerebro-spinal meningitis 3, erysipelas, malarial fever, small-pox, each 2.

From diarrheal diseases Brooklyn and Nashville 4 each. Philadelphia and Boston 3 each. Washington, Worcester, Lowell, Cambridge 1 each. From scarlet fever Boston 8, Philadelphia and Brooklyn 2 each. Nashville, Worcester, Lynn and Woburn 1 each. From whooping-cough Philadelphia 5, Brooklyn 3, Providence and Lawrence 1 each. From cerebro-spinal meningitis Providence, Worcester and Somerville 1 each. From small-pox Philadelphia 2. From erysipelas Brooklyn and Providence 1 each. From malarial fever Brooklyn and Nashville 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530 for the week ending May 18th, the death-rate was 17.5. Deaths reported 3,569; acute diseases of the respiratory organs (London) 240, whooping-cough 85, measles 69, diphtheria 52, diarrhea 50, fever 27, scarlet fever 19, small-pox (Liverpool) 1.

The death-rates ranged from 12.3 in Croyden to 28.7 in Preston, Birmingham 16.9, Bradford 17.5, Cardiff 15.1, Gateshead 13.6, Hudderfield 19.9, Leeds 15.7, Leicester 15.3, Liverpool 23.2, London 16.5, Manchester 25.7, Newcastle-on-Tyne 18.6, Nottingham 16.1, Oldham 22.2, Portsmouth 14.0, Sheffield 15.2, Sunderland 15.9, West Ham 15.0.

### OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 1, 1895.

T. C. WALTON, medical inspector, ordered to examination preliminary to promotion as medical director.

G. S. BEARDSLEY, B. H. KIDDER and W. K. VAN REYPEN, medical directors, ordered as a board to examine medical officers for promotion.

N. L. BATES, medical director, J. M. FLINT, medical inspector and J. D. GATEWOOD, passed assistant surgeon, ordered as a board to revise the "Book of Instructions for Medical Officers."

## AMERICAN LARYNGOLOGICAL ASSOCIATION.

The Seventeenth Annual Congress will be held in the Chamber of Commerce, Rochester, N. Y., June 17, 18 and 19, 1895. The profession is cordially invited to attend.

MONDAY, JUNE 17th.

*Morning Session.*— President's Address, John O. Roe, M.D., Rochester. Foreign Bodies in the Esophagus, Harrison Allen, M.D. Desiccated Thyroids in Goitre, E. Fletcher Ingalls, M.D. The Influence of Chronic Diseases of the Throat upon Certain Defects of Speech, D. Bryson Delavan, M.D. Electrolysis by a Current Controller for the Reduction of Spurs of the Nasal Septum, W. E. Casselbury, M.D. Is Acute Tonsillitis in any way Dependent upon the Rheumatic Diathesis? Geo. B. Hope, M.D.

*Evening.*— President's Reception.

TUESDAY, JUNE 18th.

*Morning Session.*— Some Remarks on Removal of the Tonsils, and Case of Lipoma of the Larynx, J. W. Farlow, M.D. A Case of Melancholia cured by Intra-nasal Operation; and a Case of Suppurative Ethmoid Disease, followed by Invasion of the Sphenoidal Sinus, Abscess of the Brain and Death, F. H. Bosworth, M.D. A Consideration of Some of the More Important Principles of Intra-Nasal Surgery, W. K. Simpson, M.D. Ludwig's Angina, J. E. Newcomb, M.D. Discussion on Tuberculosis of the Upper Air-Passages: Etiology, Jonathan Wright, M.D.; Diagnosis, C. C. Rice, M.D.; Treatment, E. L. Shurley, M.D. and J. W. Gleitsmann, M.D.

*Evening.*— Annual Dinner of the Association at 7.30 P. M.

WEDNESDAY, JUNE 19th.

*Morning Session.*— Cyst of the Maxillary Sinus, Chas. H. Knight, M.D. A Case of Abscess of the Frontal, Ethmoidal and Maxillary Sinuses, J. H. Bryan, M.D. Necrosis of the Middle Turbinate, and Congenital Osseous Stenosis of the Naris, A. B. Thrasher, M.D. A Naso-Pharyngeal Cyst; an Oro-Pharyngeal Cyst; and Fibroma Papillare, or True Papilloma, of Nasal Septum, Jonathan Wright, M.D. Discussion on the Relation of Vasomotor Disturbances to Diseases of the Upper Air-Tract, by F. H. Bosworth, M.D., W. H. Daly, M.D., and J. N. Mackenzie, M.D.

CHAS. H. KNIGHT, M.D., *Secretary.*

147 W. 57th Street, New York.

## ONTARIO MEDICAL ASSOCIATION.

The Fifteenth Annual Meeting will be held in the Council Buildings, corner Richmond and Bay Streets, Toronto, on Wednesday and Thursday, June 5th and 6th, commencing at 10 A. M., on Wednesday.

PRESIDENT'S ADDRESS, R. W. Bruce Smith, Hamilton.

PAPERS BY GUESTS.— Intestinal Complications in Gynecic Surgery, J. B. Murphy, Chicago. Embryonic Remains in Cases of Eczema of the Navel, Robert T. Morris, New York. Operative Treatment for Bronchocele, Francis J. Shepherd, Montreal. Laryngeal and Tracheal Tuberculosis — The Importance of their Early Recognition and Treatment, F. W. Chappell, New York.

DISCUSSION IN MEDICINE.— Diphtheria, W. J. Wilson, Richmond Hill; followed by G. M. Aylsworth, Collingwood, and J. T. Fotheringham, Toronto.

DISCUSSION IN SURGERY.— Delayed Union in Fractures, Geo. A. Peters, Toronto; followed by I. H. Cameron, Toronto, and A. McKinnon, Guelph.

DISCUSSION IN THERAPEUTICS.— The Physiological and Therapeutic Action of Iron, with a discussion of its newer Pharmaceutical Compounds, H. A. McCallum, London; followed by J. H. Sangster, Port Perry, and A. T. Rice, Woodstock.

DISCUSSION IN OBSTETRICS.— The Primary Repair of Genital Lesions of Child-birth, K. N. Fenwick, Kingston; followed by H. Meek, London, and H. T. Machell, Toronto.

PAPERS.— The Present Position of Antitoxin in the Treatment of Diphtheria, Chas. Sheard, Toronto. Antitoxin in the Treatment of Diphtheria, with Clinical Notes of Cases, J. D. Edgar, Hamilton. Calomel Fumigation in the Treatment of Diphtheria, T. F. McMahon, Toronto. Phlegmasia Dolens, Report of Cases, J. Campbell, Seaforth. Constipation, H. Arnott, London. Treatment of Pulmonary Tuberculosis, D. Marr, Ridgetown. A Few Remarks on Home and Foreign Climate in Consumption, E. Playter, Ottawa. Science in Medicine, F. Oakley, Toronto. Hydrotherapy in the Treatment of Exanthematous Fevers, A. K. Sturgeon, Petrolia. Inflammations of the Optic Nerve, their Causes and Prognosis, G. S. Ryerson, Toronto. Cataract, R. A. Reeve, Toronto. A Case of Pneumo-Peritoneum, C. J. Hastings, Toronto. Puerperal Insanity, N. H. Beemer, Mimico. Narcotic Addiction, D. Lett, Guelph. Notes on Paresis, Ezra H. Stafford, Toronto. Use of the Stomach Tube, G. Hodge, London. A Case of Scurvy in a Child, H. T. Machell, Toronto. A Case of Progressive Unilateral Facial Atrophy, T. F. McMahon, Toronto. A Case of Morphœa, A. McPhedran, Toronto. Notes on an Epidemic of Herpetic Tonsillitis, J. R. Hamilton, Port Dover. The Antiseptic and Eliminative Treatment in Typhoid Fever, W. B. Thistle, Toronto. Traumatic Hysteria, D. C. Meyers, Toronto. Currents and Counter Currents in Therapeutics; or, a Plea for Rationalism in the Treatment of Disease, J. H. Sangster, Port Perry. Intelligent Use of Rectal Injections with Improvement of Ordinary Enema Syringe, P. P. Burrows, Lindsay. Some Remarks on Pneumonia, with Report of an Interesting Case, R. V. Bray, Chatham. Metallic Sutures in Fracture of the Patella, J. J. Cassidy, Toronto. Cases of Post-Pharyngeal Abscess, Double Cephalhematoma, Leucoma, Colitis, etc., G. Acheson, Galt. Traumatic Septicemia, J. C. Mitchell, Enniskillen. An Operative Procedure for Spina Bifida, H. Howitt, Guelph. Intestinal Anastomosis, with Murphy's Button, J. L. Davison and L. Teskey, Toronto. A Case of Anterior Abdominal Nephrectomy for Calculus, with Patient, L. MacFarlane, Toronto. An Operation for Hair-Lip, A. Groves, Fergus. A Case of Ectopic Gestation, and a Case of Mental Aberration following Removal of an Ovarian Cyst, W. J. Gibson, Belleville. Tumors of the Bladder; Report of Cases, F. LeM. Grasett, Toronto. Seminal Vesiculitis, E. E. King, Toronto. Foreign Bodies in the Knee-Joint, G. Bingham, Toronto. Modern Experimental Surgery on Man and Woman; A Criticism of Operations done and the Results obtained, J. F. W. Ross, Toronto. The Use of Ichthyol in Gynecology, L. Sweetnam, Toronto. Use of the Projection Microscope in the Teaching of Anatomy, A. Primrose, Toronto. Display of Bacteria, J. Caven and F. N. Starr, Toronto. Notes on Carcinoma, H. B. Anderson, Toronto.

A luncheon at the New Yacht Club (City), will be tendered by the City members of the Association, to all members present at this meeting, on Thursday, June 6th, at 1 P. M. A yacht trip will follow the luncheon.

JNO. N. E. BROWN, Toronto, *General Secretary.*

## SOCIETY NOTICE.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.— The Annual Meeting of the Society will be held on Tuesday, June 11, 1895, at 11 o'clock, A. M., in the hall at 19 Boylston Place, Boston.

The usual business of the Annual Meeting will be transacted, and the following communications will be presented:

"The Anatomical Evidences of Death by Drowning," by G. DeN. Hough, M.D., of New Bedford.

"A Case of Criminal Abortion with Peculiar Features," by W. S. Birge, M.D., of Provincetown.

F. W. DRAPER, *Recording Secretary.*

## RECENT DEATHS.

SIR GEORGE BUCHANAN, M.D., F.R.S., late principal medical officer of the Local Government Board of Great Britain, and Chairman of the Royal Commission on Tuberculosis, died on May 5th. He had been in failing health for some time, and had postponed submitting to an urgent operation in order to finish the report of the Royal Commission on Tuberculosis. He was operated as soon as possible after the report was issued, but died on the eighth day. His courage and devotion to duty could hardly be shown in a more striking way than by the manner of his death.

ARTHUR E. DURHAM, F.R.C.S., consulting surgeon to Guy's Hospital, died May 7th.

## BOOKS AND PAMPHLETS RECEIVED.

Some Observations Concerning a New Test for the Detection and Quantitative Estimation of Free Hydrochloric Acid in the Gastric Juice. By Julius Friedenwald, A.B., M.D., Baltimore, Md. Reprint. 1895.

The Prevention and Treatment of Ophthalmia Neonatorium, and the Necessity for More Efficient Legislation to Prevent Blindness from this Cause. By Charles H. May, M.D., New York. Reprint. 1895.

Abstract from the Second Annual Report of the Dairy and Food Commissioner of Pennsylvania, Report of Analytic Work. By Henry Leffmann, A.M., M.D., Chemist to Dairy and Food Commissioner of Pennsylvania.

The Pre-tubercular and Pre-bacillary Stages of Consumption. A Consideration of the Early Diagnostic Signs of Pulmonary Tuberculosis — A Plea for the Recognition of Premonitory Symptoms. By Charles Manley, A.M., M.D. 1894.

Typhoid Ulcer: Perforation (?), Operation, Death. Cerebral Cyst: Operation, Recovery. Direct Fixation in Fractures. Dislocation and Double Fracture of the Upper Third of the Humerus. By B. Merrill Rickets, M.D., Cincinnati, O. Reprint. 1894-5.

Amputation of the Entire Upper Extremity (including the Clavicle and Scapula) for Sarcoma following Fracture of the Clavicle, Extensive Thoracoplasty by Shede's Method. Amputation of the Female Breast. By H. W. Keen, M.D., LL.D., Phila. 1894-95.

## Address.

### THE PHYSICIAN'S EXTRA-PROFESSIONAL DUTIES.[1]

BY ALFRED WORCESTER, A.M., M.D., WALTHAM, MASS.

On this one day of the year when we leave our patients to the restorative care of Nature, now so beautiful and bountiful, it seems not unfitting that we should ourselves turn from strictly professional themes towards our other interests.

And I am the more inclined to this course by my inability to present any deductions from my own experience in general practice which would be worthy of this occasion. Let us then give this hour to the consideration of our extra-professional duties.

However right it may be under other governments for professional men to devote themselves exclusively to their professions, under our form of government such seclusion is not justifiable. I need not speak of the common duties of citizenship that we share with the laity, for such political duties however much neglected, can hardly escape recognition.

But I call your attention rather to those duties of citizenship belonging particularly to us as physicians, and yet not sufficiently recognized.

As our civilization becomes more complex the different duties of citizenship become less plain but not the less binding. In earlier and simpler stages of social growth these different duties are very plain. Thus, in colonial life, where the common welfare depends upon every man's doing each his part, there can be no question as to the respective public duties of the carpenter, the lawyer and the physician.

In the struggling out-posts of civilization it is not allowable for any one to shirk his share of public work; nor can any waste of power be afforded. Accordingly the carpenter is expected to direct the building of the stockade, and the lawyer must give part of his time to the shaping of the public statutes.

Nor can there be any doubt as regards the nature of the physician's public duties. Plainly he must give to the community the benefit of his special knowledge in matters of public hygiene, and he must also take professional care of all who are dependent upon public support.

This, in the present age, means that the physician must give his best advice about the water-supply and about the disposal of sewage and garbage; that he must also give attention to the educational interests of the colony — not only guarding the healthfulness of the school-children but seeing that some of them are being fitted to be his assistants and successors; and even more plainly it means that he must lead the fight against all contagion and infection, and that he must plan a hospital and devote himself to its management.

As the community, which we are now imagining, grows larger, and as many physicians follow the footsteps of the individual pioneers, these special duties of citizenship do not rest upon all the members of the profession at one and the same time, but may very properly be borne in turn. And further on in the growth of the community these extra-professional duties may be specialized and thus divided among the increasing number of physicians.

Still later in the process of development only a few of the whole number of the physicians may be needed in the public service, and then there naturally results a loss of individual responsibility for any share of the public duties that rest upon the profession as a whole.

But there can never come a time in the advance of a republic when any profession can be released from the obligation of public service. Most especially is this true of our profession.

Nor is it only a public loss when the medical profession fails in giving to the public service its due measure of devotion. For, in the charitable judgment of the people, if physicians do nothing for the State, then presumably it is not from their neglect but from their general inability and inefficiency outside of their special province. There thus results to the profession as a whole a distinct loss of influence and of usefulness.

How fitting then it is, on this occasion when we meet together for renewed inspiration in our life work, that we should consider these extra-professional duties. Let us at least look them in the face. And let us see in what ways existing conditions might be improved by a larger devotion on the part of physicians to the public service.

Bearing in mind that the physician's public duty comprises those functions of government for which his education and experience have especially fitted him, and which cannot so well be performed by the laity, we find these functions dividing naturally into three classes:

I. The direction of educational processes, so far as the physical welfare of the public scholars is concerned, and also so far as special education is carried into any part of the wide domains of our profession.

II. The care of the physical well being of all, either temporary or permanent wards of the town or State.

III. The legislation and the administration necessary in eliminating all infectious and contagious diseases.

I. The schools of Massachusetts in the past have very justly been the pride of the State. From the earliest days when the feeble Bay Colony gave so freely of its scanty store to the founding of Harvard College "in yon dim unventured wood," no expense has been spared to increase the efficiency of the public schools. And yet from our point of view is their present condition what it should be?

Is it creditable at this late day that school-children should be promoted from class to class without regard to their physical, but solely according to their mental accomplishments?

After such efforts as have been spent in perfecting the system that produces uniform mediocrity out of natural diversity, is it not high time for more attention to the easier problem of giving fairly well shaped bodies to the boys and girls who so soon will be the men and women upon whom our race depends. At least, is it not time for precautions against the actual damage of the scholars' bodies while their minds are being improved?

Shall tuberculous children continue to be huddled together with the healthy in improperly ventilated school-rooms, and shall the regular increase of diphtheria and of scarlet fever, that now comes with each school-year, continue to rob the State of her boys and girls? Surely it is possible to prevent the attendance of desquamating children and to separate the tuberculous scholars from the healthy. At least, the school-

[1] The Annual Discourse before the Massachusetts Medical Society delivered at the One Hundredth and Fourteenth Anniversary, June 12, 1895.

rooms could be kept scrupulously clean; the misnamed "sanitaries" could be made decent; and the dangerous modern custom of giving the old, soiled school-books to the new comers could be rescinded.

If the question be asked why such reforms are not at once inaugurated, the answer is easy. The school authorities do not understand the importance of taking such radical steps as would be necessary.

It must be remembered that we are descended, and not so very remotely, from ancestors who were not afraid of dirt. Cleanliness, though long held to be next to godliness, has not been considered pre essential. Nor has dirtiness been thought incompatible with finest scholarship. The love of cleanliness is an acquired taste not yet possessed by all of our race. And school-teachers who themselves hate dirt, hesitate to interfere with the independence of families who appear to hate bodily cleanliness. And, again, if the teachers should dare to insist upon having clean scholars, they have at hand no facilities for carrying out the reform.

School-books are freely given, out of the public purse, upon the subjects of physiology and hygiene, but soap and towels and bath-tubs are not provided. How can hygienic principles be inculcated where their application is impossible?

Such provision may not as yet be demanded by public opinion; nor is the half of what at present is taught in the schools so demanded. But were the people and their school-committees alive to the dangers that lurk in the dirt and in the noisome air of the school-rooms, there would soon be a national house-cleaning of the schools.

Now, physicians know, as others do not know, that dirt is dangerous, and that foul air is even more to be feared. They also know that many of our endemic infectious diseases are propagated in the public schools. Physicians are therefore in duty bound to work for the remedying of these evils.

Moreover, physicians are especially able to foresee the advantages that would result from greater attention to the physical growth and well-being of the school-children. Surely it need not be that the graduates of one school in this great country will always be distinguished from others by their splendid carriage. Each High School in Massachusetts could give at least this much of a West Point training. Not by the scanty, spiritless teaching of gymnastics, nor by the perverted sports of the present age, but by a reasonable share of the time and attention now given to far less valuable training, the public schools could certainly improve the bodies as well as the minds of our children.

For the inauguration of such a reform physicians are the natural leaders. True, such leadership is likely to carry the physician into local politics, where the scholar is not always welcome, but where least welcome the most needed. After thorough acquaintance with the actual condition of the schools in his district, and with the best conditions elsewhere, it is the physician's duty to persuade the school-committee, if possible, of the necessity of improving the hygiene of the schools. This failing, then he must reform the school-committee; and this means that he himself must be willing to serve on that committee, caring neither for any threatened unpopularity at the polls nor for any hostile criticism of his best endeavors. His efforts may not at first avail. Much that is disagreeable is likely to be encountered. Public service is generally thankless; and it is to no easy enjoyment that the high duty of citizenship invites us. Nevertheless, the obstacles to reform are not so mountainous as at first they appear. The people, however much they may indulge in grumbling and in cheap newspaper abuse, are yet not slow to follow good leadership. Parents who at first object to innovations that affect their children and their purses are, nevertheless, quick to recognize real improvements. Moreover, the times are fast ripening for thorough reforms in the public-school system. Parents are learning the dangers of infection. When the school-bell rings for their children, they hesitate as never before to let them go. And if the medical profession could be prevailed upon to devote especial attention to the healthfulness of the schools, there would be general rejoicing.

Before leaving this subject we should note the fact that teaching is one of the obligations resting upon all professional men. Galen's famous oath requires every physician to impart his knowledge to the generation following. And although the medical student of to-day has no preceptor, and although the *science* of medicine is so splendidly taught in the great school close by, yet we must not forget the obligation resting upon us to pass on to others, in the measure we have ourselves received, the art of healing.

True, it may nowadays be somewhat awkward for the old physician to find room in the young graduate's head for any hints as to the treatment of patients. But, on the other hand, if our elder brothers, instead of combating the germ theory, would only teach us what they have learned about patients in life-long practice, if they would teach us what they have learned of comfort's art, then we should be nearer our professional millenium.

It is not, however, only to medical students and to younger physicians that we are under bonds. To the laity we are even more bounden to teach the healing art, so far as we can, to all who are willing to learn it.

We hear nowadays of political campaigns of education directed against financial heresies. Of far greater use would be common-sense crusades against the ignorance and superstition that now so flagrantly defy physiological laws.

In earlier times, when everybody knew all about everybody else, the village doctor was also in truest sense a teacher of his art, for then his precepts as to the care of the sick were widely known. Bedside watching was in vogue, and the physician's minute directions were faithfully followed by the kind neighborly nurses and treasured by them for subsequent use.

Such times are gone by. The art of nursing is no longer a matter of inheritance or of tradition. In place of the neighbors we have nurses now who have devoted their lives to this work. They take the place of the physician's private students, who formerly in return for their instruction gave great assistance. In the same way these modern nurses look to the medical profession for instruction. And every physician, both for his own interest and for his patients', ought to do something towards their training. Even in the smaller towns this great work should be undertaken. Otherwise only the rich patients can be properly cared for, whereas under the former *régime* the sick poor fared as well as the rich. This is a matter for most serious consideration. The most effective opposition

to socialism and anarchy can be made by removing every such injustice. Rank and fortune ought not to flourish where love and charity for the sick neighbor die out.

I beg you to think of this. Call to mind your poorer patients who suffer for nursing which is now entirely beyond their reach. Think also of the many young women who would gladly and gratuitously do this nursing under your instruction, if only you would undertake their training. And then remember that fine old saying, *Noblesse oblige*, or, superior advantages bind to larger liberality.

A very mistaken idea has become current that nurses can be properly taught only in the large hospitals. Of course, it is quite true that nurses *for* hospitals must be trained in hospitals. But for private nurses such training is not by any means sufficient. The new profession of nursing did not originate in large hospitals nor in great cities. And in the original schools, hospital work is still only one of the many departments in which the nurses are trained.

The best nursing service in any community can be secured only by the efforts of the physicians in practice there. In the smallest towns, where as yet a training-school is not feasible, great advantages can nevertheless be obtained by the co-operation of the local physicians with the nearest nurses' school. Such affiliations are happily fast multiplying throughout the State. And even greater blessings will result as physicians more generally recognize their obligations as teachers of nurses.

II. In founding and in carrying on hospitals it would naturally be thought that physicians would be the leaders.

Within the last few years, as you well know, there has been a great increase in the number of hospitals in this country. And even in many of the smaller towns hospitals are now being projected. As the greater efficiency and safety of hospital treatment become more widely known, and as the many advantages of cottage hospitals become apparent, Christian charity more and more readily manifests itself in this form. The old time neighborliness and kindness is not lost, but in the hospital has become organized and centralized.

Physicians know best these and other great advantages; they know how rapidly modern surgery advances where hospital facilities exist; they know how effective isolation wards are in fighting epidemics; and they know best the blessings that the hospital affords for the otherwise homeless sick and injured.

And physicians also know best the requirements that must be fulfilled in the erection and in the management of the hospitals best suited for their different localities. Why is it then that the new hospital movement in Massachusetts is not everywhere being guided by the Fellows of this Society? True, in some places such is the case, but in many other places the hospital movement encounters either the opposition or the apathy of the medical profession. Too often it happens that the physicians whose co-operation is sought, unless given dictatorial power, sulk in their tents. This comes from not being accustomed to public service, or from ignorance of American institutions. Dictators do not flourish here. And the people, who are the rulers, can be persuaded but not driven. If the first physicians are not willing to work with the hospital leaders, then they can meekly work for them or let others do so after the hospital is in running order. This they do in some of our cities. And in natural consequence we find one of the newest hospitals built without an operating-room, because, forsooth, the need of it was not suggested to the building committee. In several other hospitals the Fellows of this Society accept appointments on "mixed" or "double" staffs, where the different schools of practice are said to be represented, and where the rules and regulations for their guidance are drawn by lay managers. This they do "for the sake of harmony," and because of their conviction that except for such compliance on their part there would be either no hospitals or only homeopathic hospitals possible in these communities. But do they not thus overlook the fact that this compliance on their part formally recognizes and so perpetuates the false distinctions which we all so devoutly wish to have obliterated.

The roots of this modern difficulty lie buried in the indifference of physicians as regards their extra-professional duties. After hospitals have been inaugurated without the encouragement and guidance of those best fitted to guide such undertakings, then it may be necessary to accept the dictation of those who know no reason why patients at the hospital door should not be asked if they prefer homeopathic or allopathic treatment. But where the Fellows of this Society assume their rightful position in the community, where they show their hearty willingness to do their full share of public work, such awkward predicaments do not arise. In such places there is no necessity for accepting distinctions and designations that ought not to exist, but instead there is grand opportunity for demonstrating that perfect liberality which should be our greatest pride and glory.

Of far more importance, however, than any question of medical ethics is the duty of the physician as a public-spirited citizen to see that proper care is given to those for whose care the community is responsible. Not only in the hospitals, but even more in the asylums and in the almshouses a constant watchfulness is needed to ensure for the unfortunate the best care that a constantly increasing enlightenment makes due to them. Nor can such oversight be relegated solely to officials, who indeed are the least able to secure even the reforms that they desire. In the almshouse infirmaries of England the sick and dying paupers have long had the best nursing that the kingdom can supply. Why should not the aged and the impoverished of Massachusetts in their sufferings and in their last hours on earth have like blessings?

The people, if fully informed, would not let their enfeebled neighbors in the almshouse suffer for lack of improved methods of treatment or for lack of proper appliances for their relief and comfort. Nor would the people, if they knew it, allow delicate orphans to be educated by the harmlessly-insane paupers. Again, if the people heard the sorrowful tales told to the officials in the outside poor departments of our cities — if the woes due only to sickness among the poor were generally known in the community — then there would be far less misery. But in our crowded, hurried life those who can give help and would willingly give it, do not actually see the needs. The physician is in the best possible position to bring into relationship the helpers and the helpless. Difficult as is the great question of alms-giving, in cases of physical helplessness there can be no question. Suffering obliterates

all social distinctions. As regards the able-bodied paupers, let the professional scientific philanthropists have their way; but for the sick and the dying, for the maimed and the feeble-minded, let us follow the prompting of our hearts! Of course, there is here great need of good leadership. At the outset there is need of professional skill in discovering the extent of the physical suffering and helplessness, and in pointing out the proper measures for relief. It is the physician's public duty also to strive for the execution of these needed measures. He must follow the footsteps of Dorothy Dix. Her work was that of a true physician who recognizes his extra-professional duties.

III. The greatest advance ever made in medical science has been made during this last third of the century in making possible the prevention of many of our most dreaded diseases. Indeed, it may almost be thought that sanitation is a new science quite distinct from the science of medicine. But in reality there is no such separation, and the prevention of diseases will always be only a special department of our profession. The apparent separation is owing mainly to the fact that the sciences of organic chemistry and of bacteriology, which are the foundations of hygienic science, are younger than the leaders of the medical profession. Comparatively few physicians have had opportunity for such studies, and in consequence the profession as a whole has not grasped the glorious opportunities which the microscopes have already revealed. Even where attempts have been made to realize these advantages, disappointments have often resulted. Surgeons have clutched at the shadows of great principles. Too often they have trusted to antiseptics regardless of the essentials of asepsis, the new-found goddess of hygiene.

After such wondrous revelations as to the causation of diseases it might perhaps be expected that a whole generation of physicians must go and come before the full advantages of these great discoveries can be realized. But it need not be so long.

There is no sense in the separation that exists today between the physicians in active practice and their brothers in the laboratories. Theory and practice must always go hand in hand if either is to be of greatest use. The bacteriologist, if he gives not half his heart to the widest clinical application of his knowledge, will lose his highest inspiration. And the busy practitioner who aspires to the highest fulfilment of his mission must now keep in touch with the searchers in the dimly-lighted world of germs.

The common meeting-ground for bacteriologists and for physicians and surgeons can be found in hospital work and also in the work of health boards. Fellows of this Society should never forget that Massachusetts owes her pre-eminence in public sanitation to the efforts of our former Fellow, the late Dr. George Derby, who organized our State Board of Health — the first in this country, if not in the world. I need not remind you of the great work now being done by this board under the guidance of its distinguished chairman and untiring secretary. But I ask you if the local health boards in our cities and towns deserve corresponding credit. The answer is shameful. The trouble is, that the men best fitted to operate this splendid machinery have not given to the Commonwealth that devotion she has the right to expect from all her sons. No grander opportunity has ever been offered to the medical profession than this of directing the work of public sanitation. Health boards have been authorized by the State in every city and town.[2] To these boards the State has granted almost dictatorial power, and yet in more than one-third of our towns no health boards have been formed. One of these derelict towns has over 10,000 population. Although many of them are small, that is no excuse for sanitary obtuseness. Where the community has been properly taught the importance of public sanitary work, such work has been cheerfully supported. And yet, in spite of the provision that in the larger towns one member of the health board shall be a physician, so negligent have we become of our extra-professional duties, that in many towns it has been almost impossible to persuade any physician to serve on the board of health, and in many other towns only second-rate men undertake such service. The best physicians say they have not the time, or they shun the notoriety and the possible unpopularity. As a necessary result the local health board too often lacks the confidence of the public and the co-operation of the medical profession.

Already, however, there are signs of improvement. Within the last few years the local health boards have formed a State Association for mutual improvement; and during the past year there has been a distinct advance in the co-operation of the bacteriologists and practising physicians. For this we are in part indebted to the City Physician of Boston, Dr. J. H. McCollom, who for many months generously gave his services to the physicians of this vicinity in determining for them the presence or absence of the diphtheria bacillus in suspected throats. Already in several other cities similar work has been undertaken. But is it not discreditable that this investigation of diphtheria is not being carried on in every city and town? Surely the health board in every community ought to provide for such work. Then might this modern curse of diphtheria be fought to some purpose. If not exterminated, at least it might be "in straiter limits bound."

Leprosy and small-pox have been conquered; and, as a crowning triumph of sanitation, the last invasion of Asiatic cholera was repelled from our shores. Why should we not also drive out every infectious and contagious disease? At least, the complete disinfection of materials — dwellings, furniture and clothing — is possible and practicable. In other countries disinfecting stations are so well arranged that a private house or a school-house or a factory can be promptly and thoroughly disinfected. This is done for the good of the public and, of course, at the public expense. Why should this not be done in Massachusetts? Why should we longer allow the public to be fooled with the useless fumes of sulphur?

Ever since the pilgrims, perhaps in consequence of their previous close confinement on shipboard, succumbed in such frightful numbers to the "white pestilence," pulmonary tuberculosis has maintained in New England its deadly pre-eminence.

Until Koch's discovery of the bacillus of the disease settled all questions of diagnosis, the physician might have been excused for sharing with his patients at first that feverish hopefulness so characteristic of the early stages, and afterwards the absolute hopelessness that so long precedes the end. But now there is no excuse for such professional helplessness — at least the disease must be recognized. In the early stages there is undoubted opportunity for cure. In the middle stages

[2] Chapters 218 and 473, Acts of 1894.

there is still a fair chance. And in all stages of the disease there is the absolute necessity of preventing the infection of others.

The modern treatment of tuberculosis and of diphtheria, as well as the recognition of these diseases in their earliest stages, depends largely upon bacteriological work which very few physicians have time and facilities for doing. One central laboratory, however, can easily serve a great many practitioners. And such laboratories should be organized, so that these modern weapons against infection may be freely placed in the hands of every physician in the State. This is the proper work of the boards of health. But how can such work be done except under the direction of the highest medical intelligence? No better illustration could be offered of the importance of our extra-professional obligations.

Massachusetts has taken another of her great forward steps in exterminating tuberculosis from our herds of cattle. No longer is it unavoidable that the seeds of this disease shall be given to our children in their daily food. Would that we also kept the germs out of the air that they must breathe!

True, it is a gigantic task that confronts us. Patients already infected with tuberculosis cannot be segregated as lepers are, and yet much might be done both for their relief and for the greater safety of others. Hospitals for diseases of the throat and chest might be established in our pine woods, in imitation of Sharon, and in our hill townships as well. Such sanitariums, properly equipped and properly managed, would effect the cure of thousands now doomed to die for lack of salubrious surroundings and modern treatment. To other thousands, already far advanced consumptives, such hospitals would give every possible chance, and at any rate give great comfort and relief; and at the same time, by bringing such patients under intelligent superintendence, much would be accomplished in preventing the further spread of the disease. Such measures, it is true, would entail a great outlay of public money. But the investment would bring most blessed returns. By affording every possible comfort to the hopelessly sick, and by giving to those who cannot afford either a change of climate or expert professional attention, the best hygienic surroundings and the recently greatly improved medical treatment, the State would have the moral right to require the stricter quarantine that is so important.

Tuberculous and healthy children should not be allowed to attend the same schools. For the tuberculous even better schools should be provided, and might well be afforded by any community where the safety of the young is properly valued. Tuberculous operatives should not be allowed at the same benches nor in the same crowded rooms with others. In any shop or factory it would be wise economy for both proprietors and employés to arrange for this separation even by pensioning the afflicted.

But the separation necessary to prevent the spread of tuberculosis among school-children and operatives is only a small part of what sooner or later must be undertaken in every enlightened community. It is even more necessary to educate every tuberculous patient to such personal habits as will prevent repeated auto-infection, and at the same time ensure the safety of other members of the family and of the public.

That our foe is so mighty, so insidious and so firmly intrenched, ought to make us all the more eager to begin the fight. We must look out, too, that we stand shoulder to shoulder. Individual efforts will count for nothing. Even a single city or town could do little more than to set the example.

Plainly the lead must be taken by the health boards of the State, working in unison. This co-operation can be secured only by a greater devotion of the physicians in the public service. It is in this sort of extra-professional work — in stimulating the health boards to united, vigorous action — that physicians now have grand opportunity for usefulness.

We have now briefly considered three departments of public service where the knowledge and experience of physicians is greatly needed, in order to provide for all our people the advantages that now separately may be had here and there in other countries.

Under monarchical governments we might petition the king and his councillors for these reforms. But in a republic, reforms originate not in professional petitions, but in popular demands. The people are willing to be persuaded, and must be persuaded before they undertake reforms. Direct responsibility, therefore, rests upon those who alone are able to lead such movements.

In the evolution of this country we have not yet attained the condition of a perfectly representative government. And it is only in the higher development of this grand policy that our national hopes safely rest. Geographical sections may be represented, and voting districts may already be numerically equal, even political parties may be justly represented, but real representative government requires also that each class and profession and trade shall be represented. Such government, so far as our profession is concerned, can easily be obtained by concerted action. And one of the functions of the District Societies, and especially of the local circles of Fellows ought to be the nominating of our representatives for public service in those departments where the help of our profession is needed. Such nominations would have the binding force that honor always imposes. And the physician's public service would be far easier if undertaken at the request of his professional brethren.

But it is not enough that we strive merely to secure the election of our professional representatives. It is even more important that we shall take a greater interest in the public work. One of the sections of our annual meeting might very profitably be devoted to sanitary science. Public measures that especially concern the medical profession should be discussed; and our opinions as physicians should be made known at the proper times, that is, in the formative stages of legislation when such opinions may be of some use. There would then be less ground for pessimistic criticism of school and hospital and health boards.

The three great needs are, first, an individual recognition of our responsibilities for extra-professional or public service; second, concerted effort to secure proper professional representation in the government; and, third, a continued interest in the public service of our Fellows for their encouragement and support.

It may not be uninstructive for us to look at the amount of public service now being done by the nearly two thousand Fellows of this Society, who are practising medicine in two hundred and forty of the cities and towns of Massachusetts. Twenty-five are serving on school-committees, and twenty-five others are serving on health boards.

In pointing out our present failures in these respects, I should not be forgiven if I did not make honorable exceptions. I see before me many of our older Fellows who in previous years have nobly earned exemption from further public service. It was their privilege to serve our country in the dark days of her sorest need. They gave freely of their youth and of their prime. No words of ours, at least in their presence, can fittingly express our joy and pride in having these heroes in our ranks. May they long enjoy our love and honor and gratitude!

And there were others, the comrades of our living heroes, who returned not from the battle-fields, but who there gave to our country the last full measure of devotion. At this memorial season it is especially fitting that we should hold them in remembrance. Nor could any anniversary of this Society be complete without their commemoration. Their lot it was to die in the midst of the nation's travail. For them there was no rejoicing over the new birth of perfect freedom, and over the restoration of the Union. But, like Dr. Warren, whose life-blood shed on yonder hill still quickens the pulses of patriotism, so these brave war surgeons, whose bones lie in the Wilderness, on the hills of Gettysburg, or in the swamps of the Chickahominy, have bequeathed to us the priceless blessing of noble examples.

Shall we prove ourselves worthy of our inheritance? In times of peace and prosperity shall we begrudge giving some small portion of our time to the public service in which they gave up their lives? Rather, as we return to our routine responsibilities, shall we not also willingly assume our extra-professional obligations?

I plead in behalf of anxious parents, who would give their all to ensure the health of their children, but who do not know as you know, in what ways this might be done. I plead in behalf of the distressed, for whom the public would gladly do more if only the way were pointed out. And, finally, I plead in behalf of generations yet unborn, that this dear land of ours shall be more jealously preserved from contamination, in order that the Commonwealth of Massachusetts for the coming ages may be the healthful home of succeeding generations.

God grant that it may be so!

### AN EXAMINATION OF SOME RECENT STATISTICS IN REGARD TO ETHER, AND A CONSIDERATION OF SOME PRESENT METHODS OF ITS ADMINISTRATION.[1]

BY JOHN B. BLAKE, M.D.,
*Surgeon to Out-Patients, Boston City Hospital; Physician to Genito-Urinary Department, Boston Dispensary.*

(Concluded from No. 23, p. 562.)

CONSIDERING briefly some of the present methods of giving ether, let us first discuss the general principles underlying etherization. That life may continue, a certain amount of oxygen is necessary, and it is also necessary that carbonic droxide, $CO_2$, should not be present except in small quantities. If there be either too little oxygen, or too much $CO_2$, or both of these conditions simultaneously, the patient will become asphyxiated, and if subjected to such influences long enough, will die. Therefore, it must not be forgotten that any method of etherization is bad which favors the development of the above-mentioned conditions, and is good in just so far as it avoids them, other things being equal. This seems so self-evident as to make its repetition almost absurd; but an examination of some of the well-known ether-inhalers would indicate that if it had not been forgotten, at least it had not been suitably provided for in mechanical construction of these instruments. To produce anesthesia, it is necessary to introduce into the system a certain amount of the vapor of ether (or chloroform); and to combine this with a sufficient quantity of oxygen, and the removal of $CO_2$, is the essential problem underlying all anesthesia.

The absolutely essential characteristic of any ether-inhaler is, therefore, to present to the patient sufficient ether and sufficient oxygen, and to permit the $CO_2$ to escape. To these characteristics, an ideal inhaler would add cleanliness, lightness, simplicity, adaptability, a minimum amount of ether wasted externally to the patient, and so far as may be, a removal of the unpleasant irritation of the ether vapor itself.

The various mechanical arrangements for giving ether may be roughly divided into three classes: (1) the cones, (2) the mask, and (3) the inhaler proper. In this classification the sponge is included among the cones, though it does not properly belong there, for in reality it forms a little class by itself, not only in its action, but in its use. It might be considered a cone without sides. All three of these classes have, of course, a common object in view, and that is the presentation of ether vapor to the patient in a safe and acceptable manner. And if we may judge, as we are told, of the degree of resistance of a disease to drugs, by the number of remedies suggested for it, so may we argue from the number of mechanical contrivances which are described for the administration of ether and offered for sale, how far we still remain from an ideal ether-inhaler. And though one naturally shrinks from offering another machine to increase the already too great number which exist, still it is pardonable to endeavor to grasp firmly the essential principals of etherization, and then to suggest some of the necessary characteristics of that wonderful instrument of the happy future, the ideal ether-inhaler. But before consulting the future, let us consider the past and present.

Considering first, the sponge, it is perfectly obvious that with a good ether sponge there is ample opportunity for a sufficient supply of oxygen, and for the dissipation of the undesirable $CO_2$. In this respect, the sponge is perhaps the best known method of giving ether; at all events, there is no other inhaler with which the writer is familiar, that excels it in this regard. The objections to the sponge are mainly the large amount of ether required, and the complete saturation of all the assistants; the liability of vomiting into the sponge, in which case it is extremely difficult to clean; and the fact that many patients dislike to use a sponge with which others have previously been etherized. It is unquestionably true that with a sponge more time is consumed in producing anesthesia, and for obvious reasons. That the sponge hardens and tends to freeze, as is said to be the case in the Ormsby inhaler (Buxton), has not been observed in Boston; and there are no other considerable objec-

[1] Being one of two papers receiving the second Lyman Prize for 1894

tions that the writer has found. All these are unquestionably valid, as they are unquestionably secondary in importance to the fact that with the sponge the patient is etherized and not asphyxiated; and the fact which seems to be unquestionable, that there has never been a death directly traceable to ether in the Massachusetts General Hospital, where the sponge is used to the practical exclusion of all other methods, must make us a little cautious in moving too lightly to other and more complicated inhalers.

The cone, which is essentially a sponge or a spongy substance, enclosed in more or less impermeable walls, comes next under consideration. The essential principle upon which it rests is, that when placed upon the patient's face, all the air which enters his lungs shall first pass through an ether-bearing medium, and, conversely, that no air which has not passed through such a medium, shall enter his lungs. For this reason, the cone should not be placed directly over the face at the first inspiration, but held at a little distance until the trachea and bronchi have become accustomed to the ether vapor. In the cone, it is absolutely essential that the ether-bearing medium shall be so arranged as to allow complete and easy respiration, and that all the air necessary shall pass easily through it. The towel cone more nearly approaches the sponge in character, since air passes through its sides as well as through the apex. The various modifications of the towel cone — the paper cone, rubber cone or metal cone — all aim to possess qualities more or less desirable. A good cone, for one who really wants a cone and not a sponge, should fit snugly and comfortably over the mouth and nose, should be easily cleaned, light and strong, so arranged that it may be rapidly made ready for etherization, and when so made ready, should be perfectly comfortable to the patient when breathing deeply; in other words, should offer no obstacle to a forced deep inspiration. Such a cone combines the desirable qualities of the sponge with other desirable qualities which the sponge does not possess. It is perfectly safe; it does not waste much ether; it is not in any way objectionable to the patient, and it may be fed with ether without removing it from the face.

The ether masks are seldom seen in this country. In Switzerland and Germany and France, however, they are extensively used. Perhaps the best known is that of Juillard of Geneva, and its modifications by Dumont and Ritsche. In the excellent article on ether narcosis by Garre, a detailed description, and pictures are given both of the Juillard mask and of the Dumont modification, while the Ritsche modification is described and pictured in his own article below referred to. A metal or wire basket, large enough to cover the entire face, is covered with oiled silk, and at its vertex contains a tuft of flannel upon which the ether is poured. The mask is then held down on the face, and, as a rule, in much less than half a minute, pressed down so as to exclude the external air as much as possible, surrounding the edge of the mask with a towel, and the struggling patient is restrained by assistants. The mask is removed as seldom as may be to pour on more ether. Slight modifications of the above exist in both directions. In Lyons, a longer time is taken in making the patient accustomed to the fumes, before tightly covering the face. In the second method, a large quantity of ether is poured on at first, and "after a few breaths," the mask is pressed down on the face. The author naïvely adds that "the patient believes that the concentrated ether vapor will suffocate him, and fights for a short time very energetically, but soon loses consciousness." He adds, that if the mask is not removed, a long narcosis may be obtained, the expired ether being again inspired, without producing any signs of a $CO_2$ asphyxia. Since this was the apparatus employed and the rules followed by Miculicz, it is possible that American surgeons may not wonder so much as they otherwise might, that he has abandoned ether for chloroform.

The modifications of Juillard's mask do not vary its workings. That of Dumont is merely to employ a second wire basket within the first, and between the two to place the ether-bearing medium. This at once ensures greater cleanliness and offers a larger surface for the evaporation of the ether. The Ritsche modification is to make the mask with metal sides into which glass windows are placed on the sides. The objections to this mask are very obvious; in all except Ritsche's form the entire face is invisible; corneal reflex and pupil, as aids, are removed, and the irritating effect of ether on the conjuctiva is substituted. And in spite of the assertion that $CO_2$ poisoning is not developed, a condition closely analogous to it, would often, if not invariably, be revealed, if the masks were removed often enough to allow of its being observed; at least, similar conditions would produce such results in America.

We come now to the inhalers proper (or improper), which are, as a rule, more complicated instruments. They are often furnished with a reservoir to contain ether, which moistens the ether-bearing medium over which a stream of air plays, or else the inspired air is brought through the ether reservoir itself.

The simplest of all inhalers is the Allis. In reality it is rather a cone than an inhaler. The original form, in which the many times reduplicated folds of a bandage on which the ether is poured, were fitted into a rubber cylinder, was perhaps the most satisfactory of the varieties of this inhaler. In its latest modified shape, "aseptic" so-called, the rubber cuff is omitted, and the shell is of metal, which is supposed to fit snugly over any face, and which springs open along one side to permit the removal of the bandage. The outer shell is clasped by two projecting hooks with sharp corners (enough alone to condemn it) and the inhaler itself is practically a rather inferior variety of cone. Its chief merit is the rather ingenious arrangement of the bandage, which holds the ether well, and permits a free passage of air. The Allis inhaler consumes much ether.

Next to the Allis, come a series of inhalers furnished with bags which receive the expired air and ether and hold it until the patient inspires it again, protecting the general atmosphere, and the occupants of the room at the expense of the patient.

The simplest of these is the Wauscher inhaler, modified by Landau (Vogel). A rubber mouthpiece, shaped somewhat like the mouthpiece of a nitrous-oxide gas apparatus, has attached to it a short neck, a large bag of thin rubber. The mouthpiece, neck and bag are all detachable. Into the bag the ether is poured, and the mouthpiece applied to the face; the bag is shaken to hasten evaporation of the ether. Unless the apparatus be lifted from the face, a fresh supply of air is not offered to the patient. It is interesting to note that Vogel, after describing this apparatus,

enters into a long exposition of the $CO_2$ poisoning which must necessarily result from the use of the Juillard mask. If he describes his own inhaler accurately, it would seem to be rather a Hobson's choice between them.

Ormsby's inhaler is similar in general shape to Wauscher's but has a sponge in the neck of the bag; a tube leads from the outside to this sponge, and ether poured into the tube is distributed over it.

Canfield's inhaler has a much larger neck. Part of this metal neck is an ether reservoir, and the remainder an open tube connecting the mouthpiece and the bag, and loosely filled with a sponge. By pressing a button, ether is allowed to trickle down upon the sponge.

Clover's is at once the most complicated and the best known inhaler used in English-speaking countries, and does not need description. Its mechanism is in many ways admirable, and unlike many inhalers, it may be used in almost any position which it is necessary for the patient to assume. The inspired air is carried through the ether on its way to the mouth, and a valve leading directly through the mouthpiece permits undiluted air to enter in moderate quantities, if so desired. A large part of the air, however, is expired into the bag and immediately inspired again. Buxton, in commenting on it, says that cyanosis and asphyxia may be avoided by lifting the inhaler from the face every seven or eight inspirations. The bag is the chief objection to all of these, and in the judgment of most American surgeons, an objection sufficient to condemn them in spite of other and better qualities and their mechanical advantages. It is not good for an unetherized person to breathe and rebreathe the same air, and why it should be good for one etherized, to whom the shock of the anesthesia is added, to do so, is not at all obvious.

Battershall has produced a remarkable-looking inhaler, which seems both clumsy and needlessly spread out, but yet contains principles which, theoretically at least, should place it ahead of any yet considered in this paper. A rubber mouthpiece is fitted to a (long) tunnel, into which, in turn, a cylinder fits. The cylinder is partially filled with cotton to be saturated with ether, a valve which opens towards the cotton is placed at the distal end of the cylinder, and a valve which opens towards the external air, is placed upon the upper edge of the mouthpiece. A screw permits a small quantity of pure air to enter the tunnel above the mouthpiece at will. When the patient inspires, the valve in the mouthpiece closes, that in the cylinder opens, and the air rushing in enters the lungs after passing through the ether-laden cotton (the screw in the tunnel being closed). On expiration, the air rushes out through the valve in the mouthpiece, that at the end of the tunnel being closed. If pure air seems indicated, the screw in the tunnel is partially closed. Of the practical working of this inhaler, the writer is ignorant; theoretically, it is much better than any of those previously considered. Its present construction could be definitely improved.

Packard has invented an inhaler consisting of a bottle for ether, a mouthpiece connected with this bottle by a rubber tube, and a Davidson bulb acting into the bottle, and when contracted, forcing the ether vapor into the mouthpiece, whence it is sent by expiration into the bottle again.

Khrone and Seseman, in London, have a similar principle, better developed and more mechanically perfect, in which the really excellent mouthpiece is furnished with a valve, after the manner of Battershall, and also a valve at the entrance of tube to mouthpiece, shutting off expired air from a return to the ether bottle. On inspiration, ether vapor is forced in from the bottle and is expired into the open air. A very small amount of ether is used, and it is entirely unirritating to the patient. The only objection to the arrangement is its size, and the rubber tubes at which an excitable patient might clutch and easily destroy the apparatus.

Dr. Williams, of this city, has constructed an inhaler which is probably, on theoretical grounds, the most perfect that has been made. In it the valves acted as in the two above described, but the ether vapor was not forced from the reservoir but simply inhaled with the air by the inspiration of the patient. A screw also admits pure air directly from without. The only objection to this instrument, is the minor one of size, and certain mechanical and constructive details. The principle of inhaling into the lungs air which has passed through a body of ether, and then exhaling it into the surrounding atmosphere, appears to be unquestionably the most perfect foundation for ether anesthesia. The production of an apparatus embodying this principle, which shall be of a convenient size, light, strong, durable, simple, and so arranged that it may be used in any position, upright or inverted, is the main problem that now confronts any one who would produce an ideal ether-inhaler. The difficulties are greater than is at first apparent, and many forms sufficiently obvious and easy of construction, combine in themselves several of the above enumerated qualities. But the mechanism which possesses them all has not yet been devised; and while waiting for its appearance, it is evident that a cone which has proved by experience to be trustworthy, and ether, which, as Vallas says, is as effective as chloroform and less fatal, are respectively the best agent and method for producing anesthesia at the present time.

It is impossible to leave this subject without a word of regret for the lack of careful and trustworthy statistics in this country upon ether anesthesia, and equally impossible to omit an earnest appeal for the development of such statistics in the future. Particularly in Boston, the birthplace of ether (and of anesthesia), is it appropriate that reliable and complete notes upon all points of etherization should be taken as a matter of course, and collected to make a basis for scientific conclusions. It should be the duty of the etherizer to make such notes, and it would at once demand a more thorough training upon the part of that assistant, a more complete concentration of his attention upon the etherization alone, and an elevation of the standard of his position. The sentiment that "any one will do to give ether" is gradually dying, and the quicker it is buried the better. Granting that the etherizer is thoroughly familiar with and understands completely his duty (and this should be a *sine qua non* just as much as with the operator himself), the complete care of the anesthesia should be placed in his hands. To it he should give his entire attention, and to the patient as little ether as is consistent with complete unconsciousness. The etherizer should be the one appealed to in regard to the patient's condition, and on his judgment should depend the question of the necessity of stimulation, its character and its amount,

subject only to the final authority of the operator, which need be only occasionally invoked. The etherizer has had both the respiration and the pulse-rate constantly before his eyes and under his fingers, and should be best able to judge of variations in either of them. It should be his privilege to ask for the discontinuation of the operation or to call for artificial respiration, if the case seemed to him to demand it. In this way, the position of etherizer would be made one of much importance, and the necessity for more judgment and skill in the administration of ether would be demanded and undoubtedly developed. The record of a surgical case should not be complete without the notes upon the anesthesia, made by the etherizer himself, and they should comprise —

The time required to produce complete anesthesia.

The duration of anesthesia.

The quantity of ether used, if a special form of cone be used.

The presence or absence of vomiting both during and after the operation, and if present, its amount and character.

The character of the recovery from ether, and the occurrence of collapse, cyanosis, unusual conditions of the heart, or respiration, and any other circumstances that seems worthy of comment.

Such notes, combined with the results of the examination of the urine, before and after, in at least a certain proportion of cases, would undoubtedly teach us much that would be valuable upon the subject of anesthesia. It would be a practice in line with the increased care of details in other branches of the science, and it would certainly enable future surgeons to avoid the mistakes, few though they be, that have been made; and it would probably contribute not a little to the comfort of the patient. And is it not appropriate that the city which was the mother of ether anesthesia should follow most carefully the development and growth of its offspring, and in intimate and accurate knowledge be not only its foremost champion, but its final authority?

## BIBLIOGRAPHY.

The list of references given below consist mainly of articles which have appeared since 1892, and contain practically all of the important German articles, and most of the French monographs, since that date. Those which are starred, are supplemented by exhaustive bibliographies of their own, which refer to papers of previous years, and will amply repay investigation.

## BICYCLING FOR WOMEN.[1]

BY CHARLES W. TOWNSEND, M.D.

As an aid to the discussion on this subject of bicycling for women I have sent to a number of female physicians in Boston and throughout the State a list of questions. The answers of eighteen of these I have been able to classify, and I wish to express here my indebtedness to these physicians[2] for much valuable information.

The questions asked were:

(1) Do you consider bicycling good for the average woman?

(2) Have you seen any harm from it? If so, what?

(3) Would you advise it in any form of uterine disease?

(4) What is your personal experience, if any, with bicycling?

The answers I have classified as follows:

(1) All but one stated decidedly that they considered bicycling of value to the average woman, ten of them adding one or more of the following qualifications:

(*a*) If used in moderation, both as to length of ride and speed.

(*b*) If properly dressed, one adding without corsets.

(*c*) If in proper posture.

(*d*) If at proper times.

(*e*) If protected from falls while learning.

(2) Nine had seen no harm from bicycling. Four more had seen harm only from excessive use in the form of general fatigue and jarring of the head and spine. One reports severe pain in the head in a stout woman of forty following excessive strain in climbing a steep hill. Another has seen serious ovarian trouble directly due to riding long distances or during or near the menstrual period.

Another reports a case of renal hemorrhage; a case of profuse metrorrhagia; a case of oöphoritis with antiflexion and intense dysmenorrhea in a patient hitherto entirely healthy; and a case of miscarriage.

Another physician has seen uterine congestion and dysmenorrhea in a patient with no previous history of pelvic trouble.

[1] Read before the Obstetrical Society of Boston, April 13, 1895.

[2] Answers were received from Drs. R. Barnard, F. Berlin, E. L. Call, E. M. Davis, S. E. Palmer, M. Perry, A. G. Richardson, L. M. Robinson, M. A. Smith, S. R. Stowell, J. Tolman, L. F. Vickery, G. Wolcott, E. W. Mooers, S. M. Crawford, S. E. Crocker, H. L. Harrington, L. V. G. Mackie, M. O'Callaghan, and C. J. Alexander.

Another has seen harm in a case of extensive adhesions and contracted ligaments; where there were active inflammatory processes present; and in one case where there was a small subperitoneal fibroid in the uterine wall.

One physician reports contusions from an improperly fitted saddle, a difficulty which can be avoided, she adds, by proper adjustment of the saddle.

(3) The question, "Would you advise it in any form of uterine disease?" was answered in the negative by two only. The remainder had recommended the exercise or might recommend it in suitable cases. The majority of these limited the exercises to chronic cases, especially where the circulation was sluggish and the muscular system relaxed, cases of uterine neurasthenia, dysmenorrhea, amenorrhea due to chlorosis, moderate displacements and imperfect development.

A number of cases are reported as benefited by bicycle exercise. They are briefly: Several cases of retroversion, one case improved so that pessary was discarded, others not harmed; a cured case of retroversion learned to ride, the falling off, etc., doing no harm, general health improved. One had "seen improvement in patients with enlarged and even prolapsed uteri after taking systematic exercise on the wheel."

The following cases are worth reporting at some length:

Young married woman, retroflexion of uterus and prolapsed ovary with adhesions; dysmenorrhea and pain on walking. Learned to ride a bicycle and used it all summer with the exception of the menstrual periods. Rode thirty and forty miles in a day at times. At the end of this time examination showed that "the inflammation has entirely subsided, her menstruation causes her very little pain, and she considers herself a perfectly well woman. The displacement is still there but not so sharply defined."

Another case is as follows:

A young woman of delicate physique with great dysmenorrhea requiring rest in bed. Use of bicycle begun last April followed by improvement in general health with menstruation fairly comfortable, not requiring rest in bed.

Several speak of the beneficial use of the bicycle where walking was difficult or impossible. One says: "Several patients with uterine and ovarian disease, who were unable to take walking exercise have received marked benefit from bicycling," and adds, "due I have thought to the general tonic effect of an out-of-door life, change of thought, etc., all the organs of the body partaking in the good results." This strikes the key-note of the situation.

(4) It is interesting to note that these favorable criticisms were not obtained from bicycle enthusiasts, as only one of these had used a bicycle herself. Three had begun to ride only, while the remainder had no experience in bicycling.

The one rider says, "My own personal experience leads me to consider bicycling a decidedly healthful, safe, agreeable and cheap form of exercise."

These replies, it seems to me, cover the field of bicycling for women very satisfactorily, showing that the bicycle is of great value to the average woman, even to the woman with various forms of uterine disease. They also show that the bicycle when improperly used is liable to do harm.

It remains to sum up briefly the subject.

Out-of-door exercise, it is unnecessary to state, is of great value to every one, and, it is also unnecessary to add, that women as a class suffer greatly from the lack of it. Another thing from which women suffer is too heavy and too tight clothing. Both of these ills the average woman is entirely unconscious of, and will deny the need of more exercise on the one hand, or the existence of heavy and tight clothing on the other. No amount of dress-reform preaching or of calisthenic exercises will remedy these evils, or awaken the woman to a knowledge of the possibilities of the enjoyment of life. This is what the bicycle is doing, and is destined to do in the future.

The bicycle provides not only an agreeable method of exercise in the open air, but also demands a comfortable loose and light costume. Whether it will change woman's dress so far as to discard the skirt and substitute the divided garment or loose knickerbockers remains to be seen.

Patients who have substituted the comfortable loose "health" waists for corsets, while they were riding, have found that corsets were unnecessary for their every-day dress, and decidedly uncomfortable.

In talking with several ladies' tailors on this subject I have found that short corsets which do not press on the abdomen are used, and that, while some cling to the regulation corset, many are using waists simply. One tailor writes me, "I make bicycle costumes for a great many that do not wear corsets, but the Equipoise waist, and make them just the same style and cut as if they wore corsets."

Like all forms of exercise the bicycle can do harm by excessive use. Too great speed or too long rides are exhausting and may injure some delicate point. The exercise is so agreeable and inspirating that there is more danger of excess than in many out-of-door sports, especially if a spirit of ambition and rivalry is allowed. The long rides on time — even "century" runs are indulged in by women — accomplish no useful purpose, and often result in great harm.

Another danger to be avoided is the strain from riding up steep hills, a case where ambition often compels the rider to persist after the effort becomes too great. A good rule is to dismount and walk up every hill where the effort of riding is at all irksome. The change of exercise is restful and beneficial.

Another evil, one which fortunately is rarely found among women riders, but is all too common among men, is the stooping posture with bent back and head thrust out awkwardly like a tortoise. This is the position of the racer on the race-course. For ordinary riding it is entirely unnecessary, and very harmful, contracting the chest and bowing the back, besides preventing the rider from enjoying the scenery. The class of riders who sit in this way, however, do not care for scenery. By raising or lowering the handle bars or seat, both of which are adjustable, any road bicycle may be so arranged that the rider is compelled to sit erect. This matter is often not understood by parents who think that the bicycle is so constructed as to require a bent posture. There is no more need to condemn bicycling on this account, than there is to condemn horse-back riding on account of the position of the jockey in racing.

The saddle, in addition, allows considerable adjustment of tilting and should be so arranged as to avoid pressure in the pudendal region. This danger has by

some been much overestimated and can be avoided. The stooping posture as well as a faulty position of the saddle tends to bring pressure in this region.

The bicycle has been compared with the sewing-machine. As well compare mountain climbing with exercise in a treadmill! The differences are great, and I have arranged them in parallel columns.

| Bicycle. | Sewing-Machine. |
|---|---|
| Out-of-doors. | In-doors. |
| Mental recreation. | Monotonous task. |
| Body erect. | Body bent over. |
| Increased circulation. | Stasis of blood in lower limbs and pelvic organs due to bent position. |
| Vision not concentrated. | Eyes fixed on fine points. |
| Exercise consisting of sweeping movements of legs and thighs, together with the use of all body muscles in swaying motion of balancing, together with more or less use of arms. | Exercise limited to restricted movements of lower legs. |
| Exercise demands deep inspirations. | Exercise so slight that deep inspirations not required. |

Those who do not ride imagine that bicycling exercises the legs only. They are very much mistaken.

Dr. G. M. Hammond[2] has found that the average expansion of the chest in bicyclists who sit erect is one and four-sevenths inches, the average in the non-exercising man being one inch.

The delightful nature of the exercise is of the greatest value. To most women gymnasium work is a bore, and so often is walking with no object in view except the exercise. Both of these forms of exercise when prescribed by the physician often accomplish but little, as the patient is not taken away from herself.

Not so with the bicycle, which breaks up morbid trains of thought, takes the patient away from herself, and in that way benefits every nervous or functional complaint. It is, moreover, an exercise which develops self-reliance, a virtue much needed by this class of patients.

It is unnecessary to speak of the advantage to town dwellers of getting easily into the country and of the small expense and great possibilities of bicycling.

In conclusion, it seems to me that bicycling is beneficial to women, not from any special effect on the pelvic organs, but because it is an agreeable, healthful form of exercise in the open air, a form which exercises the whole body, and indirectly benefits special conditions. And the converse of this holds true, that as a general exercise bicycling is not hurtful to the pelvic organs even when these are affected, unless the disease is so acute that any exercise as great as this is contraindicated.

## BICYCLE SADDLES FOR WOMEN.[1]

BY JAMES R. CHADWICK, M.D.

It has seemed to me important to inaugurate a discussion before this Society upon the subject of the bicycle saddle for women, in view of the great and increasing resort to this mode of exercise. I feel my incompetence to decide upon the various considerations presented by the topic, because I have never been a bicycle rider. My concern has been, however, awakened by the admissions of two patients. (1) A married woman, thirty-four years old, complained that after the menstrual period (during which she abstained from riding) she invariably was conscious of an irritation in the vulva which persisted for several days. I could not discover that any permanent lesion was produced. She attributed the discomfort to the fact that the vulva rested upon the pointed projection of the saddle in front. She subsequently obtained an English saddle — the Brooks Oval Saddle by name — which differed from the other chiefly in being broader behind and less high in front. Upon this saddle she has since ridden without discomfort. (2) A few months later a married woman, forty-seven years old, who had been referred to me by Dr. Weir Mitchell, of Philadelphia, for neurasthenia, amenorrhea, etc., reported to me that she had taken to bicycle-riding with the greatest benefit to her general health, but that she had been much troubled with leucorrhea. This last symptom I found attributable to a chronic vaginitis and apparently produced by the exercise. In view of the great improvement in her general physique I did not deem it necessary to forbid bicycling, but prescribed an astringent for the vaginitis; with what effect I have not since learned. These experiences have led me to give much attention to the saddle of the bicycle and its fitness for women.

I find that no serious attempt has as yet been made to produce a saddle that shall be adapted to a woman's anatomy. The bicycle saddle for men seems to have been modelled upon the saddle that was found suitable for men riding upon a horse, being merely reduced in most of its dimensions. This has answered most of the requirements, though often found to strike against the prostate gland or the pubic arch. When women began to ride they were given the same saddle, regardless of the fact that behind the pubic bone are the external genital organs so prominent as inevitably to rest upon the anterior projection of the saddle. The result has been that women have generally had great difficulty in having the saddle so adjusted as to be rendered comfortable — in other words to avoid pressing unduly upon the vulva.

My inquiries have not enabled me to form definite conclusions, but have made evident the fact that (1) the saddles in most use require many adjustments to be comfortable to the generality of female riders; (2) that some of the saddles are absolutely unfitted for the use of women; (3) that the teachers have no definite ideas by which they can adapt the saddle to the use of women.

Now let us consider briefly in what respect the saddle needs alteration to fit it to the anatomy of woman. In the first place a woman's pelvis is broader than a man's, and the tuberosities of the ischia are further apart in woman than in man, consequently the width of the rear portion of the seat needs to be greater. No such provision has been made. This is a matter, however, easily corrected when attention is called to it. Secondly, the anterior projection of the saddle must be tilted downwards so that it will not strike against the vulva. This, however, requires the most delicate adjustment, for if the saddle is tilted too far the slope of the seat causes the rider to slide forward so as to rest almost entirely upon the anterior projection, and so defeat the object of the tilting. Again, the seat may be shifted backwards and forwards upon the frame, without tilting. When shifted backwards, the action of the leg upon the treadle tends to push the

[1] Read before the Obstetrical Society of Boston, April 13, 1895.

[2] New York Medical Record, February 2, 1895.

body backwards and thus to ensure that the ischia shall rest upon the saddle; but in this location the muscular action of the legs is less effective, which renders the work of propulsion greater.

From the foregoing it is evident that the adjustment of the present form of saddle to women is attended with great difficulty. The question therefore arises, Is the anterior projection of the saddle essential? I cannot pretend to answer this question; but it seems to me that experiments should be made to dispense with this feature of the present saddle if possible. The problem is whether without the anterior projection, the seat of the rider would be sufficiently secure. The trouble is that when the leg is straightened and the treadle at the lower point of its circuit the thickness of the thigh tends, by pressing against the anterior margin of an oval saddle, either to lift the tuberosities of the ischia from the saddle or to drag them forward, so that after a jounce they will not descend upon their proper place, and a secure seat will thereby be lost, or the skin be chafed at the junction of the thigh and the ischiatic region. The feasibility of such a saddle as this can only be determined by experiment, and should be made before women are generally allowed to ride the bicycle.

In conclusion, I would express the opinion that bicycling is a most desirable form of recreation and exercise for women, and that my only purpose in bringing it up for discussion on this occasion is to stimulate the inventive minds of its advocates to devise a saddle which shall not inflict local injury or discomfort upon women riders.

## Clinical Department.

### MULTIPLE FIBROID OF THE UTERUS WEIGHING FOUR AND A QUARTER POUNDS.[1]

BY W. L. BURRAGE, M.D.

R. H. (colored), thirty-nine years old and single, first came under observation August 17, 1894. She was a native of Virginia, and had always enjoyed good health up to two years previous to this time. During these two years she had suffered with dysmenorrhea, which had been increasing in severity, and with profuse menorrhagia and constant pains in the groins, especially on the left side.

The pain in the groin was of a bearing-down character, and prevented her from lying on the left side. She complained also of frequent micturition and of poor appetite and sleep. The catamenia were regular, of two days' duration, flow of twenty napkins. The severe dysmenorrhea was every other month, when she was obliged to give up work and suffered with a large variety of nervous symptoms.

Diagnosis: Fibroid, size of large orange; nodule behind, another to left and above; cervix behind pubic arch and to the left, in front of posterior nodule, which nearly fills the pelvis; sound goes upward three inches.

Treatment with intra-uterine galvanism was begun at once. Eighteen treatments, N. 50 to 100 milliampères of five minutes' duration each were given during three months. At the end of this time the tumor had grown perceptibly, and was distorted to such an extent that intra-uterine treatment was no longer possible. A galvano-caustic puncture, 100 milliampères, N., was then made in the posterior nodule.

At the end of seven months she was a good deal relieved as regards her symptoms, but she looked forth with terror to every other menstrual period, and was anxious to get rid of the tumor, which had increased one-third again in size and reached nearly to the umbilicus.

I operated at St. Elizabeth's Hospital April 3, 1895. There were no adhesions, and the only trace that I could find of the electrical puncture was a black spot the size of a pin's head on the posterior nodule. After the broad ligaments had been tied off, the tumor was delivered with comparative ease after the posterior nodule had been dislodged from the pelvis. The vagina was not opened, a small piece of the cervix being left behind. The canal of the cervix was touched with pure carbolic acid, the uterine arteries tied with silk, and the stump and the peritoneal edges whipped over with continuous catgut. No drainage.

The operation was ten days ago, and the patient so far has had an uninterrupted recovery. The temperature has not been above 100°; the union in the abdominal wound has been good, and aside from some nervousness at night and sluggishness of the bowels, there has been nothing abnormal to note.

Inspection of the tumor shows the futility of trying to reach all parts of such a uterine cavity as is here shown with electrode or curette; for, as you see, it is some four and a half inches deep, measured from the severed edge of the cervix, and the distorted left horn reaches through to the back of the tumor, bending in several directions as it goes.

This case exemplifies the rule that electrical treatment does not diminish the size of the tumor in a majority of cases of fibroids and it causes no adhesions.

[1] Shown at the Obstetrical Society of Boston, April 13, 1895.

## Medical Progress.

### RECENT PROGRESS IN ANATOMY.

BY THOMAS DWIGHT, M.D.

#### THE RELATIONS BETWEEN THE SHAPE OF THE SKULL AND THE POSITION OF THE PETROUS PORTION OF THE TEMPORAL BONE.[1]

DR. GARNAULT has undertaken to verify Körner's views on this question which is of much practical importance in otological operations. Körner had declared that the floor of the middle cerebral fossa is higher in long skulls than in short skulls, and also that the continuation forward of the lateral sinus before its descent, is in direct relation to the degree of brachicephaly. Garnault's studies were made on sixty skulls, of which only seven were mesaticephalic. It is needless to go into details when the conclusions are as sweeping as they are in this case, for Garnault finds, to state it most favorably for Körner, that his conclusions are of no practical value.

#### GROOVE ON SPINE OF SPHENOID.[2]

Mr. R. Clement Lucas spoke at a meeting of the Anatomical Society of Great Britain and Ireland, of a small groove which is found very constantly on the inner surface of the spine of the sphenoid caused by

[1] Comptes Rendus de la Soc. de Biol., 1895, No. 6.
[2] Journal of Anatomy and Physiology, vol. xxix, January, 1895.

the chorda tympani nerve. It is important as locating definitely the course of this interesting structure after its escape from the skull. It is situated behind and usually rather internal to the foramen spinosum. The best guide to the groove on the entire skull is the tubercle at the front of the vaginal process of the temporal bone. In some cases the groove broadens anteriorly. Mr. Lucas suggests very plausibly that this may be due to movements transmitted to the nerve through the lingual, which, of course, moves with the tongue.

### COMMUNICATION BY A LARGE VESSEL BETWEEN AN ARTERY AND VEIN.[3]

As is well known, it has been maintained by several anatomists, that there are vessels connecting arteries and veins which are too large to be called capillaries. Suquet described such vessels in the human hand and foot and introduced the term "circulation dérivative." The doctrine has experienced several vicissitudes. Professor Debierre and Dr. Gérard of Lille, now come forward with a truly remarkable observation. They found, not an excessively minute vessel, about which one might quarrel as to whether it was a large capillary or a small vein, but a vessel three centimetres long and two and one-half millimetres in diameter, forming a loop between the femoral artery and vein at the fold of the groin in a child three days old. This description applies particularly to the left side, but a corresponding vessel was found on the right. Most people would be inclined to look on this as a very exceptional and extraordinary arrangement, but the authors think otherwise. They have seen similar dispositions in the bodies of four young children, but at different points. With one exception, when there was found an anostomosis between the aorta and the inferior cava, these communications were always at the folds of the great joints of the limbs. Observations are now being made on the adult, which are promised later.

### THE CUSPS OF THE PULMONARY AND AORTIC VALVES.[4]

Professor Windle read a paper before the Anatomical Society of Great Britain and Ireland, on the relative position of the semilunar valves of the pulmonary artery and aorta. They are usually described either according to Valsalva, who gives one anterior and two posterior cusps to the pulmonary valve, and two anterior and one posterior to the aortic; or, in a directly opposite manner, according to which the pulmonary has two in front and one behind, the aorta one in front and two behind. This latter description is spoken of in the paper as that of "Gibson," which is undoubtedly a misprint for Sibson. Windle examined nearly 100 hearts himself, and brought the series up to that number by the use of notes on frozen sections furnished him by others. He finds that in 15 cases the arrangement is that of Valsalva, and in 85 that of Sibson. He adds the following judicious remarks: "In saying this, however, it is important to note that the description is only a rough one. It is only in comparatively few cases that the two anterior cusps of the pulmonary artery are equally anterior . . .; and that the same is true of the two posterior cusps of the aorta, indeed, more true; for the arrangement in the pulmonary orifice tends to be more strictly in conformity with the description than that in the aortic."

### VARIATIONS OF THE THYROID IN MAN.[5]

Dr. C. F. Marshall has examined the shape of this organ in the bodies of 60 children under ten years. His chief purpose was to obtain statistics of the persistence of the thyro-glossal duct and of the "canal of His," meaning by the latter the median cervical fissure which is occasionally met with. This latter was not found at all, nor was there ever any persistent ductus lingualis, though in 15 per cent. there was a little duct one-quarter inch long from the foramen cecum, representing its rudiment. The variations in shape were so great that Dr. Marshall declared it absurd to speak of a normal thyroid.

The lateral lobes were usually about equal. Once the right lobe was wanting, so that the gland consisted of a left lobe and an isthmus.

The isthmus was wanting six times, and was more or less fused with one lobe in about one-quarter of the cases.

The pyramidal process was found in almost half the bodies, and usually was attached to the hyoid bone.

The author notes "that there is no relation between the extent of the remnant of the ductus lingualis and the presence of the processus pyramidalis, for in the nine cases in which the ductus lingualis was represented by one-quarter inch, only four of these cases had pyramidal lobes, the other five having none at all." There are seventeen drawings of thyroids appended to this very interesting paper. It may be remarked by way of criticism that the morphology of the thyroid of the infant and of the adult is probably not the same. It would be well to have another series taken wholly from adults.

Dr. Mauclaire[6] has examined some 80 bodies and 30 dried preparations to determine the position of the isthmus of the thyroid on the trachea, which is somewhat variously stated in the books. Roughly speaking, he finds that in two-thirds of the cases the isthmus covers a part of the first ring, and more or less of the second. Next in frequency is what is commonly called the classical position, in which it rests on the second ring and leaves the first uncovered.

### THE SIZE AND POSITION OF THE STOMACH.[7]

Dr. F. Martius has made an extremely interesting preliminary communication of experiments made by Herr Meltzing in his clinic on the living stomach. The method was to introduce a sound bearing an Edison lamp into the stomach of persons on whom the boundaries of lungs and liver had been previously determined by percussion. Experiments were made with the patient lying and standing; with the stomach both full and empty.

Perhaps the most interesting result is that the empty stomach descends a great deal lower than is commonly supposed. This might, perhaps, have been expected for we are too apt to forget that our ideas of topography are gained from subjects in a position of extreme expiration. The empty organ almost invariably descended as low as the navel, and when filled with water materially lower. We come, however, here on a statement that is quite unintelligible, namely, that the lowest point reached was on a level with a plane

[3] Comptes Rendus de la Soc. de Biol., 1895, No. 1.
[4] Journal of Anatomy and Physiology, vol. xxix, January, 1895.
[5] Ibid., vol. xxix, January, 1895.
[6] Bull. Soc. Anat., Paris, tome ix, No. 3, 1895.
[7] Wiener med. Woch., No. 7, 1895.

connecting the highest points of the crests of the ilia. Now this is at practically the same level as the navel.

When the patient, who has been examined lying with the stomach full of water, rises, the lower border of the stomach and the edge of the liver fall from four to eleven centimetres.

The respiratory excursions of the lighted space are considerably in the recumbent and but slight in the upright position. The enlargement of the illuminated area on filling the stomach takes place chiefly to the right.

The observer has seen cases of really immense stomachs which to all intents and purposes are perfectly normal. Hence he declines to call an organ pathological, if we rightly understand him, whatever may be its size if it performs its functions. We are glad to learn that the author is about to publish his observations in book-form.

### THE CECUM.[3]

One would think that this organ had received so much attention that little new remains to be said of it, but there is no cessation of new contributions. Dr. Richard J. A. Berry gives a detailed examination of 100 cases, from which the following points may be gleaned.

There has always been some uncertainty as to how the upper boundary of the cecum is to be determined on the unopened organ. Of course the cecum is that part of the intestine below the opening of the ileocecal valve, but this point is not always to be known from external inspection. When the frenal furrows are to be seen the position of the valve is clear; when they are not Dr. Berry would have us take a point midway between the upper and lower borders of the cecum, just where it enters the ileum. As he justly premises that the solution can only be approximate, there can be no hesitation in following his plan.

The dimensions were taken on 42 ceca of which casts had been made, with the results shown in the following table:

| Age. | No. Cases. | Av. length. | Av. breadth. |
|---|---|---|---|
| Below 10 years . . . | 11 | 2.8 cm. | 3.7 cm. |
| 10 to 30 years . . . | 3 | 7 cm. | 8.5 cm. |
| 30 to 40 years . . . | 11 | 6.4 cm. | 7.4 cm. |
| 40 to 60 years . . . | 11 | 6.8 cm. | 8.8 cm. |
| 60 to 80 years . . . | 6 | 6.8 cm. | 7.7 cm. |

The author emphasizes two points as shown by this table, first, that the cecum is much larger in the adult than in the child, and, second, that the breadth is always greater than the length. Sex apparently has no influence on the size.

Treves describes four types of cecum, which it may be worth while to recapitulate for our readers who cannot easily turn to the original. The first is a conical prolongation of the gut something like a cornucopia. The second is short and bulging. These two forms resemble each other in one important respect, namely, that the three muscular bands are about equidistant and on the whole the cecum is fairly symmetrical, with the appendix springing from its extremity. In the third form the pouch to the right of the anterior band has grown to such an extent that it forms a great part of the cecum which is entirely lobsided, the appendix arising from its left side near the end of the ileum. The fourth form is an exaggeration of the preceding, the anterior band runs by the lower border of the ileum to the origin of the appendix.

Treves found the relative frequency of the types as follows: I, 2 per cent.; II, 3 per cent.; III, 90 per cent.; IV, 5 per cent. Berry finds in his 100 cases the following percentages: I, 10 per cent.; II, 6 per cent.; III, 80 per cent.; IV, 4 per cent. It is to be noted, however, that Berry included children and fetuses. Now six of his ten cases of type I were fetuses and this is the fetal type. Of the four others, three were from young children, thus leaving one adult case of the first type. The second type, which is an evident modification of the first was represented by six cases, but only two of these were from adults.

When all not adults are stricken out of Berry's series, we find his table reads as follows: I, 1 per cent.; II, 2 per cent.; III, 94 per cent.; IV, 3 per cent., which is strikingly like that of Treves. The practical surgical deduction is that in over 90 cases in 100 among adults the origin of the appendix will be found not far from the ileum.

Dr. Berry found the cecum completely invested by peritoneum in 94 per cent. of his cases.

## Reports of Societies.

### THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

REGULAR Meeting, April 13, 1895, the President, DR. JAMES R. CHADWICK, in the chair.

DR. W. L. BURRAGE reported a case of

#### MULTIPLE FIBROID OF THE UTERUS,[1]

and showed the specimen, weighing four and one-quarter pounds.

DR. JAMES R. CHADWICK read a paper on

#### BICYCLE SADDLES FOR WOMEN.[2]

DR. CHARLES W. TOWNSEND read a paper on

#### BICYCLING FOR WOMEN.[3]

The subject of bicycling for women was then discussed by the Society, especial attention being paid to the saddles, of which Dr. Chadwick had brought a number for criticism. The general opinion seemed to be favorable to bicycling as an exercise for women, although the present form of saddle was thought by some to be objectionable.

DR. E. J. FORSTER reported

#### A CASE OF VESICO-VAGINAL FISTULA

so large that it was possible under ether to look in and see the urine coming out of the ureters.

DR. EDW. REYNOLDS remarked that a curious fact of the case was that the ureters opened on the anterior surface of the bladder owing to the cicatricial adhesions.

---

FURTHER LIGHT ON THE "KEELEY CURE."—Rev. Dr. J. M. Buckley, the editor of the *Christian Advocate*, has obtained the information from 68 clergymen and 25 physicians, that of 534 persons known to have taken the bichloride treatment 251 relapsed, 13 became insane, 11 died, 2 committed suicide and 275 were cured. The quality of bichloride furnished must be poorer at present than it was when the 95 per cent. of cures claimed by Keeley were effected.

## ASSOCIATION OF AMERICAN PHYSICIANS.

TENTH ANNUAL MEETING, WASHINGTON, MAY 30 AND 31, 1895.

### THURSDAY. — MORNING SESSION.

THE Association met in the Army Medical Museum Library and was called to order by PRESIDENT WM. OSLER, of Baltimore, who delivered

### THE PRESIDENTIAL ADDRESS.

Dr. Osler reviewed the work of the Association for the past nine years, and concluded that the Association had thus far abundantly fulfilled its prime object, "the advancement of scientific and practical medicine."

This Association, he said, has already had a potent influence on the study of pathology and clinical medicine in this country. We need, however, a larger group of men who are devoting themselves exclusively to these branches. The rapid progress of the medical schools has increased the teaching positions in the scientific branches, and there is at present an actual scarcity of thoroughly trained pathologists and bacteriologists to fill them. There is no need to insist upon the necessity of accurate and prolonged training in the development of workers in these branches; but I do not think that the profession of this country as yet understands the art of training special clinical physicians. We have taken it too much for granted that such develop readily in the routine of family practice. True, along this path some of the most noted men in our ranks have travelled; but the time has come when able young men should be encouraged to devote themselves to internal medicine as a specialty. Content to labor and wait, during the first ten or fifteen years of professional life, with pathology as the solid basis of development, such men will pass to the wards through the laboratories, thoroughly equipped, to study the many problems of clinical medicine. They will gain the confidence of their professional brethren by accurate and thorough work, and through them, if they wish, the public and practice. The opportunity for such a career is in every city with a hospital of fifty beds. Of such — of physicians (in contradistinction to surgeons, gynecologists and general practitioners) and of pathologists and bacteriologists — should our Association in large part be composed.

We should all understand that this is a working Society; and when any of us cease to attend regularly, or when our interest grows lukewarm, we will promote best the common welfare by quietly retiring.

We have lost year by year very heavily by death, 16 of a total of 111 members. While some have passed away in the fulness of years, with their work accomplished, others have been taken in their prime, and several of our most valued members have been removed while still in the days of promise. This year we mourn the loss of two men who could ill be spared from their respective spheres of labor and from us.

Of Alfred Lee Loomis I need not say much to this audience, before which, as well as before a much larger, he played a strong rôle. Energy and determination, so clearly stamped on his features, led him early into the path of success, and each decade added reputation and prosperity. Threescore and four years found him one of the most prominent figures in the profession of this country — a successful writer, a much sought-for consultant, a busy man of affairs. Then the end — and happily for him, perhaps, while the harness was still on, and while the vigor of mind and body was still unimpaired. In this Society, in the Congress of our united bodies, Dr. Loomis proved a trusty counsellor, an earnest worker and a zealous supporter of the best interests of the profession. In his faithful attention to those duties which lie outside of the daily routine of our lives, duties which we are only too apt with advancing years and with assured success to neglect, he was a notable example to us all.

The death of William Cecil Dabney is in every way deplorable, untimely; and, since he died of such a preventable disease as typhoid fever, we might almost say, unnecessary. He had only reached that stage in his career when experience and judgment begin to ripen, and when we begin to discern in a man whether he is intellectually a polyp or a mammal, whether with his growth there has been development as well. Dr. Dabney was a conscientious and earnest worker, a zealous teacher and a man of wide sympathies with all that was best in the profession. He had a warm, lovable nature which endeared him to an unusually wide circle of friends and patients. To our Association, of which he was an original member, he was much attached; and we have lost in him a strong and faithful colleague, one whose ways and works were of the best and highest.

### LEUCOMAIN POISONING,

by DR. B. K. RACHFORD, Cincinnati.

Leucomain poisoning is a form of auto-intoxication etiologically related to migraine, migrainous epilepsy, and migrainous gastric neurosis. Paraxanthin, the most poisonous of leucomains, is found in very great excess in the urine passed immediately after these migrainous attacks, and is not found in increased quantities in the urine of these patients between these attacks.

Xanthin, another poisonous leucomain, is found in great excess in the urine passed just after one of these attacks, and in migrainous gastric neurosis xanthin is found not only in great excess in the urine, but it is also found in the stomach contents.

The paraxanthin separated from the urine of these cases will produce in the mouse symptoms very similar to an attack of migrainous epilepsy.

DR. F. P. KINNICUTT: I would like to ask if Dr. Rachford has had the opportunity of investigating urine in cases of tetany. I think it is exceedingly probable that a certain number of cases of tetany are the result of auto-intoxication, and that auto-intoxication is presumably due to some form of indigestion. It occurs not infrequently in cases of dilated stomach and in cases of severe gastro-intestinal disturbance, which would make it probable that it is caused by auto-intoxication. In the last few months I have seen two cases of tetany. One case was fatal in twenty-four hours after the occurrence of the first symptoms. The autopsy showed simply an enormously dilated stomach. The patient had had several previous attacks in the course of the preceding ten years, and all accompanied with marked symptoms of gastric intestinal disturbance. The other case was in a child, the tetany going over a period of three weeks. In this case there was continuous spasm. The symptoms finally entirely disappeared. Examination of the urine was not made.

DR. W. H. THOMSON: I feel extremely gratified

with the experimental demonstration that Dr. Rachford has given of the connection of migraine with auto-infection. I have long held that view; and I read a paper before this Society on the significance of intermittency in functional neuroses. The fact that some nervous diseases should be characterized by complete intermissions pointed strongly to toxic rather than to structural relations in their etiology. I do not see that the hereditary character of these functional neuroses militates in any way against such an inference, because clinical experience certainly shows in the case of gout, for instance, that we may have hereditary abnormal chemistry as well as hereditary abnormal morphology.

With reference to migraine, it has been my custom for years to treat those patients prophylactically, and I have felt that I have had a good deal of success by the free use of ammonium and sodium benzoate.

A close relation seems to exist between migraine and some cases of the uric-acid diathesis and some cases of epilepsy, and I have treated them on the same principle. This relationship was strikingly illustrated in one case that I had. The patient was one of the worst cases of migraine that I have ever had to do with. She had a son who from childhood had uric-acid renal calculus. A daughter inherited the migrainous tendency and that daughter had a son who was epileptic, an epilepsy which was very closely analogous in its symptoms to that which Dr. Rachford has described.

DR. F. C. SHATTUCK: How long does it take to find the xanthin and paraxanthin?

DR. B. K. RACHFORD: Three weeks.

DR. J. E. GRAHAM: I would like to ask Dr. Rachford if he examined the urine shortly before the attack, say a week before?

DR. B. K. RACHFORD: I have made an examination of the urine at almost all times between the attacks and as recently as one week before and have always failed to obtain these poisons. I have not yet had a case of tetany that I could satisfactorily examine. Apart from the interest which attaches to these cases this has, I think, a great bearing upon the pathology of uremia and eclampsia from uremic causes.

### SOME TOXICOGENIC GERMS FOUND IN POISONOUS FOOD,

by DRS. VICTOR C. VAUGHAN and GEORGE D. PERKINS, Ann Arbor, Mich., was read by title.

DR. A. C. ABBOTT, Philadelphia, read a paper on

### THE EFFECT OF THE GASEOUS PRODUCTS OF DECOMPOSITION UPON THE HEALTH OF ANIMALS THAT ARE COMPELLED TO RESPIRE THEM.

In a paper read by the writer at the Congress of American Physicians and Surgeons, session of 1894, were presented the results of a series of experimental studies that were made with a view of determining in how far the opinion held by many with regard to the part played by the air of sewers in causing or disseminating diseases, could be supported by evidence obtained through the employment of exact chemical, physical and bacteriological methods of investigation.

The outcome of these experiments afforded nothing to justify the view that the air of sewers, under ordinary circumstances, could be held accountable for either the causation or dissemination of infectious maladies.

Since the presentation of the conclusions embodied in that paper, a series of experiments have been made with the object of discovering the effect of the gaseous products of decomposition on the health and resistance to infection of animals that were compelled to respire them. For this purpose animals, rats and guinea-pigs, were confined under bell-glasses through which was passed continuously, for varying periods, the air from over substances (meat-infusion, sewerage and urine), in different stages of decay. Some of the animals were subjected to this treatment only, while others were inoculated from time to time during the experiment with cultures of the bacillus of typhoid fever. Of eighteen animals on which the experiments were performed, only two, which will be referred to in detail in the body of this paper, showed any effect; the remaining sixteen presenting nothing that could be attributed to the conditions under which they had lived for from one to five months prior to their being killed. The general condition of these animals during the experiments, as determined by their outward appearance, appetite and daily fluctuations in weight, was as good as that of other animals kept under the ordinary conditions of the laboratory.

As a result, the conclusion seems justifiable, that as ordinarily respired, the air of sewers, or that from other bodies undergoing decomposition and putrefaction, has either not the power of inducing pathological conditions at all, or, if it has, such conditions are not demonstratable by such laboratory methods of experimentation as we have practised on rabbits and guinea-pigs.

### RENAL AFFECTIONS FOLLOWING INFLUENZA,

by DR. G. BAUMGARTEN, St. Louis, Mo.

A report of eight cases, from which it appears that damage to the kidneys is a frequent, and sometimes a serious consequence of grippe. Besides transient albuminuria, there have been found acute degeneration of the kidney, acute inflammation, both forms of chronic diffuse nephritis, and cases of persistent albuminuria not plainly belonging to one of these groups. The injurious influence on public health exerted by an epidemic of grippe may last much longer than the epidemic itself, by reason of renal and other sequels.

DR. A. JACOBI: I know that I find renal trouble very frequently after influenza. It has appeared to me that the form of nephritis that we see after influenza is the same that we find after diphtheria and after typhoid fever and, therefore, I believe that it must be due to the same cause, to the toxines of the different germs giving rise to these diseases. The microscopical appearances of such a urine are about as follows: Specific gravity say from 1.014 to 1.022 or even 1.026, of small amount when the case is recent, a very small amount of blood, hyaline casts, hyaline casts studded with granular matter or with small epithelium and granular casts of the thin, fine variety. These characteristics I have found, not only after influenza, but also after typhoid and after diphtheria. They are contrary to what we find after scarlatina, which has its own peculiar form of nephritis. The large majority of these cases get well and get well speedily, that is within two or three weeks, but sometimes taking two or three months. I have also seen quite a number of cases that became chronic.

DR. TYSON: I have observed renal trouble in persons who were entirely well and free from evidence of

it until after an attack of grippe. I have taken no trouble to collect cases of this kind but it seems to me there would be a considerable number if I gathered them. Then there is a second class of such cases, consisting of those who had so-called functional albuminuria previous to an attack of the grippe. In a certain number of such cases, the patient returned to me after having had the grippe, with a very much more serious state of affairs, with increased albuminuria, an increased number of tube casts and an altogether aggravated condition. Of these two conditions, the occurrence of primary nephritis from grippe and an aggravation of a previous albuminuria, I can speak from experience.

It is evidently a toxic nephritis.

Dr. F. C. Shattuck: I am sorry that Dr. Charles Folsom, of Boston, is not here, because this is a subject in which he is interested. Last winter I saw a number of times with him, a young lady, previously neurasthenic but much better than she had been, who was stricken with the grippe, followed by bronchopneumonia; the next thing was an acute nephritis with almost suppression of urine and an enormous amount of albumin. She became uremic; and it seemed as if the nephritis itself would prove fatal, because the quantity of the urine remained very small. Later on, the urine increased in quantity and she was doing pretty well. Next she had a general neuritis; and then came her sudden death, apparently from gastric implication. In connection with this case, Dr. Folsom has alluded to similar cases, so far as the nephritis is concerned, which he has seen in the Boston City Hospital and in which autopsies had been obtained, the character of the kidney being generally the large, red, swollen kidney. Regarding the similarity of the process with the nephritis which we see in typhoid, it seems to me that, however it may be pathologically, there is a certain clinical distinction between them. Of course, the influenza is a disease which is vastly more common than typhoid; the number of cases affected is very much larger, consequently we might get the disease in a larger number of cases although not in a larger proportion of cases. I do not recall a case of typhoid fever in which I have seen such a very severe consecutive nephritis as I have seen following influenza.

Dr. M. H. Fussell: I have under observation at the present time at the University of Pennsylvania, at least two cases of acute nephritis, which we think are due to a previous influenza. One of the cases came to the dispensary complaining simply of malaise which had followed an attack of influenza. He had gone about to different doctors, no one seeming to think of examining his urine. We found on examination an unquestionable parenchymatous nephritis. This case, especially, points to the value of examining urine as a routine matter, as we do at that institution.

Dr. A. Jacobi: I wish to correct a mistake I may have made. I spoke of the nephritis of diphtheria and typhoid, not as a sequel of these diseases, but the ordinary affection which is found in the beginning and during the course of the typhoid and in the very first days of diphtheria. It is of the same nature as this one which is found during and after influenza, so far as I know.

Dr. A. H. Smith: It seems to me that the degree of intoxication resulting from grippe is perhaps greater than its ordinary clinical manifestations would lead us to suppose. I should regard these cases of nephritis as exemplifying that idea. I have seen recently as the result of the last epidemic, several cases in which there seem to be very marked cardiac degeneration. Taking the history now, of the several years of grippe which we can refer to, I think we may conclude that the phenomena that we observed during the prevalence of the fever are but a very small part of the damage which is likely to occur. In one of Dr. Baumgarten's cases he speaks of subnormal temperature. During the last epidemic I noticed that very frequently. It seems to me that a considerable proportion of the cases of grippe which I had last winter were followed by subnormal temperature, often persisting for a considerable time, which we may justly refer to an invasion of the nervous system by the grippe poison.

Dr. G. Baumgarten: Dr. Jacobi may be right in deciding that the usual nephritic condition in influenza is that of typhoid fever, yet I would like to point out that the condition in influenza is not always the same; that there are various forms; we have for instance, a hemorrhagic nephritis and a non-hemorrhagic nephritis, and we have nephritis which comes on during the acute stage of the disease, and nephritis which comes on much later. We have affections which result early in dropsical symptoms, and those which show no dropsy at all but develop very acute uremic symptoms. Finally we have chronic affections of the kidney which can with the greatest probability be traced to an attack of influenza and which has not passed through any acute stage of nephritis.

### Report on Immunity against Vaccination conferred upon the Monkey by the use of the Serum of the Vaccinated Calf and Monkey,

by Surgeon-General George M. Sternberg and Surgeon Walter Reed, U. S. A.

Dr. G. M. Sternberg: Three years ago at a meeting of this Association, I read a paper in which I gave the results of some experimental work which seemed to demonstrate the fact that blood serum from a recently vaccinated calf, a calf immune as the result of its vaccination, neutralized the potency of vaccine virus when it was exposed directly to such blood-serum. The method used was to expose the points charged with the virus directly to the blood-serum from the immune calf. Other points were exposed in the same way to the serum of a non-immune calf. The serum from the non-immune calf had no effect, while that from the immune calf neutralized the virus. I stated that there was an antitoxin in the serum of immunized calves which might perhaps be used for immunizing children or for the treatment of the disease. I continued these experiments on children in a different way. I wished to find whether the serum from an immune calf, or from a patient recently having had small-pox, would prevent the development of the vaccine vesicles after vaccination. I went to the orphan asylums in New York, and I had a considerable number of unvaccinated children put at my disposal. I vaccinated in some cases in one arm with bovine virus given to me by Dr. Griffiths of that city, while in the other arm I injected the blood-serum from the immune calf. In other cases I injected immediately in the vicinity of the vaccination of the same arm. I also obtained blood-serum from a recent small-pox

case. I went to the small-pox hospital, and there was a young woman just convalescing from a very severe case. She consented to let me have some blood. I drew from her arm some four or five ounces of blood in a sterilized test-tube, obtained the serum from it, and used that in the same way, injecting about five cubic centimetres, sometimes in one arm, sometimes in the other. I never have published the results of the experiments, because I hoped to continue them, and also because the results were negative.

Press of duties has prevented my continuing this line of work, so I suggested to Dr. Reed, the curator of the Army Medical Museum, that he continue these experiments; and he has done so, and I will now read his paper.

DR. WALTER REED briefly reviewed the work done by former investigators on this subject, then detailed his own experiments, concluding as follows:

Putting together the results obtained in these experiments and those given by Strauss, Sternberg and Copeman, it is believed that the following conclusions may be drawn:

(1) That the manifestations of vaccinia in Cercopithecus mona is as well marked as Rhœsus; but that in Cebus apella, an American monkey, vaccinia apparently runs a milder course.

(2) That by the injection of the serum of the blood of a vaccinated monkey it is possible to immunize Cebus apella against vaccinia, and that the immunity thus acquired may last for thirty days.

(3) That the serum of the blood of the vaccinated calf, when injected in large quantities may markedly retard the course of vaccination in the monkey.

(4) That this retardation of the vaccinia probably continues so long as there is present in the system of the vaccinated animal certain antitoxic substances contained in the serum; and that when these substances have been eliminated from the body, the process proceeds to a successful though somewhat modified course of development.

That the fact, first pointed out by Sternberg, that the serum of the blood of the vaccinated calf contains some antitoxic substances which can destroy the virus of vaccine lymph, would seem to be confirmed.

When, however, we come to inquire as to the practical use of the serum of the vaccinated calf, as a therapeutic measure in the treatment of variola in the human being, we are compelled to admit that this antitoxic substance appears to be present in such small quantities as hardly to justify its use. Unless the curative action of this serum against small-pox in man is many times greater than its immunizing effect against vaccinia in the monkey, the quantity required would be greater than could be practically used.

It remains for the discovery of some means whereby the antitoxin can be separated from the serum, or its quantity increased in the blood of the calf. Until this has been accomplished, the use of the serum for the cure of small-pox, except in enormous quantities, 1 to 50 of body weight, can hardly be expected to exert any curative action.

*(To be continued.)*

---

A MONUMENT TO LAVOISIER. — The French Institut has decided to open a subscription toward the erection of a monument to Lavoisier in Paris, his native city.

## Recent Literature.

*The Medical Register for New England.* By FRANCIS H. BROWN, A.M., M.D. Eighth edition. Boston: Damrell & Upham. 1895.

The fact that one edition of this Register succeeds another at regular intervals, and that the eighth edition has been reached, testifies sufficiently to its popularity and utility.

This last edition has been thoroughly revised and contains much new matter, especially in regard to Societies, Hospitals and Institutions of recent origin. It is a great convenience to all who have medical interests.

*Twentieth Century Practice.* An International Encyclopædia of Modern Medical Science, by Leading Authorities of Europe and America. Edited by THOMAS S. STEDMAN, M.D. In twenty volumes. Vol. II, Nutritive Disorders. New York: William Wood & Co. 1895.

The subjects treated in this second volume of the "Twentieth Century Practice," under the head of Nutritive Disorders, are: Addison's Disease and other Diseases of the Adrenal Bodies, Diabetes Mellitus, Rheumatism, Gout, Arthritis Deformans, Diseases of the Muscles, Obesity.

This forms a very interesting and important group of systemic derangements, which are still entirely in the hands of the medical practitioner, into none of which has the all-pervading surgeon's knife found an entrance.

The different subjects, in the order given, are treated by Sir Dyce Duckworth, of London; Dr. Carl H. von Noorden, of Frankfort-on-the-Main; Dr. Thomas J. Maclagan, of London; Dr. Henry M. Lyman, of Chicago; Dr. Archibald E. Garrod, of London; the late Dr. Dujardin-Beaumetz, of Paris; Dr. Max J. Oertel, of Munich. The titles of the contributions and the names of the contributors are in this instance a trustworthy indication of the value of the volume to the physician.

Those who are familiar with Maclagan's "Rheumatism: its Nature, its Pathology and its Successful Treatment"; with Lyman's "Practice of Medicine"; with Oertel's theses on Exercise in Affections of the Heart; with Sir Alfred Garrod's writings on Gout and Kindred Diseases, will find themselves at home in this volume. In general, however, these and the other well-known writers give here their maturer judgment and their enlarged experience, and the reader finds between two covers what he must otherwise search for in many different sources.

A very good index at the end of the volume adds materially to its value for the busy man.

*De l'Hysterectomie Vaginale.* By DR. EMILE BAUDRON. Paris. 1894.

The full title of this book explains its scope. It is an account of vaginal hysterectomy applied to the surgical treatment of bilateral lesions of the uterine appendages, and describes the operation of Péan. It is based on a study of the first two hundred cases of Dr. Paul Segond, and contains thirty-eight illustrations. It is of particular interest at this time when this operation is being actively discussed in medical circles.

THE BOSTON

# Medical and Surgical Journal.

THURSDAY, JUNE 13, 1895.

## A NEW THEORY REGARDING THE PHYSIOLOGY OF THE NERVE CENTRES.

It is not unnatural that the various revelations concerning the minute structure of the nervous system, which recent methods of staining are forcing upon us, should lead to new speculations regarding its physiological action. The researches of Golgi, Ramon y Cajal, and all who have followed in their footsteps must be regarded as perhaps the most significant histological advance of the last twenty-five years. It is certainly too early to determine all its physiological bearings, and we must look with interest, it may be, but at the same time with much scepticism, upon broad deductions drawn from anatomical data thus far at our disposal.

A bold theory in explanation of physical and even psychical processes has recently been formulated by Professor Matias-Duval, of Paris, on the basis of our present knowledge of nerve structure, of which we give the essence in the following paragraphs. The paper embodying his ideas was read at a recent meeting of the Société de Biologie of Paris. He first takes up the now almost universally accepted theory of nerve conduction by contiguity rather than by continuity, and speaks of the anatomical arrangement of the terminal processes of cells. As a result of this, it happens that the bridge of transformation of sensory into motor excitation, the reflex centre, is represented not only by a nerve cell, but by articulation of prolongations at a distance. Such agents as strychnia and potassium bromide modify reflex activity, by acting upon cell processes, instead of upon cells themselves. Such an idea is confirmed by what we know of the action of curare upon the terminal arborizations of motor nerves.

By an extension of this theory to all the nerve centres we are much better able to understand the anatomical conditions underlying such phenomena as memory, the association of ideas, imagination, and even to comprehend histologically the results of habit and education.

Thus, recently, E. Tauri[1] remarks, that, since every reiterated functional act causes hypertrophy of the locality of its occurrence, the repeated passage of nerve currents must provoke an hypertrophy of the nerve cells which are in function; if this hypertrophy take place in the sense of an increased length of a prolongation, it will diminish the distance between the parts which ought to communicate; when, by greater proximity, the passage from one to another neuron becomes much facilitated it also becomes unconscious; this is why habitual automatic actions are unconscious. But one may ask whether this be a question of proximity definitely established between the terminal ramifications, or of a facility acquired by these ramifications, through a veritable ameboid property of their protoplasm, of prolonging themselves at a given moment and retracting themselves at another moment.

Wiedersheim's investigations on the brain of Leptodera hyalina[2] and a certain analogy in olfactory cells would indicate the possibility of amebiform movements of nerve cells and their prolongations, in general. The hypothesis of such ameboid movements in the brain cells of man has therefore a certain basis in observed fact. We may, then, believe that the connections between nerve cells in nerve centres are not only by contiguity, pure and simple, but may be more or less intimate under varying circumstances. It may consequently be conceded that imagination, memory and association of ideas become more active under the influence of certain agents (tea, coffee) whose action without doubt (?) would be to excite the amebiform movements of the contiguous nerve extremities, to bring together their ramifications and facilitate the passage of nerve influence.

This conception, which ranks cerebral actions, even the most elevated, with histological processes similar to those which we observe in the ameba and leucocytes, would find its application in the analysis of the phenomena of sleep and waking, and would give us what he (Duval) designates as the *histological theory of sleep*. In an individual who is asleep, the cerebral ramifications of the sensitive central elements of a neuron (see the nomenclature of Van Gehuchten for sensitive neurons) are retracted just as, under the microscope, are the pseudopods of a leucocyte which is anesthetized by absence of oxygen and an excess of carbonic acid. The feeble excitations exerted upon the sensory nerves of a sleeping person provoke reflex actions, but do not pass on into the cells of the cerebral cortex; stronger excitations cause prolongations of the ramifications of the sensitive neuron and, in consequence, the current passes into the cells of the cortex, the result being an awakening, the successive phases of which clearly explain the re-establishment of a series of passages of the nerve current, which, previously, had been inter-

[1] Rivista Sperim. di Frenatria e Med. Leg., 1892.
[2] Anat. Anzg., 1890.

rupted by retraction of the pseudopodic ramifications. But, just as violent and non-habitual excitations will cause retractions in the ameba, in the same way, in man, special excitations will induce retraction of the pseudopods of neurons and the arrest of the corresponding nerve function (acts of inhibition, chorea from nervous interference); and by the same mechanism, violent and abnormal excitations will cause anesthesias and hysterical paralyses.

Researches by M. Azoulay on the pathological anatomy of general paralysis, by methods of Golgi-Cajal, have shown a partial atrophy of nerve tufts in certain motor elements; in other words, a partial disappearance of the pseudopodia of the neurons.

From this the author goes on to quote other evidence from the lower forms of life, and concludes as follows:

"The ideas which we have set forth are a legitimate development of these comparisons. The similarity between a neuron and an ameba may elucidate many other questions than those here indicated. To point out one more, we may show, by the light of this comparison, how vain and how lacking in *raison d'être* the famous hypothesis of the neurility or the indifferent conductibility by a nerve fibre ought to seem and, as a consequence, how much the ingenious but always unprofitable attempts of Paul Bert to induce union between a sensitive and a motor nerve lose in interest. These experiments, which formerly excited our enthusiasm, now seem to us without reason, or resolve themselves into the problem of discovering, after having cut the pseudopod of an ameba, whether this pseudopod can be made to unite with the body of another ameba."

Had the above ideas not been enunciated by a man of recognized scientific attainment, in all seriousness, we should have passed them by without comment. As it is, we can but wonder at the poverty of the evidence, which Professor Matias-Duval regards as sufficient for the maintenance of his hypothesis. It goes without saying that the matter under consideration is one of the utmost subtlety. It concerns itself with an ultimate problem, which to many minds has long been regarded as unsolvable by any means at the disposal of physical science. That imagination, for example, should find its explanation in the ameboid movements of cells and the pseudopodic retractions and prolongations of their processes, savors of anything but exact science.

Altogether to be deprecated, at the present state of our knowledge, are hasty generalizations from the rapidly accumulating but still few facts at our disposal. Psychology cannot fail to be the loser by the formulation of laws which are based on insufficient data, and exact medicine should not be called upon to labor under a heavier burden of unproved hypotheses, than she already has to bear. The ingeniousness of M. Matias-Duval's theory we cannot but admire; the foundation upon which it rests we must regard as altogether insufficient.

## A MEDICAL-PRACTICE LAW IN RHODE ISLAND.

ON May 16th, the Legislature of Rhode Island passed an Act Regulating the Practice of Medicine. This Act, a copy of which is before us, is to take effect sixty days after its passage, and provides that the necessary qualifications for practising medicine in Rhode Island shall be either "a diploma from a reputable and legally qualified medical college, endorsed as such by the State Board of Health," or satisfactory evidence that the physician desiring to qualify was reputably and honorably engaged in the practice of medicine in Rhode Island prior to January 1, 1892. Any person, not qualified as above described, must submit himself to such examination as the State Board of Health may require. Ten dollars must be paid by the applicant to defray the expenses of the examination.

Section 4 provides that no itinerant doctor shall be allowed to register or to practice medicine in any part of the State.

The Act further provides that the State Board of Health may refuse certificates, or revoke certificates already issued, to any individual guilty of grossly unprofessional conduct of a character likely to deceive or defraud the public. Appeal from the decision of the Board may be made to the Supreme Court, whose decision shall be final.

Section 6 provides that no discrimination shall be made against any particular school or system of medicine, and that women shall not be prevented from practising midwifery.

The penalty for violation of the law is a fine of fifty dollars for the first offence, and a fine of one hundred dollars and imprisonment for thirty days, or either or both, for every subsequent conviction.

The phrase "engage in the practice of medicine" within the meaning of the law is defined as opening an office for such purpose, or announcing to the public in any other way a readiness to practise medicine or surgery in the State.

The State of Rhode Island is to be congratulated upon having secured at length a medical practice law which is excellent in many of its provisions. The efforts which have been made for many years to secure such legislation have at length borne fruit in the passage of the Act of which we have given an abstract above, and these efforts would have been well worth while if nothing had been secured but the passage of the clause preventing itinerant physicians from practising in the State. The physical and financial harm done by these travelling quacks and impostors can hardly be overestimated.

Under the Act the State Board of Health is made responsible for the enforcement of its provisions, and will have entire charge of the examination of candidates and their credentials. Upon the intelligence, honesty and faithfulness of this board the value of the law to the people of the State will absolutely depend. Let them see to it that their work is well and faithfully done.

One clause in the law can well be criticised, namely, that one which allows women to practise midwifery without registration or examination, as if midwifery were a branch of medicine in which ignorant and fraudulent practitioners could do no harm, and therefore no legislation on the subject were required.

The law on the whole, however, is a distinct step in advance, and one which will undoubtedly accomplish much for the protection of the people of the State against unqualified practitioners.

## MEDICAL NOTES.

Bacteria in Clothing. — Dr. Leitz of Munich, according to *La Médecine Moderne*, has found that a little disc three millimetres in diameter, which has been placed upon a woollen stocking which has been worn, produced 356 colonies on nutrient gelatin. A cotton stocking gave 712 colonies. From a glove which had not been worn, 33 colonies were obtained. Among the colonies there are always a few pathogenic bacteria, the staphylococcus pyogenes albus being the commonest. Leitz has found the typhoid bacillus in clothing after twenty-one and twenty-six days; the anthrax bacillus obtained from cloth was virulent at the end of a year. An encouraging fact was that the linen of tubercular patients after profuse night-sweats, did not apparently contain the tubercle bacillus; the results of inoculation were negative.

A Special Football Lesion. — In the *Centralblatt für Chirurgie*, No. 16, 1895, is an abstract of an article by Magg (*Hospitals Tidende*) in which he states that he regards a subpatellar bursitis, a lesion which he has frequently observed in football players, as a special lesion due to the repeated action of the quadriceps femoris muscle in kicking.

The Association of German Alienists. — The Association of German Alienists will hold its annual meeting this year in Hamburg, on September 13th and 14th. The following are the principal questions on the programme: "The Diagnostic and Prognostic Significance of the Knee Phenomenon in Mental Diseases" (to be introduced by Dr. A. Cramer, of Göttengen); "Action-bringing Insanity in its Nosological and Forensic Relations" (to be introduced by Dr. Koppen, of Berlin); "Transitory Mental Disorders of Epileptics in their Medico-Legal Relations" (to be introduced by Professor Siemerling, of Tübingen.

Music for the Sick Poor of Paris. — A French gentleman, M. Guzman, has left 50,000 francs to the Assistance Publique, the Paris Municipal Charity Department, to defray the cost of musical entertainments to be given to the sick poor in the hospitals and asylums under its control.

Symphysiotomy at the Maison Bandelocque. — In the report of the Maison Bandelocque for 1894, Pinard reports that during the year 21 symphyseotomies were performed in the service, 12 on primiparæ and nine on multiparæ. Of the 12 primiparæ there was one death from septicemia with suppuration of the wound on the tenth day. Of the children 11 lived. Only one died during labor. Among these 12 cases, ten were face presentations, one of them being a brow. Among the nine multiparæ there was one death from puerperal sepsis. All the children were born alive, except one in whom numerous attempts at forceps delivery prior to admission to the hospital had produced multiple fractures of the skull. Of the 21 operations 17 were performed in cases of vertex, two of face, two of breech presentations. One woman had symphyseotomy performed twice with perfect result as to both mother and child.

### BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — During the week ending at noon, June 12, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 101, scarlet fever 38, measles 140, typhoid fever 7.

Hospital for Consumptives.—The bill to establish the Massachusetts Hospital for Consumptives and Tubercular Patients has been passed by the Massachusetts House of Representatives with an amendment making the establishment of the hospital mandatory instead of permissive.

The Massachusetts Medical Society. — The Committee of Arrangements for the meeting this year have, as stated in their announcement, made special efforts to make the visit of the members attractive and profitable. The arrangements for entertainment at the theatres and concerts, the harbor excursion, etc., can hardly fail to add greatly to the enjoyment of the visitors. The committee are to be commended for the enterprise shown in their preparations for the entertainment of the visiting physicians.

The American Neurological Association. — The members of the Association during their recent meeting in Boston were entertained at luncheon on Wednesday, June 5th, at the Hotel Vendome by Dr. James J. Putnam, Dr. Morton Prince, Dr. Henry R. Stedman and Dr. William N. Bullard. In the evening there was a reception to the members at the University Club, under the auspices of the Boston Medico-Psychological Society, to which were invited also the staffs of the Massachusetts General and Boston City Hospitals and the Faculty of the Harvard Medical School. On June 6th the Association accepted an invitation from the Trustees of the Massachusetts General Hospital to visit the new McLean Hospital at Waverly. The annual dinner took place at the University Club on Thursday evening.

### NEW YORK.

The Janitors of Public Schools. — In the future the public schools are not likely to be closed on account of the presence of contagious disease in janitors' families. At a meeting of the Board of Education held June 5th the report of the committee on

buildings recommending that all janitors be required to reside outside of the school-houses was taken up and adopted, and the Board voted to ask the Board of Estimate and Apportionment for $4,000 additional appropriation for janitors' salaries, or so much of that sum as may be necessary to enable them to secure living quarters elsewhere than in the school buildings.

Dr. Doty's Change of Route. — Health-Officer Doty, who started for Cuba recently, found when he arrived at Tampa that the United States Medical Inspector, Dr. Burgess, had left Cuba. Consequently he decided not to go there, and continued his trip to New Orleans, where he has been examining the new quarantine station.

Early Opening of the Swimming Baths. — Twelve of the fifteen free swimming baths situated along the East and Hudson Rivers were opened to the public on June 5th. This is considerably earlier than the usual date for opening, and the change was made on account of the intense heat of the early days of June.

Deaths from Heat. — On Monday, June 3d, the last day of the hot weather, the coroners were called upon to attend no less than fifty-eight cases of sudden death, a large proportion of which were due more or less directly to the heat.

Death of Dr. J. Marshall Hawkes. — Dr. J. Marshall Hawkes, of New York, died suddenly after an operation for the relief of complicated mastoiditis on May 26th. Dr. Hawkes was a graduate of the College of Physicians and Surgeons, New York, and was especially identified with orthopedic surgery. He was best known by his invention of the paper jacket as a support in disease of the spine.

Death of Dr. William B. Wallace and Dr. Alphonse M. Wallace. — Dr. William B. Wallace and his son, Dr. Alphonse M. Wallace, both died of pneumonia on June 7th. The elder Dr. Wallace was taken ill on May 25th. The attack was a very severe one, but he successfully passed the crisis and was thought to be on the way to recovery when he began to fail and he rapidly succumbed. He was born in County Limerick, Ireland, fifty-three years ago, and was educated for the priesthood at Mount Mellery College. He decided to abandon this career, however, and entered All Hallows' College, Dublin, where he took his degree in Arts. In 1868 he came to this country and studied medicine at the College of Physicians and Surgeons, New York, where he was graduated in 1871. He soon built up a large practice and at the time of his death he was visiting physician to the City Hospital (Charity) on Blackwell's Island, and consulting physician to St. Joseph's Hospital, Yonkers. It was as an ardent Irish patriot that Dr. Wallace was best known to the public. He was considered one of the most eloquent orators among his countrymen in America, and he was a leader in all the Irish national movements inaugurated here. He was one of the organizers of the Irish National Land League of America, and when that went out of existence, 1882, he was one of the chief promoters of its successor, the Irish National League of America. When the Irish Parliamentary party became divided owing to the Parnell divorce case, Dr. Wallace became an advanced anti-Parnellite, and with Dr. Thomas Addis Emmet and other well-known Irishmen, formed the Irish Federation of America, of which he was elected Vice-President, an office he held at the time of his death. The younger Dr. Wallace was a devoted watcher by the bedside of his father, and four days after the latter's illness commenced was himself taken with pneumonia. He died within twelve hours of his father. Dr. Alphonse Wallace was born in New York and was twenty-seven years of age. He was educated in the public schools and St. Francis Xavier College, and received the degree of M.D. from the College of Physicians and Surgeons in 1888. He afterwards served as house physician at St. Vincent's Hospital, and for four years had been an examining physician of the Department of Charities and Correction. He was a widower, his wife having died two years ago. They had no children. The elder Dr. Wallace left a widow, two sons and three daughters. The funerals of father and son were held together at St. Patrick's Cathedral on June 10th.

## Miscellany.

### SUDDEN DEATH.

In his book on "Death and Sudden Death," M. Brouardel gives a number of causes of sudden death which are little known, and fortunately extremely rare. Gonorrhea, for instance, may lead to sudden death. Four or five cases of sudden death from gonorrhea in the male have been reported in Germany. In France only one case has been reported. The medico-legal autopsy showed a phlebitis in the prostatic venous plexus and pulmonary embolism. Of a similar nature was the case of a girl of sixteen upon whom Brouardel performed the autopsy. A gonorrhea resulted in phlebitis of the veins of the left broad ligament, which was followed by thrombosis of the left iliac vein, and fatal embolism.

In such a condition as this, in a pregnant or a non-pregnant woman, with disease of the adnexa, or uterus, an ordinary vaginal examination may be the cause of sudden death. In addition to a case seen by Brouardel while he was an interne, he has twice seen cases of this sort, namely, sudden death from vaginal examination, in a physician's office. Lovain had a case in which sudden death of a young girl was caused by a vaginal douche given in the treatment of gonorrhea. It is well to remember that vaginal examination may have a result less grave, but none the less important from the point of view of the physician's responsibility. M. Tarnier has reported that two women upon whom he had practised vaginal touch aborted on the same evening, and that neither of them could[1] be suspected of having taken any measures to bring on abortion.

[1] La Médecine Moderne.

## THE LATEST REPORT ON ANESTHETICS.

At the German Surgical Congress, Gurlt, of Berlin, made a report on anesthesia, which is of great interest. During the year, he had examined 77 reports from operators, 63 of whom were Germans. The reports embraced 51,957 anesthesias, of which 31,083 were produced by chloroform, 15,712 by ether, 2,148 by chloroform and ether, 1,554 by A. C. E. mixture, 1,426 by bromide of ethyl, and 34 by pental. There were 23 deaths under chloroform, to which may be added eight in which the cause of death was doubtful, five deaths from ether, and none from the mixture.

The complete statistics of anesthesia now extend over 266,151 cases. Chloroform has been fatal in one out of 2,909, ether in one out of 6,004, ether and chloroform mixture in one out of 10,162, A. C. E. mixture in one out of 5,745. The ether statistics are therefore rather more favorable than those of chloroform, especially considering the doubtful cases alluded to above.

Severe pneumonia has followed etherization in a not inconsiderable number of cases, namely, 30, and has proved fatal in 15, of which 13 were operations on the abdominal cavity. The explanation of this is found in the fact that patients who have undergone abdominal section avoid coughing as far as possible, on account of the pain in the wound which it causes. Thus the pneumonia is allowed to progress. As far as possible, therefore, ether should be avoided in abdominal operations.

In the discussion which followed Trendelenburg and Landau spoke strongly in favor of ether as an anesthetic.

## Correspondence.

### "END OF A VACCINE VIRUS CONTROVERSY."

ROXBURY, MASS., June 7, 1895.

MR. EDITOR: — Owing to a similarity of names, there has been some confusion in regard to the legal controversy above referred to.

The plaintiff in that case was my mother, the widow of Dr. Henry A. Martin. Since the death of her son, Dr. Stephen C. Martin, the production of vaccine virus at Brookline has been carried on by A. A. Reed for a few months, and for the last year by Dr. Everett M. Bowker. Dr. Bowker did business under the title of "Dr. Everett M. Bowker, successor to Dr. Henry A. Martin & Son." My mother sought to enjoin him from the use of her husband's name of "Henry A. Martin" as a part of his business designation; but our Supreme Judicial Court has just decided that he may continue under this designation; in fact, deciding that the words "successor to Henry A. Martin & Son" are mere words of description, and not a part of his business name, and has dismissed her bill. This leaves the parties exactly where they were before any bill was brought, but does not give Dr. Bowker any additional rights whatever. He may continue to do business under the title of "Dr. Everett M. Bowker, successor to Dr. Henry A. Martin & Son," but that is all.

This legal controversy in no way affects my business of producing vaccine virus, which I have continued uninterruptedly since the death of my brother, Dr. Stephen C. Martin, under my own name.

The threat of prosecution at the end of the item referred to is plainly meant for me, but with the above explanation it will be seen that it has no foundation whatever, and is absurd.

Very respectfully,

FRANCIS C. MARTIN, M.D.

[The JOURNAL must consider this correspondence as closed. — ED.]

## METEOROLOGICAL RECORD,

For the week ending June 1st, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Amesbury | 10,920 | 4 | 0 | 25.00 | 25.00 | — | — | — |

Deaths reported 2,443; under five years of age 816; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 324, acute lung diseases 309, consumption 329, diphtheria and croup 113, diarrheal diseases 53, measles 62, scarlet fever 32, whooping-cough 19, typhoid fever 29, cerebro-spinal meningitis 6, erysipelas 6, small-pox 2.

From scarlet fever New York 14, Brooklyn 4, Philadelphia, Boston, Cleveland and Lawrence 2 each. Washington, Providence, Cambridge and Amesbury 1 each. From whooping-cough New York 10, Cincinnati 3, Brooklyn 2, Philadelphia, Boston, Providence and Cambridge 1 each. From typhoid fever Philadelphia 8, New York and Brooklyn 5 each. Boston, Cleveland, Fall River and North Adams 2 each. Washington, Cincinnati and Lawrence 1 each. From cerebro-spinal meningitis New York 3, Cleveland, Worcester and North Adams 1 each. From

erysipelas New York 4, Philadelphia 2. From small-pox New York and Cincinnati 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530 for the week ending May 25th, the death-rate was 17.4. Deaths reported 3,529; acute diseases of the respiratory organs (London) 245, whooping-cough 95, measles 84, diphtheria 64, diarrhea 55, fever 29, scarlet fever 26.

The death-rates ranged from 9.5 in Croyden to 27.3 in Liverpool, Birmingham 15.5, Bradford 17.3, Cardiff 15.1, Gateshead 12.0, Hull 14.9, Leeds 17.5, Leicester 11.8, London 16.3, Manchester 26.0, Newcastle-on-Tyne 21.4, Nottingham 17.9, Oldham 17.7, Sheffield 14.6, West Ham 18.6.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 1, 1895, TO JUNE 7, 1895.

So much of the order as directs CAPTAIN RUDOLPH G. EBERT, assistant surgeon, to report in person to the commanding officer, Fort Columbus, New York, for duty at that post is amended to direct him to report for duty at Vancouver Barracks, Washington, relieving CAPTAIN WILLIAM H. ARTHUR, assistant surgeon.

CAPTAIN ARTHUR on being thus relieved, will report for duty at Fort Columbus, New York.

Leave of absence for one month and fifteen days, to take effect on his arrival in New York City, en route to his station in the Department of the East, is granted MAJOR TIMOTHY E. WILCOX, surgeon, U. S. Army.

## OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 8, 1895.

J. E. GARDNER, surgeon, detached from Naval Station, New London, Conn., and wait orders to sea duty.

CLEMENT BIDDLE, passed assistant surgeon, detached from Naval Hospital, Chelsea, Mass., and to naval station, New London, Conn.

FRANKLIN ROGERS, surgeon, detached from U. S. R. ship "Wabash," and to the Navy Yard, Boston, Mass.

J. L. NEILSON, surgeon, detached from Navy Yard, Boston, Mass., and to the U. S. R. S. "Wabash."

## SOCIETY NOTICE.

AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION.—The fifty-first Annual Meeting of this Association (late Association of Medical Superintendents of American Institutions for the Insane, founded in 1844), will be held at the Brown Palace Hotel, Denver, Col., June 11, 12, 13 and 14, 1895.

HENRY M. HURD, M.D., *Secretary.*

## BOOKS AND PAMPHLETS RECEIVED.

Transactions of the Medical Society of Virginia. Twenty-fifth Session. Richmond, Va. 1894.

Early Diagnosis of Cancer of the Uterus. Chloroform in Labor. By Edwin Ricketts, M.D., Cincinnati, O. 1895.

A Modification of Hedin's Hematokrit. By W. F. Arnold, M.D., passed assistant surgeon, U. S. Navy. Reprint. 1894.

Malattie Predominanti Nei Paesi Caldi e Temperati. Dott. Filippo Rho, Medico di 1st classe nella Regia Marina. Roma. 1895.

The Significance of the Presence of Lactic Acid in the Stomach. By Julius Friedenwald, A.B., M.D., Baltimore. Reprint. 1895.

The Etiology, Pathology, and Treatment of Intestinal Fistula and Artificial Anus. By N. Senn, M.D., Ph.D., LL.D., Chicago. Reprint. 1894.

A New Method of Examination and Treatment of Diseases of the Rectum and Sigmoid Flexure. By Howard A. Kelly, M.D., Baltimore. Reprint. 1895.

Indigestion, an Introduction to the Study of the Diseases of the Stomach, by George Herschell, M.D., London. Second Edition. New York: G. P. Putnam's Sons. 1895.

The Surgical Treatment of Inguinal Hernia. By Henry O. Marcy, M.D., Boston, Mass. Reprinted from the Transactions of the New York State Medical Association, Vol. 11, 1894.

The International Medical Annual and Practitioner's Index; a Work of Reference for Medical Practitioners. By Thirty-seven editors. Thirteenth year. New York: E. B. Treat. 1895.

Infection and Immunity, with Special Reference to the New Diphtheria Anti-Toxine. By Charles Russell Bardeen, B.A., Assistant in Histology, Johns Hopkins University. Reprint. 1895.

Medical Gynecology; a Treatise on the Diseases of Women from the Standpoint of the Physician. By Alexander J. C. Skene, M.D. With illustrations. New York: D. Appleton & Co. 1895.

Leçons de Chirurgie (La Pitié 1893-94) par le Dr. Felix Lejars, Professeur Agregé à la Faculté de Médecine de Paris, Chirurgien des Hôpitaux, avec 128 figures dans le texte. Paris: G. Masson. 1895.

Transactions of the Sixteenth Annual Meeting of the American Laryngological Association, held in the City of Washington, D. C., May 30, 31 and June 1, 1894. New York: D. Appleton & Co., 1895.

A Bacteriologic Study of Oysters, with Special Reference to Them as a Source of Typhoid Infection. By Charles J. Foote, Demonstrator of Bacteriology in the Medical Department of Yale University. Reprint. 1895.

Seventeenth Annual Report of the State Board of Health of the State of Connecticut, with the Registration report for 1893, Relating to Births, Marriages, Deaths and Divorces. New Haven: Printed by the State. 1895.

Transactions of the Obstetrical Society of London (Vol. XXXVI, for the year 1894. Part IV, for October, November and December. Edited by William Duncan, M.P., Senior Secretary, and Percy Boulton, M.D. London: Published by the Society. 1895.

The Evolution of the Diseases of Women, by W. Balls-Headley, M.A., M.D. (Cantab.) F.R.C.P. (London.) Lectures on Midwifery and the Diseases of Women at the University of Melbourne. London: Smith, Elder & Co. Melbourne and Sidney: George Robertson & Co. 1894.

Fourth Biennial Report on Vital Statistics of the State of Minnesota for the Years 1892-93, With a Comparative Study of the Leading Causes of Mortality in Minnesota for the Quinquennial Period 1887-93. Arranged and Edited by Charles N. Hewitt, A.M., M.D., Secretary of the Board of Health and Vital Statistics. 1895.

Immunity, Protective Innoculations in Infectious Diseases, and Serum Therapy by George M. Sternberg, M.D., LL.D., Surgeon-General U. S. Army, Ex-President American Public Health Association; Honorary Member of the Epidermiological Society of London, of the Royal Academy of Medicine of Rome, etc. New York: William Wood & Co. 1895.

### THE TREATMENT OF ADVANCED (HOPELESS) CASES OF PHTHISIS.[1]

BY EDWARD O. OTIS, M.D.,
*Visiting Physician to the "Free Home for Consumptives."*

It is human nature to evince a more lively interest in any undertaking which offers a reasonable hope of success, than in one in which the result is inevitably failure.. This is true in medical work as well as in other departments of labor. The acute or chronic disease which possesses the possibility of a cure naturally excites in the physician that eagerness of the chase, that enthusiasm in its treatment which the hopeless case does not. Every true physician, however, with love and sympathy for his kind, recognizes the duty of employing the same conscientious care in the treatment of his hopelessly sick patients as in that of those who offer the possibility of a cure. "Here it is," says Musser,[2] "that the exercise of the high and holy qualities typified of old by the Master Physician are essential." Moreover, quite as much skill and judgment are often required in the care of the former class; and the experience one gains is not only of exceeding value but available in any and all varieties of medical work.

In this climate and region, advanced cases of phthisis are by far the most common of this hopeless class. Every general practitioner has his share of them. They are long drawn out and possess an infinitude of ills, and demand fertility of resources and a large knowledge and skilful use of therapeutic expedients. But it is no unworthy goal to strive for, to make the lingering and weary days of the consumptive as comfortable and free from pain as the conditions will allow. Surely no class of patients are more grateful to the physician for his exertions in their behalf.

A patient with advanced phthisis is very frequently in a state of sepsis, and presents the various symptoms of the septic condition; the peculiar temperature, sweating, chills, cardiac debility, progressive muscular weakness, and loss of flesh, etc. A clear recognition of this fact will aid greatly in our intelligent treatment. In addition, of course, there are the various symptoms which are the result of the tubercular virus and its ravages; cough, vomiting, diarrhea, hemorrhage, various digestive disturbances, pains, pleuritic and others; catarrhal and irritable conditions of the upper air-passages, nervous instability, insomnia, and others.

I. The Sick-Room. — Patients in this stage of the disease have their lung capacity greatly reduced; the average of a dozen male patients I found to be 90 cubic inches, the normal average being 235.7. Consequently they need a large supply of oxygen, and it is of the first importance that they should be in an airy, well-ventilated room. If one is well covered in bed or protected from a direct draught the window can almost always be kept open even in the colder portions of the year. An open fireplace is very desirable, and sunlight a necessity; it is a tonic and antiseptic and conduces to a cheerful mental condition. If we spent as much care and pains in giving our phthisical patients sunlight as we do creosote, I believe we should obtain as good results and in a more agreeable manner.

II. Food. — The feeding of these patients is a very difficult and delicate matter; more or less anorexia exists, the digestive powers are impaired, the appetite is capricious, and vomiting not infrequent. If the patient is able to be about, the three regular meals may be taken with supplementary lunches, such as milk and egg, koumiss, cream and hot water, bouillon, cocoa or coffee with bread or biscuit, a glass of porter, ale, or some light wine. Often no regular meals are possible the digestion and appetite are so impaired, and then one must have recourse to frequent feeding with small amounts of easily digested or partially digested food. Milk, either plain or with some alkali — lime-water or soda-water, Vichy, Seltzer, Apollinaris; raw eggs with a little alcohol in some form, sherry, whiskey, or port; carefully prepared soups; some of the various beef juices or extracts; peptonized foods. I have found the liquid peptonoids very serviceable; some of the malt preparations can also be used. Even with the most careful feeding various digestive disturbances will arise and persist which call for special treatment.

The most generally serviceable combination for these disturbances I have found to be the pepsin, bismuth and charcoal tablet of Wyeth, which seems to meet a variety of unpleasant symptoms. For flatulence aromatic spirits of ammonia, bismuth, bicarbonate of soda, tincture of cardamon, creosote or napthol. For pain after eating, Dettweiler finds salicylate of bismuth of service. For the anorexia nothing seems to avail for any length of time; the various bitter tonics in various combinations for a while aid — gentian, cinchona, quassia, quinine, nux vomica, strychnia, malt. The mineral acids may also be combined with some of these.

It was almost a routine practice in my service at the Free Home for Consumptives to give all, except the extreme cases, malt with creosote, often combined with cod-liver oil when no fever existed, and it has seemed to me that this combination not only assisted the appetite but the digestion as well. As to alcohol, I have used it freely in its various forms. Necessary, as a rule, in all stages of this disease, it is especially so in the advanced stage. I have found whiskey, brandy, and the malt liquors the most generally serviceable.

III. Fever. — The fever of advanced phthisis is generally the result of septic absorption from suppurating cavities or foci, and unless it produces unpleasant symptoms it is my experience that direct treatment is uncalled for, and is a menace to the already weakened heart. The inunction of guaiacol has been tried for this purpose and it does produce a most marked and rapid reduction in temperature but at the same time a depression which is often alarming, and the same danger exists to a less extent in the use of all the coal-tar antipyretics. The patient with fever should be kept in bed and free from excitement, given easily assimilable liquid nourishment, and from one-half to one hour before the expected rise of temperature a glass of Cognac and water or strong wine.

This is the plan pursued at the Sanitarium of Görbersdorf, and generally by the German specialists in this disease. An ice-bag over the heart is much used also by the Germans, but my limited experience is in accord with that of Wolff, that seldom does any

[1] Read before the Clinical Section of the Suffolk District Medical Society, March 20, 1895.

[2] The Treatment of the Final Stage of Phthisis, J. H. Musser, Medical News, Philadelphia, October 15, 1892.

definite result follow its use.[3] If the fever has daily exacerbations and is productive of much discomfort, we are obliged to have recourse to some direct antipyretic; antipyrine, thallin, antifebrin, salicylate of soda or phenacetine may be used, but cautiously. Daremberg[4] with the characteristic French enthusiasm, says the treatment of the fever of tuberculosis was revolutionized when Knorr discovered antipyrine, but few of us, I think, would agree with him. The antithermic, he says, should be used to prevent the rise of temperature rather than to lower it after it has risen, and consequently should be given three or four hours before the expected rise or exacerbation. Of the various antipyretics mentioned perhaps phenacetine is the least harmful and given in small doses as Yeo[5] recommends, two or three grains in combination with hydrobromate of quinine two to four grains. When antipyrine is used and there is an inclination to sweating, Székely[6] advises the use of atropia or agaracin half an hour before the antipyrine is given. It is also advised to give it an hour before, or two hours after eating. A preparation known as pyretine, the composition of which is unknown to me, and which was first called to my attention by my colleague, Dr. Fillebrown, has given me as good results with as few evil effects as any of the antipyretic group. Salicylic acid and salicylate of soda so highly extolled by Jaccoud[7] for the fever of phthisis, is especially useful, says Székely, in the fever of resorption (septic). It should be given, he says, in the late evening, and to avoid the annoying ringing in the ears, combined with ergot. My experience with it, however, has not been very satisfactory. If the fever is continuous no antipyretic is of much avail, but if used, should be given before the fever has reached its height, otherwise sweating and vomiting may be produced.

IV. SWEATING. — This is not an infrequent occurrence in advanced phthisis, and is another of the symptoms of the septic condition which prevails so largely as I have said in the latter days of the disease. Simple means will often serve to modify or avert this troublesome symptom; a glass of milk with two or three teaspoonfuls of brandy at bedtime, together with gentle friction either dry or with alcohol or vinegar and water. The drugs for this symptom are numerous: atropia, ergot, picrotoxine, oxide of zinc, camphoric acid, chloralose, extract of Coto bark (strongly recommended by Székely), and agaracin. Of all the antisudorifics I have used, agaracin has been the most satisfactory, given in doses of one-twelfth of a grain or larger; as its action is slow it must be given early. Atropia is efficient, but its after-effects are not always agreeable, and after my favorable experience with agaracin, I have abandoned its use.

V. COUGH. — No one symptom is so distressing to the patient and all about him as his cough; it harasses him by day and renders his nights wretched. From the very nature of the conditions he must cough much, for the material secreted from the various diseased areas is constantly collecting and must be expelled. This constant coughing keeps the mucous membranes of the upper air-passages in a state of continual irritation; so that the poor sufferer is subjected to a two-fold stimulus to cough, one from below and the other from above. Cough he must sufficiently to expel the secretion; but cough he does, as a rule, far more than is necessary to accomplish this. Now this unnecessary and useless coughing can, to a greater or less extent, be restrained by proper training. One must establish a coughing method, and learn how to cough with effect and economy of strength, and to restrain the dry, unproductive cough. Daremberg speaks of taking lunch at Falkenstein with Dettweiler and his one hundred and fifty phthisical patients, and not hearing a cough ten times in three-quarters of an hour. In expressing his wonder at so little coughing among so many tuberculous patients, Dettweiler replied that he taught his patients not to cough, by telling them that when they itched in public they did not scratch, and that cough without expectoration was a scratching of the throat which itched, and, therefore, they should not scratch the throat in public.

The medicinal treatment of the cough, and in this stage it must be treated medicinally, includes the whole materia medica pretty nearly; but opium in some form is the one drug upon which we must chiefly rely. As some one has said, "Without opium the treatment of phthisis would be impossible." My experience coincides with that of Wolff,[8] that codeia is the most useful form of this drug. It does not disturb the stomach as other forms of opium often do, and it quiets the cough. After a trial of a variety of cough preparations, I obtained the most satisfactory results when almost every patient in the hospital was put upon this drug. I used a watery solution in the proportion of 1 to 100. It can be given frequently, and a couple of teaspoonfuls of the solution at night will generally produce a good night's rest.

In most cases of advanced phthisis there is an irritable condition of the mucous membranes of the upper air-passages, the pharynx and larynx which, from the slightest cause, produces a cough of irritation. Local applications will aid us here. If the cough is caused by laryngeal irritation sipping ice-water will sometimes calm it. If the pharynx and larynx are in a chronic irritative catarrhal condition, we can first clean the surfaces by some alkaline solution like Dobell's, or warm borax and water, and then make such applications as cocaine, menthol, insufflations of morphia, iodoform and starch, inhalations of balsamic vapors, or a solution of nitrate of silver. Almost every phthisical patient has a paroxysm of coughing in the morning, on arising, if he is well enough to get up, or upon taking food. This is a cough of expectoration, and all we can do is to make the paroxysm as short, easy, and effectual as possible. A glass of some warm alkaline drink, Apollinaris, soda, Vichy, or Seltzer water with a little alcohol in it, brandy or rum; or a glass of warm milk and water with a little bicarbonate of soda and common salt in it, will often accomplish this.

VI. VOMITING. — This is an annoying symptom after taking food; and the cause, as given by Yeo, and which seems to be reasonable, is the increased secretion in the air-passages, already in a catarrhal state, caused by the stimulus of the circulation by the food and the rapid absorption of fluid from the surface of the stomach. Acting on this theory, he gives about half an hour before a meal, a glass of hot milk with some alkaline water (Ems, Seltzer, or the like), with a tablespoonful of brandy or whiskey, and so

[8] Die Moderne Behandlung der Lungenschwindsucht.

favors free expectoration, just as previously mentioned in the morning paroxysm of coughing. The meal should consist of as little fluid as possible; and immediately after it a few grains of pepsin, with a few drops of hydrochloric acid, is given. I have followed this plan partially with more or less success. Peter, quoted by Yeo, ascribes vomiting to the irritation of the gastric portion of the vagus by the contact of food, and just before the meal he gives a rapidly absorbable sedative such as a few drops of laudanum in a teaspoonful of water, and immediately afterwards three drops of hydrochloric acid in water. If the vomiting seems to be caused by laryngeal irritation, local applications of astringents and anodynes can be used. If digestive disturbances seem to be the cause of it, antifermentatives such as carbolic acid, creosote, napthol, charcoal, iced lime-water, Vichy, soda-water and the like, may prevent it. When it is an oft-recurring symptom, perfect rest in bed and frequent feeding with a small amount of easily digestible nourishment, such as liquid peptonoids or peptonized milk, will aid greatly.

VII. Pains. — The phthisical patient in this stage complains of many and various pains and aches — pleuritic, painful affections of the intercostal nerves; pains in the back, joints, abdomen, muscles, etc. The variety of local applications is great, and one after another has often to be tried: Tincture of iodine; dry heat by means of dry cloths and the hot-water bag; belladonna, in liniment or plaster; chloroform; and, what I have found perhaps as efficacious as anything, equal parts of guiacol and glycerine painted over the painful area. If the pain is pleuritic and aggravated by respiration, and situated at the base of the chest, strapping with adhesive plaster, diagonally applied, as first suggested by Roberts, restrains the respiratory movement, and consequently stops the pain. If the pleuritic pain is at the upper part of the chest, one must have recourse to some counter-irritation.

VIII. Diarrhea. — This is either septic, or due to gastric or intestinal irritation, or perhaps most frequently in this stage, is the result of tubercular ulceration. If septic, salicylic acid or napthol may be used. When the diarrhea is not dependent upon intestinal ulceration, milk and lime-water, and tannate of bismuth are serviceable. If tubercular ulceration exists we can only hope to mitigate it, and opium with bismuth and some astringent have served me the best. Yeo and Székely recommend highly extract of Coto bark; a solution of nitrate of silver can also be used per rectum. The patient must be kept quiet in bed and given some partially predigested food like liquid peptonoids or peptonized milk.

IX. Hemorrhage. — Hemoptysis occurs in this stage as in the earlier ones, and, in the main, requires the same treatment — perfect rest in bed, an ice-bag over the heart region, and opium in the form of morphia, or codeia, with the addition of ergot subcutaneously if indicated. I believe that in the hemoptysis of this stage more or less alcohol is of benefit, contrary to the common usage in the treatment of this symptom. Cold liquid food is always recommended, and ice. Daremberg mentions "a very useful application" which is new to me, ice to the testicles or vulva; he applies it twice a day, and keeps it in contact with the skin about five minutes. He mentions the case of a consumptive who always carried a box of ice with him when he travelled; he had so much confidence in this practice. In the profuse, sudden, and alarming attacks of hemoptysis in advanced cavity cases, Yeo recommends frozen compresses as "one of our best resources."

X. Insomnia. — Sleeplessness is a frequent and trying symptom, not only as a result of the cough, but from the unstable, nervous condition. Some simple nourishment at bedtime, or a glass of wine or whiskey and water may produce the desired result; if not, I use some one of the non-depressing hypnotics — trional, chloralamid or sulfonal. The two former I have found the most satisfactory, in doses of ten to fifteen grains.

XI. Edema. — Edema of the lower extremities often ushers in the final event, as if the poor sufferer's cup of woe was not full. I know of nothing better for this painful symptom than a comfortable position in bed, gentle friction with alcohol and water, a light bandage, or wrapping the limb in some soft material like cotton or woollen.

XII. The mouth, tongue, and lips need attention at this stage. For the apthous condition of the mouth and tongue frequent cleansing with some alkaline wash, such as Dobell's solution or a boric-acid lotion is comfortiug; tincture of myrrh or menthol in almond oil can also be used. For the dry, parched lips, camphor-water and glycerine, benzoated oxide of zinc ointment, simple glycerine or cold cream.

XIII. This stage is accompanied with more or less anemia, and calls for iron when it can be borne. I have used quite extensively a preparation known as pepto-mangan, first called to my attention last winter by Dr. von Ruck, of Asheville. It is easily assimilated, causes no disturbance of the digestion, and can be continued for a long time.

XIV. The heart sympathizes with the general condition, and cardiac debility and irritability is a constant concomitant of this stage. The pulse is feeble, quick, easily compressed. For this condition I have found strychnia invaluable, and during my service the majority of the patients are taking it. It is not only a most efficient heart tonic, but it influences favorably many of the other symptoms. It is an admirable tonic in anorexia, relieves constipation, is a good respiratory stimulant in dyspnea, will often relieve vomiting, moderates the cough, reduces nervous irritability, and relieves many of the various pains of this stage of the disease. Indeed one is inclined to share the enthusiasm of Mays,[1] who places this drug third in importance in the prominent measures which he employs in the treatment of this disease, putting only physical rest and nutritious food before it.

Such in brief seem to be the main features in the treatment of advanced cases of phthisis. It is necessarily a symptomatic one, and I have only attempted to deal with the more common and prominent symptoms. Their variety indeed is legion, taxing to the utmost the skill and patience of the physician; but he has his reward in the satisfaction of knowing that he has at least smoothed the downward way of the weary traveller, as well as gained for himself added skill and experience in professional work. It is a losing fight at the best, and both the patient and physician know it; but the gratitude of the one, and the satisfaction of the other in duty well and patiently performed, mitigates the bitterness of defeat.

"The physician who treats phthisis," says Dett-

[1] The Strychnine Treatment of Pulmonary Consumption, by Thomas J. Mays, 1894. Reprint.

weiler, "needs the greatest patience and self-sacrifice, and genuine sympathy for the sufferer, and must, therefore, as Nothnagel beautifully expresses it, 'Auch ein guter mensch sein, soll er ein guter Lungenarzt sein.'"

## PUERPERAL SEPTICEMIA, WITH CASE.

BY JOHN Z. CURRIE, M.D., S.M., PH.D., CAMBRIDGE, MASS.

FOR various reasons puerperal septicemia is one of the most important diseases with which the medical practitioner has to contend. Notwithstanding the fact that our increased knowledge respecting its cause and nature and the consequent improvement in the means resorted to for its prevention and cure, have reduced the frequency of its occurrence and somewhat lessened the rate of mortality from this source, the fact remains that this disease is liable to occur in the practice of any obstetrician, frequently when least expected, and is even under the most favorable circumstances an affection of an extremely grave character. The rate of mortality from this disease is still extremely high; when death occurs it is under circumstances which are peculiarly sad and likely to excite a great deal of comment; moreover, some one who has been connected with the case, usually either the doctor, or nurse, or both, is almost certain to be censured. There are other reasons also why puerperal septicemia is one of the most undesirable diseases which can occur in any practice: recovery is usually slow and frequently imperfect, treatment requires a great deal of personal attention on the part of the medical attendant and when the nature of the disease becomes known it does not in any sense contribute either toward the excellency of the physician's reputation or to the increase of his professional business.

Considerable discussion has arisen at different times in reference to the use of the term puerperal septicemia, but if it be understood that puerperal septicemia differs from septicemia occurring under ordinary circumstances, only in the peculiar conditions under which it occurs, no uncertainty should exist as to the precise character of the disease referred to. It is simply a case of wound infection, and various terms are applied to the resulting conditions, according to the parts or organs chiefly affected. As has been pointed out by Dr. H. C. Ernst, for its production there is required the same combination of circumstances as for the production of septicemia in any other case, namely, (*a*) a specific virus, (*b*) a means of entrance for the virus into the system, and (*c*) a constitutional condition which under existing circumstances favors the development of the disease. In this case the specific virus is a pathogenic bacterium, the result of a morbid process which has either taken place within the genital tract or has been communicated from without by something which has come in contact with the parts. The wounded genital tract furnishes abundant means of entrance for the bacteria either at the original placental site, where a rent or abrasion has occurred, or even where the mucous membrane has been denuded of its epithelium. The reduced vitality of the parturient woman, the result of gestation increased possibly by a protracted labor or an excessive hemorrhage, together with the difficulty which exists of keeping the wounded parts in a septic condition, renders the woman particularly susceptible to infection.

I have selected the following case, which occurred in my own practice quite recently, not for the purpose of giving a detailed statement of its progress from day to day, but because it illustrates in a marked degree certain important peculiarities of the affection under consideration and because it affords an opportunity for a practical illustration of such treatment, as, in my opinion, is most likely to promote a cure.

Mrs. ——, a healthy, robust woman, aged twenty-one years, was delivered of her first child April 19, 1894. The labor, although somewhat tardy during the second stage, was quite natural and completed without interference of any kind. The external parts were small and somewhat rigid and in order to prevent a rent posteriorly a slight cut was made on each side of the vaginal outlet during the expulsion of the head. Notwithstanding this a small rent occurred posteriorly during the passage of the shoulders. The placenta and membranes were expelled intact with comparatively no assistance and but little hemorrhage followed. After the vaginal canal was well washed out and the rent properly cleansed, it was repaired and covered as well as possible with an antiseptic dressing. The rent was quite superficial but two stitches being required to retain the parts in apposition. For the sutures kangaroo tendon of moderately large size and which had been purchased ready for use, was used.

The progress of the case for the first three days was uneventful. The secretion of milk was established by the third day. There was no increase of temperature at any time up to this period and no discomfort of any kind was experienced. On the morning of the fourth day the patient's appearance had changed sufficiently to attract attention and upon inquiry it was learned that she had a slight chill during the early morning. The chill was very slight there being no rigor and no external appearance of its occurrence. It consisted simply of slight, creepy, chilly sensations, referred especially to the back and lower extremities. When I saw her about three or four hours afterward, the face was flushed, skin dry and hot, tongue dry and somewhat furred, temperature 105°, pulse 126. There was constant complaint of headache, great thirst and "bad taste in the mouth." Later the tongue became thickly furred, there was profuse and almost constant perspiration. Jaundice was apparent on the second day of the attack, and on the third day diarrhea occurred. The stools were liquid, of light color, very offensive, and soon became involuntary. Food was taken in fair quantities throughout the attack, was well retained and caused no inconvenience. The secretion of milk was not suppressed until near the end of the attack. After the occurrence of the diarrhea the pulse fell to 108 and the temperature to 103°. The highest temperature attained at any time was 105.3° on the morning of the second day. This condition continued for about seven days when improvement in every respect began. The temperature fell to 101° and pulse to 98. The jaundice gradually disappeared, control over the action of the bowels was regained, perspiration became less profuse and the desire for food more marked. Internal examination within four or five hours after the occurrence of the chill revealed an unhealthy condition of the edges of the posterior rent. The tendon in the most superficial stitch was apparently unchanged and was surrounded by a small but appreciable amount

of pus. As far as could be ascertained at this time, in approximating the edges the tendon had been drawn through the skin on one side. Several small lacerations were found within the vagina and the external os was considerably lacerated. Each portion of broken surface was covered with a grayish pseudo-diphtheritic membrane. The uterus was large, uncontracted, loose and flabby and the outline difficult to trace. The external os resembled a loose opening, unhealthy in appearance and studded thickly with pseudo-diphtheritic patches. The uterine cavity contained nothing but the ordinary amount of discharge and a small amount of *débris*. No shreds of membrane, clot or anything else likely to cause infection were found.

The treatment resorted to in this case was as follows. The uterus and vagina were well irrigated with hot water. The uterus was then emptied of its contents, a sharp curette being used for the purpose. Another warm-water injection was used followed by one of bichloride of mercury, 1–2,000. Every portion of broken surface about the cervix uteri and within the vagina was cauterized with stick nitrate of silver, and subsequently dressed with a powder composed of equal parts of iodoform and boracic acid. The unhealed portion of the external wound was re-opened, the remaining tendon removed and after being properly cleansed and cauterized, the wound was dressed with the powder just referred to. Every rent or abrasion was treated in the same manner. For several days the uterine cavity was washed out with warm water followed by a mild antiseptic solution, once daily, the vaginal cavity twice daily, and every portion of broken surface was either cauterized or well covered with the powder once daily as appearances indicated. As improvement took place the wash was used less frequently; and as the sores assumed a more healthy condition, powdered oleate of zinc was substituted for the powder before used. At the end of the second week after the chill, and after all applications excepting the vaginal douche had been discontinued, another chill occurred. This was more pronounced than the first, but was not an actual rigor. The general condition of the patient after the second chill was much the same as after the first and all the symptoms which resulted were about the same as in the first instance, excepting that the jaundice and diarrhea were less marked. A vaginal examination revealed the presence of a large sore of the same appearance of those before described, in the fold between the cervix uteri and the posterior vaginal wall. The same treatment was resorted to as in the first instance and after about five days, improvement again began. Recovery after this was uninterrupted but not rapid. Constitutional treatment was supporting and symptomatic. Quinine was given in one large dose at the outset, and afterward in four-grain doses every five hours. Occasionally phenacetine was given to relieve restlessness or headache, or if the temperature for several hours exceeded 104° and was not reduced by alcohol baths. The exhibition of phenacetine was never trusted to the nurse. Milk, or some form of liquid nourishment, was given every two hours during the day and at night, in such manner as would least disturb the patient. In about five weeks after the birth of her child, the patient apparently needed no further attention, and has remained quite well up to the present time.

The treatment just described gives a fair general idea as to what course, in my opinion, should be pursued in every case of puerperal septicemia; and just in proportion as this treatment is resorted to at an early date and carried out effectually, will be the number of recoveries.

An examination of the whole genital tract should be made at once; and even although a probable source of infection may be discovered, no part of the genital tract should be omitted in consequence of that. After thoroughly washing out the vagina, it is better to begin by treating all external broken surfaces, if there be any. Then every portion of the vagina and the cervical canal, as far as possible, should be exposed, and abrasions and lacerations sought for. Each of these, after being thoroughly cleansed, should be cauterized. This not only insures destruction of all septic material at that point but also seals the broken surface temporarily and promotes repair. Garrigues recommends that equal parts of chloride of zinc and water be used for this purpose and that it be kept in contact with the part for at least one minute. This, however, is very painful, and difficult to apply at all extensively without an anesthetic. I have been accustomed to use stick nitrate of silver for this purpose and always with apparent good effect; it acts very promptly, destroys the virus sufficiently, does not injure the tissue deeply, and seals the opening effectually for the time. When this has been done the uterine cavity should be washed out with warm water and then thoroughly emptied of its contents. For this purpose a large, moderately sharp curette is most desirable and if used with care no ill-effect should result from its use. Some operators prefer a dull curette, while others are satisfied with swabbing out the uterus with antiseptic gauze or other soft material, especially in mild cases. No doubt one operator succeeds better with one instrument while another does the work more effectually with another. The means by which the uterus is emptied is not of so much importance as that it should be done thoroughly and without injury to the organ.

In November, 1894, Alberti reported the case of a woman who was curetted for retained placenta and in attempting to remove the material which had been scraped away, a small loop of intestine was drawn down. Notwithstanding all the effort which was made she subsequently died in consequence of the uterus having been punctured by the curette. The curette should be used carefully to avoid injuring the weakened, flabby walls, but at the same time every portion of the internal surface of the uterus should be gone over and all the contents including the diseased decidua should be removed. A curettement under existing circumstances is much more difficult than under ordinary circumstances, owing to the enlarged cavity and non-resisting walls. In a case of moderate puerperal sepsis, which occurred in my own practice not long since, after the curettement the patient's condition was still very unsatisfactory, and the operation was repeated on the following day. It was then seen, as had been suspected, that the first attempt had not removed all the contents. In all probability, in many instances of this kind in which no improvement follows the use of the curette, the explanation is that the uterine cavity has not been thoroughly emptied of its contents. The point sought to be accentuated is that the uterus should be completely relieved of any accumulation at as early a moment as possible and without

injury being inflicted upon the organ. The cavity should then be washed out with warm water which has been boiled, followed by a moderately strong antiseptic solution. If the antiseptic selected be one of an actively poisonous nature, it should be followed by another warm-water douche to prevent any danger from absorption. The manner of giving the intra-uterine douche is of considerable importance, as serious accidents have resulted from its use. Rather than to trust to any of the complicated instruments devised for this purpose, it is better to see that there is ample space for the return of the injected liquid and that it actually does all return. If even a small quantity remain within the uterus, it frequently occasions a severe uterine colic. While this may not be a very serious matter, the pain is sometimes very great and produces considerable constitutional disturbance. It is well to remember that at this time the uterine cavity is simply a loose sac, and that there is nothing to favor the outflow of the liquid excepting gravitation. After the liquid has ceased to flow from the uterus, the cervical canal should be gently opened and depressed until no more liquid escapes. If there be no tenderness over the region of the uterus, external pressure and turning the patient on the side favor the return of the liquid. It is better to introduce the liquid at the fundus, as this favors its return and insures its coming in contact with the whole cavity. It is better also that the liquid should enter the uterus by force of gravitation than that any additional force should be used. In this way the force is not great, the flow is steady, the return of the liquid is likely to be established at once and the danger of its being forced in any harmful direction is reduced as largely as possible. It is also well to use a soft instrument for entering the uterus. I have known a uterus so attenuated that a Simpson's sound punctured the wall simply by its own weight. I have learned of another case also, in which the uterus, soon after death, when laid over the end of an upright Simpson's sound, apparently offered no resistance whatever to the entrance of the instrument through its walls. For this purpose I frequently use a soft-rubber male catheter. With a sound in the eye it is easily carried to the fundus and there is comparatively no danger of inflicting injury.

The most desirable intra-uterine injections are a two-per-cent. solution of carbolic acid or creolin, or a solution of bichloride of mercury, varying in strength from 1 to 2,000 to 1 to 4,000. In my opinion, especially in serious cases, for the first injection at least, a moderately strong solution of bichloride of mercury is by far the most reliable. For subsequent use a weaker solution of the same character or a carbolic-acid solution should be substituted. Creolin is somewhat objectionable on account of its color. When using creolin in this way it is impossible to judge accurately of the character of the discharge which is present. The use of eucaline in the proportion of 1 to 100 of water has recently been recommended for this purpose. It is one of the coal-tar products combined with eucalyptus and it is alleged that while it possesses all the virtues of creolin as an antiseptic, its use is not objectionable on account of its color. For simply cleansing the vagina, in my opinion, there is nothing so agreeable to the patient, and at the same time so effectual as one or one-and-a-half per cent. solution of lysol. After the use of the intra-uterine douche an iodoform suppository should be placed within the uterus and carried up to the fundus. It is occasionally difficult to accomplish this with ordinary dressing forceps, and there is some liability of injuring the uterus by their use. It is much more easily accomplished with a long, curved instrument made for the purpose; some authorities recommend that the uterus be measured with the forceps before inserting the suppository in order to insure its reaching the fundus. Garrigues recommends that a suppository containing about 40 grains of iodoform be used once daily, after the intra-uterine injection, until the sloughs come off and the fever abates. After this it is of the utmost importance to secure and maintain perfectly free drainage. In general, especially at the beginning of the disease, the entrance to the uterus is so relaxed that no effort in this direction is required. When necessary, drainage should be secured by packing lightly with antiseptic gauze. Some recommend that this be done in all cases; but if the passage be free and intra-uterine injections are used as suggested once daily, there is no apparent necessity for it and it is just possible that in some cases the gauze might act as an obstruction rather than otherwise.

After-treatment may depend very largely upon existing circumstances; however, an examination should be made at least once daily and if there be any foul discharge from the uterus, the intra-uterine injection should be repeated and the iodoform suppository placed in the uterus as before. Each sore should be observed at least once daily and either cauterized or dressed with an antiseptic dressing, as appearances may indicate. As long as there is any tendency to the formation of membrane, cauterization has a better effect than anything else. Patients seldom complain of any pain from its use. As an antiseptic dressing the powder before referred to composed of iodoform and boracic acid, answers the purpose very well. It has the advantage of being easily applied by an insufflator and of adhering to the parts for some time. When the sores do not heal readily, after the sloughs come away, I have found the daily application of finely powdered oleate of zinc especially useful. Daily inspection should be continued until all broken surfaces are either healed or are in a healthy condition although improvement may have taken place in other respects. If a single point be overlooked fresh infection may occur.

As to constitutional treatment no general rules can be laid down. Quinine is undoubtedly useful and should be given in four or five grain doses every five hours. It is claimed by some authorities that quinine in addition to its tonic properties, possesses the power of preventing the emigration of the leucocytes from the veins and capillaries, and is thus especially useful in these cases. As in all similar cases it is of importance to nourish the patient as well as possible, but as to how this can be done most effectually can be determined only by the circumstances in each case. Some authorities recommend the free use of stimulants in in all cases from the beginning of the attack, but the legitimate use of stimulants in these as in all other cases appears to be, to withhold them until a stimulant is actually called for and to depend upon the various forms of food for nourishing the patient.

The first interesting feature in the history of the case referred to in this paper, is, its unexpected occurrence. In my judgment there was no legitimate reason to anticipate an attack of this kind under ex-

isting circumstances. The labor was normal, not of unusual duration or severity, was conducted on strictly aseptic principles, and completed without interference of any kind. Internal examinations were made very infrequently, external manipulation being relied upon very largely to determine the progress of the case. The hands were thoroughly prepared before any examination was made, and never entered the genital tract without being held in an antiseptic solution prepared for that purpose; moreover, the patient was a strong, robust young woman and apparently was not much exhausted by the labor. Within twelve hours after the completion of the labor, I attended another case of parturition, in which the circumstances were almost identical, excepting that the labor was shorter. The child had evidently been dead for some time, as it, as well as the retained discharges, had undergone decomposition to such an extent as to be extremely offensive. The manner of conducting the labor was the same in each case, and no greater effort to prevent infection was made in the latter than in the preceding case. This woman made an excellent recovery. In the first case, without any legitimate reason to anticipate such a result, a septicemia of so malignant a nature as to threaten destruction to life in a very short time was suddenly developed, whereas, in the second case in which some danger of septic infection might reasonably have been expected, recovery was rapid and without any interruption.

Another interesting feature in connection with this case is, that notwithstanding the violence of the attack, and the rapidity with which such extremely grave symptoms were developed, there was no well-marked chill at the outset, and no increase of temperature at any time previous to the slight chill on the morning of the fourth day. The second chill was decidedly more pronounced than the first, and yet the symptoms following it were not in all respects so alarming as at the beginning of the attack. This, I think, is a forcible illustration of how little reliance can be placed upon the occurrence or character of a chill as indicating the beginning or gravity of an attack of this kind, and of how easily one might be misled and valuable time lost. Another point of interest in this case is the fact that, notwithstanding the prolonged constitutional disturbance and the continuance of a moderately high temperature for some time, the secretion of milk was not wholly suppressed throughout the entire attack. The amount of milk secreted was such as to give hope that as convalescence progressed this function might be wholly restored. This, however, was not the case.

Still another feature to which I wish to refer, is the recurrence of the attack. This undoubtedly was due to the sore in the fold between the cervix and posterior vaginal wall being neglected before it was healed. This point is, under existing circumstances, the most difficult of inspection of any part of the vagina. It is also the most difficult to treat and keep in a cleanly condition, and so it is here that re-infection is most likely to occur. Unfortunately a knowledge of this fact does not always prevent its occurrence as in the present instance, but a result such as this should emphasize the necessity of keeping every portion of broken surface under observation until repair has taken place to such an extent as to prevent the possibility of infection taking place.

Another matter worthy of notice in this case is the particularly loose and flabby condition of the uterus. While this condition, to a greater or less extent, is common to all cases of puerperal septicemia, in this case it was particularly marked, the external os and cervical canal being quite unrecognizable as such and the entire shape of the uterus being lost. The point to which I wish to call attention is that, in my opinion, this condition obtains to a greater or less degree in proportion to the gravity of the attack, and that the earliest indication of improvement is seen in the return of tone to the uterine muscles. The first indication of the uterine muscles regaining tone is seen in an attempt at contraction, which can first be recognized in the rounded outline of the external os. This occasionally precedes but is usually coincident with the first fall in the temperature. I am not aware that this statement has been made by an authority upon this subject; but, from my own experience, I am so convinced of its truthfulness that I have come to estimate the progress of the case, very largely from the appearance of the os and cervix as disclosed by the speculum.

## ABDOMINAL HYSTERECTOMY IN THE TREATMENT OF SEPTIC PELVIC DISEASE AND FOR CANCER OF THE OS UTERI.

BY J. C. IRISH, M.D., LOWELL, MASS.

In the treatment of pus-tubes and other pelvic abscesses, especially when due to an extension from the uterus of septic infection, removal of the tubes and ovaries has failed to cure the patient permanently in quite a large proportion of cases. After the operation the infected uterus has become an entirely useless organ, deprived of the support of the broad ligaments, and sometimes the seat of a permanent septic invasion. In this condition of disease it is without doubt the starting-point of many reflex disturbances.

Deprived practically of all support the uterus becomes displaced, congested, and the source of a very intractable leucorrhea. For these reasons hysterectomy, which adds little, if anything, to the danger attendant upon the removal of tubes and ovaries, is now being quite generally accepted as a substitute for oöphorectomy.

Therefore in the treatment of most of these cases the question of operative procedure is reduced to a choice between vaginal and abdominal hysterectomy. It is to the question of our choice between these two operations, not only in septic pelvic disease, but also in cancer at the mouth of the uterus, that this article refers. My conclusions will be deduced entirely from personal experience with the two operations.

In septic diseases of the uterine adnexa, Péan and his followers do vaginal hysterectomy. Following the lead of the French surgeons, several distinguished American gynecologists are advocating the vaginal operation as preferable to the removal of the infected uterus and its diseased appendages by the abdominal route. The trend of professional favor at this moment in the treatment of these cases seem to be toward vaginal hysterectomy almost to the exclusion of the abdominal operation.

Until the advent of the Trendelenburg table, in cases of cancer of the uterine neck, vaginal hysterectomy was the only operation practically possible. But now in these two widely different diseases, pus-tubes

and cancer of the os, we have the choice between vaginal and abdominal hysterectomy. From my own experience I believe that in all cases of pelvic disease requiring the removal of the uterus and in a majority of cases of cancer of the os, complete abdominal hysterectomy is the safer, simpler and more successful operation.

In cases of pelvic suppuration, extensive adhesions of omentum and intestines to the diseased structures is an almost constant complication and oftentimes a very serious one. These adhesions can certainly be dealt with much more easily through the abdominal incision, than through the vagina. With a patient nearly in the complete Trendelenburg posture we can most readily and carefully separate pus-sacs from surrounding tissues. Whenever the abscess has opened into the rectum or bladder the fistulous opening in either of these viscera is well within our reach for repair. I have had occasion three times to close such openings in the intestine, in all of which the closure was permanent.

When doing hysterectomy through the vagina such repairs would be impossible. In the abdominal operation, it goes without saying that we can ligate more easily the ovarian arteries, and the uterine arteries fully as safely and readily as is possible by the vaginal route.

In some of these cases of pelvic disease, vaginal hysterectomy would be impossible, and I know no way in which the greatest diagnostic skill can unerringly separate these non-operable cases from the others.

In general, in those patients where vaginal hysterectomy is possible, it is a more difficult operation than abdominal. The field of operation is left in a much more satisfactory condition after abdominal than vaginal hysterectomy.

After the removal of the uterus through the abdomen, we entirely close the abdominal cavity by a running stitch that unites the peritoneal flaps that we have made. The bottom of the pelvis can be readily cleaned so thoroughly, that, except in very rare instances, there will be no need of drainage through the abdominal wall. The latter being completely closed through its entire length, the danger of subsequent hernia becomes extremely small.

So that all the drainage we have in this case is the gauze entirely outside the abdominal cavity and brought out through the vagina.

While, after vaginal hysterectomy, the abdominal cavity cannot be entirely closed with safety, and the drain extending from within the pelvic abdomen out through the vulva is a necessity, and at the same time a danger as a possible carrier of infection, so in this matter of drainage, abdominal hysterectomy has manifest advantages.

In some cases of vaginal hysterectomy, complete ligation of the broad ligaments and the contained vessels cannot be done, then clamps must be used. The objections to them, and the dangers attending their use, have been too well established to require any enumeration.

In this comparison of the two operations in the treatment of pelvic disease, this can be said in favor of vaginal hysterectomy, that the immediate danger from shock is greater in the abdominal operation. I doubt, however, if a patient will ever die from shock, when the operation is being done through the abdomen for pelvic disease, except possibly in some of those cases where vaginal hysterectomy would be impossible. Extrusion of the bladder, which is a more serious inconvenience to the patient than ventral hernia, never occurs after abdominal hysterectomy, but follows vaginal hysterectomy in a larger proportion of cases than hernia does after an abdominal section through the median line. Convalescence after abdominal hysterectomy, so far as my own experience goes, has been more uneventful and rapid, than after the vaginal operation.

What I have said in favor of abdominal hysterectomy in the treatment of pelvic abscesses, will apply, to a great extent, to the operation that we should choose — whether vaginal or abdominal — for removal of the uterus for cancer of the neck.

In all cases where the uterus is high up in the vagina, and the latter narrow, or where the malignant infection has extended under the broad ligaments, or the uterine appendages are involved, the advantages of abdominal hysterectomy are at once apparent.

It is an easier operation to do, and the infected structures can be more easily and thoroughly removed. I would reserve vaginal hysterectomy entirely for cases of cancer of the os, where there was probably no extension of the disease beyond the uterine tissues, and where the uterus was very movable and the vagina capacious.

## Reports of Societies.

### MASSACHUSETTS MEDICAL SOCIETY.

ONE HUNDRED AND FOURTEENTH ANNUAL MEETING.

THE sessions of the Sections in Medicine and Surgery were held at Mechanics Building on Tuesday, June 11th.

The Shattuck Lecture was given on Tuesday afternoon by DR. ROBERT T. EDES, of Jamaica Plain, on

THE NEW ENGLAND INVALID.

The Exhibits this year were of more than usual interest, by far the most striking and unusual, however, was an exhibition of pathological and anatomical water-colors and sketches by William J. Kaula. The drawings, many of which were to illustrate Prof. J. C. Warren's Surgical Pathology, and others of larger size to illustrate lectures on pathology, are remarkably accurate both in line and color. Such work as this marks a distinct advance in illustration of lectures and text-books over the old careless line-work.

The exhibits of surgical supplies, sterilized ligatures, sutures, dressings, etc., showed the remarkable perfection to which the preparation of sterilized materials has been carried of late, and the exhibits of instruments, sterilizers, etc., was well worthy of mention.

The One Hundred and Fourteenth Annual Meeting was held at Mechanics Building, Boston, June 12, 1895.

ANTITOXIN IN DIPHTHERIA.

The following papers on this subject were read:

"The Etiology of Diphtheria and the Use of Antitoxin," by DR. H. C. ERNST, of Boston.

"The Pathology of Diphtheria," by DR. W. T. COUNCILMAN, of Boston.

"The Prophylactic Use of Antitoxin," by DR. F. G. MORRILL, of Boston.

"The Preparation of Diphtheria Antitoxin," by DR. J. L. GOODALE, of Cambridge.

"The Clinical Use of Antitoxin," by DR. W. H. PARK, of New York City.

Discussion by DRS. C. F. WITHINGTON, of Roxbury; G. G. SEARS, of Boston.

THE ANNUAL DISCOURSE[1]

was delivered at twelve o'clock by DR. ALFRED WORCESTER, of Waltham.

THE ANNUAL DINNER

was served at one o'clock, at the close of which the Anniversary Chairman, DR. H. L. BURRELL, introduced the first speaker, His Excellency Hon. F. T. Greenhalge, in the following words:

FELLOWS OF THE MASSACHUSETTS MEDICAL SOCIETY: — Why do we gather on these annual festivals? That we may freely exchange counsel and advice, and that we may have relaxation from our daily cares. Our profession is one of the noblest which can engage man's energies if its functions are rightly conceived and its obligations fully realized.

A society that has among its past members men who have exercised a world-wide influence on the well-being of mankind, men whose names will endure for time, such as Jackson, Bowditch, Bigelow, Holmes, Waterhouse and Warren, must have ideals of development.

As medical men we are often too engrossed in our daily work to fully realize the breadth of our duty to mankind. In the community in which we live there is more respect paid to the rights and comfort of the individual than in any part of the world. We are justly proud of this standard. As medical men our first duty is the care of the individual, but we should not be warned into forgetting our broader, although less obvious, duty of adding by research to the knowledge of disease that we may improve all mankind.

The material, mental, and often the moral well-being of the world with all the possibilities for a larger usefulness and a richer, more fruitful civilization which such well-being implies, are directly influenced by our profession, especially in our capacity as medical societies.

A society like ours should establish and maintain good fellowship and honorable conduct among its Fellows. It should stimulate by emulation its members to their best work. It should foster the healing art, advance medical science and diffuse knowledge influencing the public health. Membership in this Society should be an assurance that the man is well educated and a gentleman.

The Society should never degenerate into trades-unionism. It must always stand ready, as it has so often in the past, to judiciously co-operate with the State in the greatest of all branches of our profession, preventive medicine.

Our obligations to the Commonwealth associate us closely with its government; and I beg to present to you one in whom we all delight in honoring on this occasion, an executive who conscientiously stands for the right, His Excellency, Frederic T. Greenhalge.

[1] See page 585, No. 24, of the Journal.

GOVERNOR GREENHALGE spoke as follows:

I understand from the remarks of the Anniversary Chairman that the standards are to be maintained and increased, and I regret that in the very fine innovations that have been made to-day it seems a sort of valedictory performance in that system of Anniversary Chairmen which has done so much to gladden your banquets in the past. It is like bidding a personal and an official farewell to the old *régime*, which has done so much to make matters pleasant and comfortable, and yet I myself have had the pain of parting with the Anniversary Chairmen on an official occasion. He was the surgeon-general, whom I delight to honor, and whom the Commmonwealth of Massachusetts delights to honor. And I want to pay my humble, yet fervent tribute to the effective and splendid work done by that chairman in the task of bringing the militia to its present high state of efficiency, in regard to the ambulance system and the medical department generally. So, my friends, if the system goes out, it certainly has the advantage of going out in a blaze of glory.

I am glad, my friends, to be here. This is an ancient and historic society. I remember that in the old days members of your profession were not thought so highly of as they are to-day, and that seems to be one of the marks of progress which the present century has manifested. I can remember when you were called — at least in the books — medical men, and by the somewhat invidious title of "leeches"; and sometimes people who have to pay your bills think that this term has not become altogether obsolete. But you must always remember that a jibe at a learned profession is the only consolation of the ignorant.

It is important that the standards of the profession should be maintained. It is important that you should know who are members of your organization; that you should be able to say, when a man's name is mentioned in connection with that of the Massachusetts Medical Society, that he is a man to be trusted for honorable dealing, whose aim means well for the good of the whole Commonwealth. It is not so much a matter of money-making that may be important; not so much a matter of selfish emolument. This great Society means that whatever secret science has to teach, wherever progress can be made, that progress will be made, and those secrets will be learned by this representative body of men as soon as anywhere else on the civilized globe. Therefore, my friends, it is a source of congratulation that the legislation of Massachusetts has looked forward and not backward. It is well that a just discrimination should be made by the Commonwealth which will divide the untrustworthy from the trustworthy.

It is an inspiring and encouraging fact to come here and to find that, so far from your members having diminished, they have increased, and that probably 200 or 300 more come here to-day than have come on previous occasions. The questions that will be put to you are something like this: Has your work contributed to the good of the community? Have you contributed to longevity? I think the answer will be in the affirmative. Have you made life more worth living? Have you reduced to its minimum the rack and pain of suffering? Have you added to the comfort, the happiness, the enjoyment and the rational delight of mankind? Have you made death less fearful, and have you given every comfort and satisfaction which

the science within your reach was able to contribute?

These questions, I think, the statistics would answer in the affirmative as well. It does not make so much difference what school a man belongs to; but it makes all the difference in the world whether he is true to the newest and highest dictates of science. If these things are so with the members of this Society the Commonwealth may well bring its warmest greetings, and may well bid Godspeed to the members of the Massachusetts Medical Society, as I do in these brief words to you to-day.

The Chairman in introducing Dr. F. K. Paddock, said: In 1850 the office of Anniversary Chairman was created. Since that time it has been held by many good and distinguished men. To-day that office dies. The Anniversary Chairman, after forty-five years of life, is cut off in the prime of his manhood. His impulse on this, the last day of his life, is to occupy all of your time in demonstrating to you that he falls a martyr to the grasping ambition of the presidents of the Society, who have always envied his elevated station, temporary though it might be. The waning light gives way to the fixed light who is hereafter to preside at your dinners. The President of the Society will now speak to you.

DR. PADDOCK spoke as follows:

MR. CHAIRMAN AND FELLOWS OF THE MASSACHUSETTS MEDICAL SOCIETY: — In pursuance of my official duty, during the last year, I have visited District Societies in the different sections of the State, and I recognize in this great throng to-day many familiar faces.

We are assembled to observe the one hundred and fourteenth anniversary of the organization of this Society; and on this occasion it gives me pleasure to assure you that prosperity and harmony prevail through the Commonwealth.

I am certain that the respect of the community at large for this organization is increasing from year to year and I feel confident that in the immediate future the great and general court will demand that every practitioner in the State shall be a part of this body, and thus restore the prestige which was denied it many years ago.

It is with pleasure and surprise that I have observed the rapid dissemination and inculcation of new ideas and methods through the State. A new departure in medical or surgical practice in Boston is utilized in a surprisingly short time by the profession all the way from Berkshire to Barnstable. The skill and resources of the rural practitioner are steadily improving, keeping pace with his city brother.

The conservatism which has characterized this Society in its recognition of "isms and pathies" has been wise and healthful in the past; but the conditions are different now, and a more liberal policy in the future may be of advantage.

I am sure you will all sustain me in the opinion that it is the aim of this Society to excel in every art and theory that prolongs life and gives health to mankind.

The waning light which has been so pathetically described by our eloquent Chairman, as illuminating his approaching death, will, I assure you, be like the light of the noonday sun as compared with the darkness which will obscure the proceedings at the next anniversary dinner of this Society; and you will hasten to restore life and health to the Anniversary Chairman.

The Chairman then introduced Prof. Charles Eliot Norton in the following words:

Bound as we are by the necessities of our work to the material things of the world, it is well that we should keep fresh our interest in those things which offer us a wholesome relaxation from our daily cares and which do much more if their full significance is completely grasped, which may illumine those tasks and all the aspects of the world by the light of a rich spiritual nature, by giving its right influence in our lives to the noblest of our faculties, the imagination. Emerson has said, "A man is a beggar who only lives to the useful, and however he may serve as a pin or rivet in the social machine, cannot be said to have arrived at self-possession."

Fellows of the Society, it gives me much pleasure to present to you Dr. Charles Eliot Norton, Professor of the History of Art in Harvard University.

PROFESSOR NORTON said:

MR. CHAIRMAN, MR. PRESIDENT, MEMBERS OF THE MASSACHUSETTS MEDICAL SOCIETY: — If a justification of the presence of a layman to take part in the celebration of your anniversary be required, it may surely be found in the fact that it is eminently becoming that some one from outside your ranks should express the gratitude of the community to the medical profession and offer to it the testimony of the general honor and respect.

No intelligent man can live to middle life without having frequent occasion to acknowledge his quite immeasurable obligations to individual members of your profession for services rendered to himself and to those dearer to him than himself.

The ideals of all the chief professions to which men devote themselves are noble and worthy of the devotion of high-minded men, but no other is loftier or more inspiring than that of the medical profession, for it is an ideal of immediate, unceasing, self-forgetful and self-sacrificing *service*. The pursuit of it tends to the development of character of the highest type. It is a mere commonplace that a good physician must be possessed of quick and exact observation, capacity of drawing rapid synthetic conclusions, sound judgment, firm decision, readiness to deal with sudden, unexpected emergencies, and that together with these, and not less essential, he must have a large understanding of human nature, tenderness of heart, and a spirit of intelligent and humane sympathy, not to be dulled by recurrent call for its exercise, nor refusing to be aroused because the individual appeal to it belongs to a general and common class.

While I name these qualifications I am describing no imaginary persons, but men whom I have known and honored, men whom you have known and honored; but why do I use the past tense? men whom you and I know and honor! The rolls of the profession in Massachusetts are full of exemplary names. I need but recall the Jacksons, the Wares, the Shattucks, the Warrens, the Bigelows, the Bowditches, the Wymans, the Cabots.

But much as we have owed the profession in the past it seems likely that we are to owe to it still more in the future. It was but the other day that Mr. Balfour, eminent alike in English politics and in English philosophy, was addressing an audience of medi-

cal men and said, "I cannot forget that great as is the debt that humanity in the past owes to those who have devoted themselves to the healing art, that it is increasing and, so far as we can venture to prophesy, seems likely to increase in a rapidly expanding ratio. The successful application of the scientific method in all the arts is one of the most remarkable characteristics of this and the last generation, and nowhere does that characteristic show itself more prominently than in the region of the great art of medicine. There science and practice are ever more and more joining hands and every day medicine is becoming less the work of the empiric, more and more of the scientific expert."

With this extension of knowledge, with the new methods of investigation opening illimitable vistas of discovery and indefinite but splendid prospects of advance, even with this great progress, a grave danger is associated.

The acquisition of the knowledge requisite for the practice of the profession whether upon its medical or its surgical side, becomes more and more arduous. The term of education is necessarily prolonged; the attainment of mastery requires more exclusive devotion to special pursuits; the profession divides itself, and many of the ablest practitioners are more and more strongly tempted to confine themselves to special departments of their art.

But the most thorough medical education, if it be an exclusively medical education, and the most complete attainment of special skill and knowledge in any one branch of the profession, whatever it may be, do not lead to the ideal of a good physician. Exclusively medical education is not enough. A good physician must know more than medical studies teach. It is not enough to know the signs and causes of disease and the remedies for it, he must know life in its largest sense, life, of which disease is but the perturbation. And the way to this is twofold: by experience and by culture; twofold and yet single, for it is culture which enables a man to put his experience to profit, to interpret it correctly, and to recoguize intelligently the enormous variety of human character through which the essential unity of human nature manifests itself.

No man should be deemed fully qualified for the practice of the healing art unless his soul has been enlarged, and his mind disciplined by the studies which are justly termed the "humanities." In the busy practice of his profession the physician may find little time for such studies. The pursuit of them must be early begun, and happy for him if the love of them be early established.

Above all should the young student who proposes to become a physician devote himself during the brief period before he enters upon his strictly professional studies to those studies which tend to the culture and development of the imagination. The imagination is the most powerful and, if left untrained, the most dangerous of the faculties. It is the most useful and the most powerful if properly trained, for then it informs and animates the moral nature; it quickens and enlarges sympathy; it guides judgment; it moderates desire; it provides innumerable resources of refreshment and recreation; it secures sanity of soul.

A great part of every physician's duty is the exercise of influence over the imagination of his patients. "A wise physician," says Pluto, "cures the body with the mind." Imagination is the futile source not only of imaginary but of real disease, and every physician knows by frequent experiences how large a part it plays in recovery from disease and in the maintenance of health. The country physician is constantly called upon to deal with the disordered imaginations of his patients, exposed to all the trials of life and wearing their hearts out in comparative solitude, while the city physician, here, for instance, in Boston, finds himself not less constantly confronted with the conditions of the imagination which reveal prehistoric modes of thought, and which exhibit in the wonder of faith cures and of Christian Science, close analogies to the mystic vision, the miracles and the *stigmata* of S. Francis.

I remember long ago hearing a story of a well-known printer in Philadelphia, Mr. Fry, who at one time was engaged in reprinting one of those encyclopedias of medicine in which different diseases are treated at length in independent volumes. He said he always opened with interest a new volume when it arrived from England in order to see what disease was to be prevalent in his office during the next two or three months.

But the culture of the imagination is requisite for the good physician not only that he may through it learn how best to deal with the troubles of his patients but that he may preserve his own health of body and mind. Every physician requires some intellectual interests beside those of his own profession, and there are no interests comparable to those which the imagination may supply. The means of culture of the imagination are easy, are not far to seek. One man may find them in his garden; another in his shelf of wisely chosen books, another, perhaps, even in his collection of postage stamps. Be sure only to take some means. It probably matters little what.

Best of all, perhaps, for true recreation is the study and the love of poetry. The guidance of the taste may safely be followed here. Happy if it lead to Shakespeare or to any of the greater masters of poetry!

I remember many years ago, that Sir John Simon, known to you all as the eminent surgeon to St. Thomas's Hospital, and still better as the man to whom England mainly owes her magnificent system of national preventive medicine, a man I hold as a high honor to speak of as an old friend, coming one day into my room and taking up from the table a volume of "Dante," turning to me, he said: "I used to know much of Dante. Let me see if I can recall something of him now." And then he repeated without an error one of Dante's sonnets in the original Italian, which he said he believed he had not looked at for twenty years. I have known few men who had a more thorough acquaintance with Shakespeare, with Milton, and with the other great masters of English literature than he.

And let me recall another illustration. When in the heat of war and under the pressure of multitudinous responsibilities of the heaviest weight, Governor Andrew, our great governor, was obliged to travel often between Boston and Washington, he told me that in order to refresh himself and to keep his mind smooth, open and tranquil he was accustomed to take with him a volume of poetry, often the "Golden Treasury," to occupy the hours of the journey in learning by heart some one of the pieces which it contained.

But, more than this, poetry may serve not only as the means of refreshing the wearied mind, it affords a never-failing source of comfort; and there is no man

who at times has more bitter disappointments and stands more in need of comfort than the physician.

The subject is leading me too far. I must stop! but I would end as I began with a word of gratitude which though spoken by my single voice, is the utterance of thousands upon thousands of your fellowmen.

The Chairman next introduced the Rev. James B. Doonan as follows:

FELLOWS OF THE SOCIETY: — As medical men, ministering to the ills that flesh is heir to, and appreciating as we do the important influence exerted by the mind on the diseased body, we know the great comfort which is brought to our patients by their spiritual advisors. Theology and medicine have always been closely allied; in fact, to the church we owe our first hospitals, and for centuries most of the practitioners of medicine were churchmen. Gradually a definition has been made between the man who ministers to our spiritual needs and him who cares for our temporal wants, until to-day we have hospitals which provide, not only for the care of the sick and unfortunate, but which are the great schools of our profession, out of which comes information which benefits and improves the whole human race. The work of the church and of medicine lie in parallel lines, frequently intersecting, never antagonistic, both striving for the good of man; and it gives me the greatest pleasure to present to you the Rev. James B. Doonan of Boston College, one who represents a most loyal ally in the care of poor suffering humanity and who is a representative of the conservative church.

REV. JAMES B. DOONAN responded as below:

GENTLEMEN OF THE MASSACHUSETTS MEDICAL SOCIETY.— An invitation to address an assembly such as, at this moment I face, when standing before the Massachusetts Medical Society, is an honor that might reasonably touch the self-esteem of any man. On the other hand, the gravity of the task that I have assumed by acceptance of your invitation is well calculated to temper any pride that may have been awakened. For what is personal in the summons you have made of my presence here this afternoon, I thank you with a cordial sincerity, which the simple language of my gratitude will not, I trust, obscure.

That which is personal, however, whether it be the grateful sense of the honor you have done me or the disturbing thought of my inadequacy to the task, is lost to view in the realization that it is rather as a representative of religion that you have called me before you to-day. The charge that you have committed to me is to speak in the name of religion, and to set forth the special relations which it holds to the great profession which constitutes the life-work of the members of your distinguished Society.

Whether one considers the lofty aims of that profession itself, the intellectual development demanded in those who embrace it, or, lastly, the high standard of moral worth exacted of those who enter upon the career of the physician, there is in any community no class of men whose opinions should command more respect or exercise more potent influence than in the great body of physicians.

With striking force, then, must avail your action in ordering that on this occasion, when custom calls for a declaration of the principles that underlie your work and direct its operations, utterance of no uncertain sound should be heard in profession of your belief in the existence of God and in evidence of the respect in which you hold religion, the summary of man's obligations to that God.

The only intelligent purpose ever assigned by human philosophy for the existence of the world of wonders encompassing us, is primarily the manifestation of the wisdom, the goodness and the power of a Creator, and secondarily the happiness in and through these visible things, to what is greater though invisible, of Man himself.

The reasoning intellect, which stands outside of even so familiar an object as the time-piece, that marks for us the hours of the passing day, the designing mind and the cunning skill of a maker; which can descry the architectural thought of a Richardson, as one gazes in admiration upon his master-work in Copley Square, cannot surely miss the existence and the activity of a First Great Cause lying beyond and outside of this world of ours, whose beauty, harmony and strength, progressive stages of study daily reveal to us.

The geologist, who finds books in stones; the astronomer, who of all students of Nature, most nearly grasps the concept of the Infinite, as he plunges into the immensity of space and calculates the gigantic tracks of celestial bodies; the botanist, who, in the tiny leaf of the wayside flower, comes upon the principle of life, a thing so mysterious that no man yet has fully made answer to the question "What is it?" All these, gentlemen of the medical profession, must yield to you in the near reading of the great Creator's wisdom and power. To your study is daily subjected the master-piece of God's fashioning — a very microcosm of marvel — the human body. Wonderful it is for harmony of design, perfection of function, teleological accuracy, and for a beauty which places it peerless among the objects that enkindle the æsthetic glow of our being. In this more wonderful than in all else, because it is a tabernacle in which dwells a spirit — a reality which sight cannot clothe with form or figure, a substance so subtile that scalpel will not disclose it, so unponderable that the most delicate balance will not declare its presence. Yet, withal, the source of all that is best in man, the principle of his intellectual power and his moral greatness.

It stands to reason then, that men of your profession, to whom study has opened the doors of the temple of wisdom, must be farthest removed from the folly of such denial. No nation has ever attained to greatness, no civilization has ever flourished without religion. Pagan Greece, with her superb ascendancy in letters and art, pagan Rome with the resistless power of imperial sway, were religious nations. Misdirected as to object of worship and perverted as to application of its teaching, paganism held many conservative truths. Men believed in a God Supreme, in the immortality of the soul, in a future state of rewards and punishments.

From some quarters we hear the cry, that Christianity has achieved its work in building up our civilization; and those who utter this cry are even willing to admit the debt of gratitude owed to religion for the beneficent results accomplished. But the claim is further made that we can now move forward on the path of progress without Christianity, Science affording all sufficient light and motive for the advance.

Were Christianity to disappear from the world, doubtless many of its achievements would for a time endure, nor would our civilization in a day lose the impress that ages of Christian influence have left upon it. Daylight lingers, even when the sun has sunk below the horizon; not all verdure dies out in the tree the moment the woodman's axe has prostrated its majestic form. But let the time come when the great truths of Christianity cease to be believed, and desolation and disaster await our nation and the generation that rejects them. We cannot return to the paganism of æsthetic Greece or mighty Rome: the sunless night of total unbelief, or the chilling blasts of a cheerless agnosticism will constitute for our age its deadly peril.

Your worthy Chairman, in his introduction, gracefully emphasized the fact that religion and medicine run on lines that are parallel and act and re-act on each other with advantage that is mutual. It is not difficult to see the reason of this truth. The field of their respective activities are not of course coincident wholly; nor yet are they entirely disproportionate or out of common touch. The aims of both are not identical, yet are they akin and harmonious. Human life and human happiness are the lines within which both religion and medical science exert their activities. Man's physical well-being and the conservation of the life he has been appointed to lead upon earth form the subject-matter of medical science. Religion, on the other side, finds its province in consulting directly for man's moral well-being and for the right ordering of his life here with a view to its bearing upon a life that is not to end. But man is not a duality: he is one nature, one person. Consequently, we must expect to see the laws that govern him in the physical order affected by those that control him in the moral order. Such is the fact. Religion not only offers the man strong motives why he should hold himself subject to the laws of hygiene, but imposes moral restraints that act beneficially on his physical nature.

To every physician must come a time when he will be called upon to

> "Minister to a mind diseased;
> Pluck from the memory a rooted sorrow;
> Raze out the written troubles of the brain;
> And, with some sweet oblivious antidote,
> Cleanse the stuffed bosom of that perilous stuff
> Which weighs upon the heart!"

In that hour what influence can he find so potent as religion, which opens up to man the designs of Providence in ordaining or permitting the trials that press upon him.

Advanced medical science of the day regards physical pain not merely as a suffering which it were kind to give a patient relief from, but as a malignant agency to be overcome, if the sufferer is to be restored to strength and health. Hence the beneficent use of anesthetics. But no one knows better than the physician the power of mind over matter: and the need to bring quiet to the former that relief may be bestowed upon the latter. Here again is evidenced the power of religion. Acting as a spiritual anodyne, it controls agitation, allays fears, restores confidence, and places the sick in that state of calm, most desired by the physician, waiting and watching for the outcome of his treatment.

Thus ever aiding, never antagonizing your skill and your science, religion awaits the final effort of your noble craft, for final some such effort must be, since it has been appointed for all men once to die: and grateful for your services to the child of the human race who has reached his appointed term, she gently takes him from your beneficent hands and gives him back to the God, whose creature he is.

Strong, enduring and lasting, then, is the tie that binds religion and medicine. Let no misconception of the one or mistrust of the other set them asunder. United, they wield the giant power that can make the race of men happy for time and for eternity; parted, they would but seek to part man himself in the oneness of his life and drag him from the high estate to which God has called him.

The Chairman next introduced Sir Wm. H. Hingston, Professor of Clinical Surgery, Lavall University, Montreal, Canada, who thanked Professor Norton for his address, and for emphasizing the importance to the physician of imagination, and a thorough training in the liberal arts. The purely scientific special branches, bacteriology, anatomy and histology, are sure to put in their claims to time and strength, and apt to crowd out the study of literature and poetry. We do not need to go beyond the seas for the higher medical education. The higher education is what should be added to classical culture, the knowledge important for medicine. The profession of medicine should be entered upon only by men already skilled in the liberal arts.

After giving pleasant reminiscences of his associations with Dr. Holmes on the occasion of his former visit, the one-hundredth anniversary of the Society, the speaker again referred to the importance of general culture to the physician.

The educated mind alone can establish the connection between, and assign their relative importance to the different departments of medical science.

## CLINICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

JOHN L. AMES, M.D., SECRETARY.

Regular Meeting, Wednesday, March 20, 1895, Dr. Geo. M. Garland in the chair.

Dr. Richard Hogner read a paper on

### INTRAVENOUS MEDICATED INJECTIONS ACCORDING TO PROF. GUIDO BACCELLI'S METHOD.[1]

Dr. Cumston: If I understand you, there was a difference in the pains and edema as you increased the quantity of the solution?

Dr. Hogner: There was no pain at all if the solution was injected directly into the vein, but if some drops were perivascular there was very severe pain.

Dr. Cumston: I happen to have in my pocket a syringe which might prove of use in the injection which Dr. Hogner speaks of. It holds one cubic centimetre. It is simply a glass barrel with metal piston which has an asbestos packing, which can be easily rendered aseptic by boiling. The needle is of platinum, and is made aseptic by passing it through a flame.

Dr. E. O. Otis read a paper on

### THE TREATMENT OF ADVANCED (HOPELESS) CASES OF PHTHISIS.[2]

[1] To be published in the Journal.
[2] See page 609 of the Journal.

DR. ARNOLD: I have had the pleasure of being associated with Dr. Otis and Dr. Fillebrown on the staff of the Free Home for Consumptives. This institution is supported by one of the charitable societies of the city, and draws its patients from the lower classes. We have 27 beds, and the cases are almost entirely of the class Dr. Otis speaks of, the hopeless cases. At first sight the treatment of those cases would seem to be monotonous and uninteresting. It certainly has been a surprise to me to find how much there is to do for them, and to see the great variety of the disease and how much experience we get from treating different symptoms. There is one drawback from the great variety of symptoms and from the fact that the cases are so commonly hopeless, and that is that in testing the effect of any one drug or system of treatment the opinion has to be made more from individual cases than from many statistics. I will speak of one or two points. I have been very much disappointed in creosote in its general use. I have found it of some use as a stomachic stimulant, but it has not seemed to me to influence the general course of the disease.

In speaking of antipyretics Dr. Otis mentioned pyretine. I have had a limited experience with that. In one case in particular it seemed to work favorably, with less depression and decidedly less sweating than any of the other antipyretics, of which I used both antipyrine and antifebrin in the same case.

In treating the pains that arose in different parts of the body, aside from the measures Dr. Otis has spoken of, I have found that salicylic acid or the salicylates in some form have been very useful.

Diarrhea has proved in some cases one of the most troublesome symptoms to control, and I think we are sometimes obliged to resort to morphine in quite large doses to control the activity of the bowels, particularly where it seems due to irritation from ulcers.

Strychnine has proved in my experience one of the most useful drugs that we have in treating cases in general, and not alone from its action on the heart; it has often given a great deal of relief to the breathing and to the distress in the chest.

There is another aspect to these advanced cases of phthisis, not connected directly with the treatment, which I should like to touch on: and that is the importance of the cases from the point of view of contagion, as foci for the dissemination of the disease. In inquiring into the history of the cases there, I found in several instances very clear proof that the case was acquired by contagion from some other member of the family. I think the advanced cases, where they are less able to take care of themselves, where the sputum is loaded with the bacilli, are decidedly more dangerous than the earlier cases of the disease. Particularly among the poor this question seems to be of great importance where the people are crowded together with improper accommodations. I feel like urging the medical profession to take some more active steps to arouse interest, not only among ourselves but in the community at large, to have something more done for the care of such cases. It seems to me it is of importance that those cases should be provided for in the public institutions, not simply as a matter of giving them proper care, but as a matter of protection to the community. The accommodations in Boston at present for such cases are painfully lacking. The larger hospitals are overtaxed in taking care of acute diseases and cannot spare beds for cases which take so long a time. Except for The Consumptives' Home which was formerly under Dr. Cullis's care, there have been to my knowledge, with the exception of the small Channing Home, no institutions where these cases are taken and properly cared for. The Free Home for Consumptives in its present form is doing good work, and its function needs little said in commendation; and I certainly hope we shall see in the near future not only an increase there, but other accommodations for such cases.

DR. FILLEBROWN: In regard to the matter of the supply of air to consumptive patients, it seems to me that we must consider it in a somewhat different light when we are treating a number of patients collected together in an institution. I have noticed that the patients have suffered from the effects of cold draughts. In the institution it is impossible to renew the air sufficiently without opening the windows, either at the top or bottom, to an extent which admits of too much circulation; and it seems to me that in the treatment of consumptives in institutions we should have special regard to the temperature and the supply of air. Our variations are so great and so frequent that the out-of-door air cannot be depended upon to provide the proper influences, therefore I think it should be modified in temperature and moisture by suitable apparatus. In a private house, of course, we can arrange that a great deal better.

In regard to the matter of digestion, I endorse the views of Dr. Otis almost entirely, and perhaps cannot add anything to what he has already said. I have found the charcoal, bismuth and soda mixture to be very useful in those cases of distress after eating. Almost invariably it has had a good effect. In the cases of anorexia I have used nux vomica and the dilute mineral acids, with perhaps whiskey or the tincture of gentian. Liquid peptonoids with creosote, where there is an inability to take food, has in a number of cases been very effective. Whether it is due to the creasote or not I do not know, but the stomach tone seems to be restored to a certain extent and the appetite has returned. It seems to me that in the earlier stages of the hopeless cases, creosote, when administered in moderate doses has been followed by good results. I have given, as a routine treatment to those able to take anything of this kind, malt and oil with creosote in milk. This combination does not sound pleasant; but they have been able to take it, and I think it is about the best way. I have in mind the case of a girl who had very serious lesions of both lungs, the apex of one and the other whole lung; she had improved a great deal and was feeling so well that she left the Home and entered employment as a domestic. As a result she returned in a very serious condition. When I first saw her after her return I remarked to the nurse that I did not think she would last very long. We put her on creosote, malt and oil, and I was surprised at the next visit to find her up and about, saying she felt better. She has steadily improved in three weeks since her entrance into the Home, and how much is due to creosote I am not in a position to say. I wish to make this point that the creosote has been followed by improvement, either by its effect upon the stomach or its elimination through the lungs.

Dr. Arnold suggested to me the use of pyretine, and in my service I made quite extensive experiments

with it. I must say it is the best antipyretic I have used. It was hinted that it was simply a combination of acetanilide and bicarbonate of soda, and to test it I had the nurse mix me some acetanilide and soda. I had previously used the pyretine on a patient suffering from extremely high temperature, and it brought it down with doses of three to five grains, within an hour or two without any apparent depression, sweating or exhaustion. Upon giving the acetanilide and soda there were great depression and fearful sweating, and the patient requested that we should not give her any more of that. I have a patient now in the Home suffering with high temperature and discomfort, and have given her the pyretine with the same result. Two-and-a-half-grain doses, at intervals of an hour will produce a change in the temperature as much as is desired.

In regard to the cough I have resorted to all sorts of things. The compound of white pine, which is so popular now, I find very useful in some forms of cough. Patients like it and seem to think it relieves them; and I think in these cases we have to rely on the feelings of the patients.

Grindelia robusta I have used somewhat, and had good results where there was much coughing and little expectoration.

I agree with Dr. Otis that the manner of coughing has a great deal to do with the ease or amount that the patient coughs. They do not know how to cough, and suggestions in regard to that are of the greatest value.

The strapping of the chest I have relied upon almost entirely where the pains were severe and would not yield to the ordinary methods of counter-irritation. That seems to satisfy the patients, and undoubtedly it relieves the pain by restricting the movements of the chest.

The diarrhea has been easily controlled by the salicylate of bismuth and the chalk-mixture. In some cases it has been so severe that we have had to resort to opium, and I have used laudanum. It seems to me the astringent effect of that is greater than in other preparations. Occasionally we have had to resort to morphia suppositories. When diarrhea is due to digestive disturbance I have found that the charcoal, bismuth and soda helps them a great deal; also the salicylate of bismuth yields good results in many cases.

Digitalis seems to be the only drug that will affect the heart satisfactorily in these cases. I have used it a great deal, and have combined it with strophanthus and nitro-glycerine where there was any congestion in the lungs. I have one patient now who has a very irritable heart due to displacement by contraction of the left lung. He has suffered from dyspnea at times, in which attacks he is seriously ill, but almost invariably he has responded to digitalis in a short time. It seems to me that that is the best heart tonic. I consider strychnia valuable and my experience bears out what Dr. Otis claims for this drug in all cases.

The sweating has been controlled by atropia. A great many of these patients expect to sweat, and do not consider it very serious or discomforting. When it is so severe as to saturate the sheets and the clothing, they call for some treatment, and I have every reason to be satisfied with atropia.

It seems to me we must, as Dr. Arnold says, come to the point of recognizing the importance of treating these cases of consumption in an institution. The worst cases are among the people who have not the care at home that is sufficient, and those are just the ones who need to be taken into a Home. We ought to recognize the importance of this for the welfare of the public in general, if not for the care of these patients. They are not a source of danger to others in an institution, as ample provision is made to do away with the sources of contagion.

DR. BARNES: I should like to ask Dr. Otis regarding the humidity of the atmosphere at which he keeps the patients' rooms? It seems to me the entire ignoring of this question in our public institutions and in our houses is something that we ought to take into consideration as physicians. We take air at zero into our houses through the cold-air boxes or the indirect system of steam-heating, and raise it to 70°, we have increased its capacity to take moisture two and a half times at least and with the exception of a small water-pan in the furnace, sometimes filled and sometimes not filled, no provision is made for moisture. Practically we convert a winter into a June temperature, and in that conversion we get a humidity of 30 or 40 in our houses, whereas with the normal June atmosphere it is 70 to 80. I think we all observe the comfort and agreeableness of a kitchen atmosphere in contrast with that of the upper rooms of our houses, and I have long been of the opinion that that comfort and that agreeableness was due to the tea-kettle which furnishes an abundance of moisture and enables us at 68° or 69° to be very comfortable, where in steam-heated apartments 75° or 80° is often required and then with feelings of discomfort from cold. Some years ago I resided at a house on Beacon Street where I was unable to get my room above 68°, and I found by hanging a wet towel over the radiator that 68° was a very comfortable temperature, while 72° or 74° in other rooms of the house would seem quite chilly. I do not know that in any of our institutions any consideration is given to the question of humidity, and I was very much surprised in visiting the Institute of Technology some years ago, to find no provision made for supplying moisture to the air, after passing over the coils of steam-pipes. This system of heating does not differ materially from the system employed for kiln-drying lumber.

I wish Dr. Otis would say something to us about the advantages or disadvantages of a high or low humidity of the air for lung patients; for it seems to me to be of consequence, materially affecting their comfort, if in a temperature of about 70° the humidity is from 30 to 40 or from 70 to 80.

DR. OTIS, in answer to questions, said: I have not experienced any untoward results in the use of strychnia in those advanced cases of phthisis. Hemorrhage occurs not infrequently, but I have not been able to trace any connection between the use of strychnia and the hemorrhage.

Regarding the care of the sputum, people are becoming pretty well educated now as to its danger and as to the methods of dealing with it, still one often meets with carelessness and ignorance regarding the danger from it and the way of avoiding it, not only in private cases, but in the health-resorts where numbers of phthisical patients live in boarding-houses and hotels. The physician needs constantly to watch his patients and their care-takers to see that no laxity in this respect creeps in.

With regard to moisture in the air, I will not go

into the consideration of the part moisture plays in the atmosphere as a matter of climatic treatment, because I have spoken of it elsewhere [3] in discussing climate in general.

As to the amount of moisture in sick-rooms and hospital wards, especially devoted to the treatment of this disease, it would be well, I think, if along with the temperature thermometer a wet and dry bulb thermometer should be used so that we could have an accurate register of the moisture as well as the temperature.

The oil of peppermint treatment has not been tried I believe — at least, I have not used it — in the Consumptive Home; the cases are all advanced ones and hardly suitable for this method of treatment.

DR. GARLAND: I recently received a letter from a patient whom I had sent to New Mexico, saying he was worse, that his cough had returned quite violently. I wrote describing this method of treatment, and asked his wife to prepare it and let him wear it. I received a letter this week saying it had worked like a charm in allaying his cough and mitigating many of the throat discomforts. This is only one case. But I believe it has been tried in a large number of cases with great success for alleviating the severe cough of phthisis and clearing out the nostrils. I think often the cough in phthisis comes from trouble in the nostrils as well as in the throat. Before I heard of this method I was in the habit of moistening the nostrils with a little peppermint for ordinary head colds. When this matter came up it occurred to me that its action might be largely local on the turbinates and on the congested mucous membrane of the upper air district; at all events, it does relieve the cough, and sometimes without the necessity of internal medication.

DR. GREENLEAF: I recall the treatment referred to by Dr. Prescott. It is that of Carossa. Peppermint by inhalation is combined with internal treatment, the theory being based on its antiseptic action, which it shares in common with other volatile oils. The combination used internally contained peppermint, creosote, glycerine and one or two other ingredients. I modified the use of the inhaler somewhat by using a small wad of absorbent cotton done up in cheese cloth which admits the air rather more freely than cotton cloth yet permits of saturation by the peppermint. I notice that there is a difference whether the peppermint is used in private or in hospital practice where patients are crowded together. In hospital practice the patients converse so much that they breathe through their mouths more than private patients do and the results are not as good.

I should like to call attention to one or two points in Dr. Otis's paper. We are not accustomed to associate digitalis and strychnia with the treatment of hemoptysis, but in certain cases there is no reason why we should not use these drugs, and we may with considerable advantage in selected cases. Of course, cases that are associated with extensive breaking down of tissues are scarcely to be treated in that way; but where they result from small oozing due to venous stasis, the use of digitalis is admirable. I have had occasion to use it in other classes of cases of hemorrhage due to venous stasis, and it works very well. I think our teachings hitherto in confining the use of digitalis so largely to cases of cardiac disease without thinking of its effect on the circulatory organs in other diseases are erroneous. Strychnia used in large doses has attracted our attention in the last few years, as a valuable respiratory stimulant. Dr. Otis's remarks call to mind the value of using any of these remedies from their physiological effect and not merely as routine treatment of so many minims three times a day.

## ASSOCIATION OF AMERICAN PHYSICIANS.

TENTH ANNUAL MEETING, WASHINGTON, MAY 30 AND 31, 1895.

(Continued from No. 24, p. 602.)

THURSDAY. — AFTERNOON SESSION.

### A CONTRIBUTION TO THE STUDY OF THORACIC TUMORS,

by DRS. WILLIAM PEPPER and ALFRED STENGEL, Philadelphia, was read by title.

### ETIOLOGY OF IDIOPATHIC HYPERTROPHY OF THE HEART,

by DR. JAS. T. WHITTAKER, Cincinnati.

Hypertrophy independent of valve disease or obstacle to the circulation in the heart itself. The term is a misnomer. The condition is more frequent than is commonly believed.

Hypertrophies are due —

(1) To increased resistance in the vascular system. For example, arterio-sclerosis.

(2) To diseases of the heart muscle from infection, degeneration, etc.

(3) To affections of the nervous system.

The hypertrophy of age, of work, of plethora, of pregnancy, of alcohol.

Hypertrophy from Bright's disease, from diseases and deformities of the chest, emphysema, kyphosis.

Hypertrophy from myocarditis, syphilis, gout and diabetes.

Hypertrophy from irritation of the vagus, from abuse of tobacco, from excess in venery, etc.

DR. J. H. MUSSER: I have recently had several cases in which the occurrence of dilatation and the immense development of a mitral regurgitant murmur — in persons who previously had hypertrophy of heart, due to vascular changes — gave relief to the cardiac symptoms, to the violent palpitation, precordial distress, and, indeed, in three instances to attacks of angina. One patient, who had an aortic lesion, had a very severe attack of angina extending over a period of four or five weeks, so that her life was despaired of, but the development of the mitral murmur has relieved her of pain and other cardiac symptoms. This has occurred to me so often that I have been rather glad to welcome the development of the murmur of mitral regurgitation or dilatation in individuals who have had symptoms due to arterial tension and to the consecutive hypertrophy.

With the occurrence of this murmur, the type of the individual changes, he is broken down physically, but lives comfortably for several years afterwards without return of the hypertrophy or symptoms due to the high arterial tension.

I might also record an instance under my care three months ago, of a naval officer who was a constant smoker. The man, only fifty-two years of age, had an attack of tachycardia, palpitation and some anginoid symptoms. I suspected that tobacco was the cause of

it, but he protested that he had smoked since the age of fourteen. I consented to the use of tobacco again, when the attacks recurred and were quite serious. The final disuse of tobacco has caused the attacks to cease. The man has hypertrophy of the heart, but without high vascular tension.

THE TRANSMISSION OF MITRAL DIASTOLIC MURMURS,

by Dr. J. P. C. Griffith, Philadelphia.

The murmur of mitral stenosis is generally described as limited sharply to the mitral area or its immediate vicinity. Although usually confined to the region of the apex, it is not at all infrequently heard much beyond the ordinarily prescribed limits. The extensive transmission of the murmur more frequently obtains than is supposed even by those who admit its possibility. This is illustrated by the fact that seven cases related in this paper were all examined by the author within the last three months. In three cases the murmur was audible in the back; in one it extended two and half inches beyond the left posterior axillary line; in four it reached the anterior axillary line, and in two the mid-axillary line. In all it was audible very high up in the axilla.

Dr. Tyson: I examined the first case which Dr. Griffith mentions, and I can confirm all he has said with regard to the extent to which the murmur was transmitted. In connection with this, I wish to present a morbid specimen illustrating in a most striking manner the enormous dilatation of the left auricle which is associated with this condition. The case was admitted to my wards in the Hospital of the University of Pennsylvania. A woman of twenty-eight, with a previous history of lung obstruction and bloody, frothy expectoration. Along with this, there were some other symptoms which pointed to pulmonary disease rather than to cardiac disease. I must admit that, according to the notes of the clinical examination, I recorded a mitral systolic murmur, which of course may have been present; but the physical condition was one in which we would naturally expect a presystolic murmur. The dilatation was so very extreme and the heart so feeble that perhaps there was not impulse enough to push the blood through this narrow orifice with the production of a murmur.

Dr. J. T. Whittaker: It is important to determine, not so much the extent of the murmur, as the point of the greatest intensity. The extent of the murmur does not by any means tell the extent of the lesion. We can have a very loud murmur set up by a very slight lesion, and we can have some very extensive lesions in the valves without any murmur at all. A number of such cases have been reported. The intensity of the murmur is not an indication of the gravity of the disease.

Dr. Charles Cary: It seems to me that all of these cases have to be explained on absolute physical ground. Where there is a presystolic murmur which is due simply to the flowing of blood producing a flapping of the valve, without there being any strong power behind it, it is not going to produce any alteration in the size of the auricle, and in such cases, there would not be much sound transmitted. Where, however, there is a positive and marked stenosis of the mitral orifice, so that there is as a result a marked hypertrophy of the auricle, then the enlargement brings the blubbering, flapping sound in more immediate contact with the chest; and it can run almost in any line, depending on the size and the force of the muscle which drives the blood through the auriculo-ventricular opening. Under these circumstances you would get marked transmission of sound. It is rather difficult to understand as a physical fact, why, if there is a sufficient amount of deformity to produce a very marked presystolic or obstructive murmur, there should not be an accompanying mitral regurgitation. Sir Andrew Clarke puts the mitral presystolic or mitral stenosis murmur as one of the most frequent of the murmurs. He states that it has to be in most cases accompanied by regurgitation, because the deformity about that valve would almost of necessity lead to the backing of blood into the auricle.

Dr. J. H. Musser: I have been familiar with the work of Dr. Griffith, and can confirm what he has said. In a case under my care, that of a middle-aged woman, a presystolic murmur was heard very loudly, at the angle of the scapula posteriorly; and in connection with it, a reduplication of the second sound was noted in the upper axilla, as well as in the precordial region. In one instance this reduplication was heard in the upper axilla and not in any other portions of the chest.

Dr McPhedran: The restriction of the murmur described by most authorities is incorrect. I have noted in many cases the murmur more widely distributed than usually described by authors. I think that in these cases the murmur depends upon the tension of the current of blood in the pulmonary circulation, and not upon a condition of the left auricle. I think it is ventricular and not auricular.

Dr. A. H. Smith: It has long seemed to me that perhaps murmurs which we class as diastolic are in some cases systolic; that is to say, in conditions where there is disease at the auriculo-ventricular orifice, the mitral curtains are necessarily more or less stiffened at their base and consequently do not coapt perfectly in the very first instant of systole. The valve may be perfectly competent ultimately, but may not be so at the very moment the ventricles contract, and there is a regurgitation in that first instance of systole, which regurgitation ceases when the pressure behind the valves arrives at a certain point. It does not seem probable, when we consider the mechanism of the valves, that even under the most healthy conditions the mitral valve closes so instantaneously as not to permit of a slight amount of regurgitation. It is like any check valve, which presupposes a previous flow in order to move it into its seat.

Dr. C. G. Stockton: Does Dr. Griffith mean by this sound that which we ordinarily call the diastolic or the presystolic murmur?

Dr. J. P. C. Griffith: I do not think any explanation has ever been given why a murmur is loud at one time and not at another time; nor why a patient with a slight lesion may have a big murmur, and one with a big murmur may have a slight lesion. In a single case you can have on different days a difference in intensity, and even on certain days no murmur whatever. It is my own experience that we can base absolutely nothing on the intensity of the murmur with regard to the severity of the lesion. These murmurs in my cases were nearly altogether pure murmurs of mitral stenosis. In two cases there was also the murmur of mitral regurgitation. Under the term diastolic, I mean, as I tried to explain, any murmur which occurs in the diastole from the time of the closure of the second sound, up, till we get the impulse.

That was gone over very carefully by Dr. Bristowe a few years ago, who showed that the murmur of mitral stenosis may be one day heard about the middle of the diastole, another time at the beginning of the diastole, and again in the presystole. To me, this is all the same murmur. Some of the older writers divide it into the diastolic and presystolic and then the accentuated sound; but clinically I do not see how we can make any very sharp distinction.

### THE USE OF THE DIFFERENTIAL STETHOSCOPE IN THE STUDY OF CARDIAC MURMURS,

by DR. ANDREW SMITH, New York.

The differential stethoscope, which in its simplest form differs from the ordinary binaural stethoscope simply by having two thoracic extremities instead of one, each connected with its respective ear piece, enables us to hear separately two sounds produced at the same time in different localities. It is useful when we find that a murmur is produced at each of two cardiac orifices, but are unable to determine whether the two murmurs occur synchronously or alternately. This doubt may arise whenever the distinction between first and second sound is lost. This distinction is likely to be lost whenever the heart's action is considerably accelerated, while at the same time the distinctive quality of the sounds is marked by the presence of murmurs. In such cases the differential stethoscope enables us to decide whether both murmurs occur at the same time, or first one and then the other. It also determines whether murmurs produced at different orifices by the the same act of the heart are, or are not, exactly synchronous; an important point in the study of the action of the valves both in health and disease.

DR. J. T. WHITTAKER: The instrument would be very valuable in some cases if we could find individuals perfect in both ears, to use it. There is unfortunately, a difference in the two ears of individuals, and sometimes a very great difference, as in the case of Addison, who was entirely deaf in one ear but became so acute of hearing in the other ear, that he was the finest auscultator in London.

After all, in these cases, it is not so much the character of the murmur or the situation of it or the reduplication of it, that is of importance, but rather the condition of the muscle of the heart. Of the factors that go to make that picture of heart disease, the murmur is the most deceptive and affords the least valuable information. It is more important to determine the condition of the heart muscle as to its dilatation, and that is determined by its frequency of action.

DR. CHARLES CARY, Buffalo, read a paper on

### THE CAUSE OF THE EXAGGERATION OF SOUNDS OVER THE RIGHT UPPER CHEST, BOTH IN HEALTH AND DISEASE.

(1) All authorities describe a disparity in the physical signs, both in health and disease, between the superior lobes of the lungs.

(2) It is not satisfactorily accounted for by any author whose work has come under the notice of the writer.

(3) The right bronchus gives off a branch to supply the upper lobe immediately at but a short distance from the bifurcation of the trachea; this branch is not represented in the left side of man. In some animals this branch to the upper right lobe springs from the trachea itself, two or more inches above the bifurcation.

(4) Our common text-books on anatomy, with perhaps one exception, make no mention of this striking difference in the two sides.

(5) Exaggerated sounds of voice, breathing, percussion and fremitus on the right side under like conditions are to be accounted for by this bronchus, which serves as a much more direct transmitting medium.

DR. J. P. C. GRIFFITH: I would like to ask Dr. Cary how commonly present this arrangement of the bronchus is.

DR. CARY: I have made a great many castings of human lungs, and lungs of cats, rabbits, dogs, sheep and calves; and in all of these, although the arrangement differs somewhat in the different species, the right superior bronchus does not fail to come off very much higher than on the left side, and in some cases it comes off from the trachea. In dogs it is arranged not unlike that of the human lung. In all of the human lungs that I have been able to make castings from, that is the uniform arrangement. I have seen it come off immediately at the origin of the right bronchus.

### TWO CASES OF FAT NECROSIS,

by DR. C. G. STOCKTON, Buffalo.

Two cases of fat necrosis were given in detail, both males, both Swedes, and coming under the author's care within two weeks of each other. The autopsies showed a very similar condition present in each case — a condition rather at variance with what is usually found in such cases. In both there was well-marked disseminated fat necrosis, and in neither was there well-marked pancreatic change. Beyond the presence of a very limited number of areas of fat necrosis in the interstitial tissues of the gland and the occurrence of hemorrhages small in number and trifling in degree, the pancreas in neither case showed more change than is often seen in the perfectly healthy pancreas taken from the cadaver and preserved in the same way. The histological alterations in the pancreas are probably accounted for by the condition of the surrounding tissues.

DR. R. H. FITZ: I would take exception to the interpretation which Dr. Stockton seems to place upon his cases, in that he does not seem to attach that etiological importance to disease of the pancreas which the recent experimental work in this country and elsewhere seems to demand. In this connection, I wish to call attention to the fact that Dr. Whitney of Boston, formerly a member of this Association, has produced typical fat necrosis by experiments on the pancreas of dogs. Quite recently, Hildebrandt has reported numerous positive results in experiments on cats. These observations are all that is necessary to show that multiple fat necrosis associated with pancreatic disease is the result of such disease, a view which is in direct opposition to that of Balser and many German writers, and which seems to be the one favored in Dr. Stockton's communication.

DR. J. E. GRAHAM made a brief reference to a case of his own almost identical with one reported by Dr. Stockton.

DR. STOCKTON: I am very glad indeed to have the opinion of Dr. Fitz on these cases. I was prepared to hear him express himself as he did. The clinical appearance of these cases was identical with what I

had seen before in a case of pancreatitis without fat necrosis, and I had no way of determining before autopsy the difference between the cases. The conclusion reached by Dr. Williams, who made the autopsies, was entirely by histological and bacteriological methods. Dr. Williams began his investigation with the belief that he would find changes dependent upon pancreatitis. He was surprised to find that little change was evident in the organ in either case.

There is one point in the second case which I had hoped Dr. Fitz would notice and speak of, and that is the presence of necrotic matter in the abdominal wall. It has escaped my mind if anything of the kind has been noticed before.

Dr. Fitz: With reference to the occurrence of fat necrosis in the tissues of the abdominal wall, instances have been reported of fat necrosis being found as a rule in the subperitoneal fat, and in such cases, usually, similar subperitoneal patches of fat necrosis were found in the adjacent mesentery or omentum. The appearances of the colon described by Dr. Stockton suggested that a fistulous communication was about to be established between it and the cavity containing the fatty *débris* (presumably an omental bursa and the colon), as several cases have been reported of evacuation of such material from the lesser omental cavity into the stomach or into the intestine, portions of the sloughing pancreas even having been discharged through such opening.

*(To be continued.)*

## Recent Literature.

*Text-Book of Abdominal Surgery.* A Clinical Manual for Practitioners and Students. By Skene Keith, F.R.C.S., Ed., assisted by George W. Keith, M.B., C.M. With illustrations. Philadelphia: J. B. Lippincott Company. 1894.

The name of Keith is so associated with abdominal surgery that any book bearing this name is not to be lightly passed by. The authors have depended largely upon their own experience and methods, but these have been modified by their intimate relation with Dr. Thomas Keith.

The book is divided into two parts: first, surgery of the abdomen; second, surgery of the abdomen peculiar to women. The authors have adopted a style which is of peculiar value to this book. It is the illustrating of diseases by recording typical cases. While reading the book one constantly feels that what is written is the result of experience, and that the work is not simply a compilation of modern ideas. There is hardly a foot-note in the book, so that it cannot be considered an epitome of the subject — not but what due credit is given where it belongs. There are a few plates here and there, and diagrams which are copied from various sources, due acknowledgment being rendered.

The book is a model of its kind; it enters into the details of operations enough to make them perfectly clear. Sound surgical principles and accurate symptomatology are a marked feature of the work. We always welcome books of personal experience; and this is one which we feel sure should be added to the library of every surgeon.

## THE ALLEGED EXALTATION OF FACULTY IN "SECOND STATES."

In that popular novel, "Trilby," the principal interest centres in a remarkable phenomena of hypnotism. The heroine of the story when in her normal state is an indifferent singer; has, indeed, a fine voice, but no ear; in fact, can hardly tell one note from another. When in the hypnotic state and under the training and "suggestive" promptings of her tutor — when, as the daily contemporaries would put it, she has been Svengalized — she has both "ear" and "voice," becomes an accomplished and popular vocalist, and obtains wide celebrity. When in the natural state, she forgets her songs — words and musical expression — her notes are discordant and the breakdown is complete.

This, the capital part of the story, has been pronounced improbable and absurd. It is improbable; but there is something to be said in its defence. It is not wholly absurd, though no historical occurrence of the kind may be on record. That in some well-attested cases there is a wonderful exaltation of faculty under hypnotic influence and in "second states" (*dedoublement de la personnalité*) seems undeniable. Instances may be cited from Ribot,[1] Charcot,[2] Janet,[3] and many others. It is not contended that hypnotism ever imparts new faculties or acquisitions; at the most it can only — in perhaps exceptional cases — heighten such as already exist. If Trilby had possessed no voice or "ear" for music (delicate appreciation of musical tones) when she came under the spell of Svengali's baton, the hypnotic state could not have made her a singer, able to entrance audiences.

Binet and Féré[4] dispute the assertion so often made[5] that a somnambulist is an unconscious automa-

ton — a puppet moving only as its strings are pulled — and allege examples of subjects who, during the hypnotic state, could perform intellectual feats of which they were incapable of in the waking state. Even natural dreaming is at times accompanied by exaltation of faculty, and mathematicians in their dreams have solved problems to which they had devoted the fruitless study of many days. Thus, Condorcet saw in his dreams the final steps of a difficult calculation which had long puzzled him; and many think that Coleridge's "Kubla-Khan," composed during sleep, may be ranked among his best efforts. The phenomena of the revival of supposed extinct memories during the delirium of fever is sufficiently well known.

Pierre Janet,[6] who believes in the essential identity of hypnotic somnambulism and states of double personality not brought about by hypnotic influence, relates some remarkable instances of complete recovery in somnambulism of sensibilities (many of these patients were anesthetic, anosmic, etc.) and of memories which seemed to be lost. Lucie and Leonie, Marie and Rose regain under hypnotism their lost senses and their memories. "If" says Janet, "somnambulism is a second existence, it is not necessarily a feeble existence without spontaneity, independence, and originality."

The case of Marguerite D. related at length by Georges Guinon in Charcot's "Clinique"[7] is an instance of heightened activity and heightened intelligence during the somnambulic state. Marie H., an inmate of the Salpêtrière, in her normal state does not know how to read or write or count. Can do coarse sewing and stitching, but cannot embroider, do lace work, or crochet work. In the second, or "vigilambulic" state, she can read and write and count, do crochet work and embroider — acquisitions taught her since she came to the Salpêtrière and in the "second state," which is her better state.[8]

As concerns the fact that the acquisitions made in the state of vigilambulism are dormant — not manifest — in the ordinary waking state, Guinon observes that this may be because the notions acquired in the second state are less profoundly implanted than those of the normal state, but a perfectly satisfactory explanation is wanting.

Ladame describes an entire change of personality in a patient of his, of which a report appears in the *Annales de la Société Medico Psychologique*, January, 1888. In the second state the patient was more active and alert than when in the normal state; she was also free from anesthesia and other hysterical stigmata which characterized the normal state. When in the latter state she always lost at a game of cards, while in the second personality she invariably won.

In the patient of Bonamaison, an hysterical female, related in Charcot's "Clinique,"[9] the mental faculties were more exalted in the second state than in the first. "The expression of the countenance is different. The eyes are more brilliant, the manner more engaging; she converses and laughs with more animation. Very docile in the normal state, she becomes in the second state wilful and capricious. In this state she can do the finest needle-work and embroidery with a dexterity utterly foreign to the normal condition. The intelligence and memory are in fact exalted. She remembers multitudes of facts which are quite forgotten in the normal state. I have often heard her sing when in the somnambulic state an English ditty learned in her childhood and of which she does not know the first word when in her normal state." Guinon regards this as a case of double personality (*dedoublement de la personnalité*) of hysterical nature.

Dufay's patient[10] in the somnambulic state is much more active, and her senses seem endowed with extraordinary hyperacuteness. "She looks for and finds objects in full darkness. She threads a needle in the dark, and with her hands under the table. She talks fluently while working, but somewhat after the manner of children, using *me* for *I*. 'Quand moi est bête' (when I am in the brute state) signifies 'when I am not in somnambulism.'"

There are a few other cases of a similar kind on record, as those of Azam, Camuset, and Verriest. These phenomena of double personality are almost always connected with hysteria. Without venturing here any interpretation of these singular psychological phenomena (a work very well done by Pierre Janet in his last treatise, "Accidents Mentaux des Hystériques"), we may refer to one more instance of heightened intellect — during the second state — the patient M., of Jules Janet, at the Hôpital Pitié, who was reduced to the last extremity by a prolonged attack of gastric hysteria. There was general anesthesia and the limbs were in a state of partial catalepsy; there was retention of urine by spasm of the sphincter. When brought into the hypnotic state, all these infirmities disappeared. Appetite, digestion, strength returned, and the patient seemed entirely well, only to fall back into her anesthesia and other morbid states when she came out of the hypnotic state. It was found necessary to keep her in a condition of induced somnambulism. This was done by the Janets for a space of five years. During this period she pursued successfully a course of professional study and passed difficult examinations. When she is in the first state she forgets a large part of these acquisitions, and the five years she has passed seem a blank. The induced somnambulism has become to this patient a second existence far more complete than the first.[11]

COMPULSORY VACCINATION IN SPAIN. — A committee of the Spanish Chamber of Deputies has reported in favor of making vaccination compulsory in Spain. It is expected that the proposed measure will encounter some opposition when it comes under discussion in the Chamber.

## SHOULD A PRELIMINARY COURSE IN THE LIBERAL ARTS BE REQUIRED FOR ADMISSION TO OUR MEDICAL SCHOOLS?

Prof. Charles Eliot Norton, speaking at the recent dinner of the Massachusetts Medical Society, emphasized the importance to the medical man of general culture, of ability to get occasionally out of the ruts of medical thought — and how deep these are only the doctors know — and take their pleasure in the wider fields of literature, art and philosophy. The requirements of modern medicine, nay, even of a single specialty, are so exacting, and even the most seemingly limited field is so wide in its important relations, that the conscientious student feels that all his time is not enough even for its mastery, and an imperfect mastery at that. All his time he must give; unceasing work day and night would not be enough. He devotes himself to his task with dogged persistence, works year out in and year out to utter weariness, becomes narrow and crabbed, acquires a kind of mental wry-neck from looking at life from the single vantage-point of his chosen specialty, talks and thinks only of his chosen work until he is capable of nothing else. Perhaps when his life draws to a close he may be satisfied with himself, perhaps not. But sooner or later he is brought into contrast with another worker in the same field. He has worked hard and late at night also, and his work has been done with enthusiasm and at high pressure; but instead of giving all of his time to it he has found a little each day for rest and healthy recreation, a little to give to his duties as a citizen, and a little to music, to good literature, to history, to philosophy, to the study of life in its wider aspects. When he returns from his relaxation to his medical work he comes to it with a vim, and snap, and energy born of his relaxation; his views are more comprehensive and human; he sees things in their broader relations. At the end of the same number of years he has probably a firmer grasp of his special subject than his brother who has done nothing but follow his single bent.

So wide and far-reaching are the relations of medicine to science, to literature, to art, to human life, that we may truly say, the broader the culture of the man, the better physician will he make. The training and discipline of a course in science or the liberal arts will, beside furnishing a man with an avocation, equip him with the ability to do greater and better work in his medical studies.

It is well recognized that in this country we have more doctors than the community needs, more than can make an honest living by the practice of medicine. Our medical schools, however, are each year more crowded, and larger classes are turned loose upon the community. The stress of competition and pressure of want drives some each year to the adoption of what is called low standards, that is, in plain language, to professional dishonesty and quackery, either open or overt. We have too many doctors. We want better doctors and less of them.

Now, how shall the standard be raised? In the first place, would it be raised by restricting the admission of candidates to the graduates of colleges or the higher scientific or technical schools, or men who could show evidence of having done a commensurate amount of work under private tutorship? Certainly it would. The men who lead the classes and do the hard work in our medical schools are now, with few exceptions, the graduates of colleges and scientific schools; and the leaders in medical science and practice are recruited with striking uniformity from the men of liberal education.

The requirement of a liberal education, then, for admission to a medical school would tend to decrease the number of medical candidates, and to raise the average standard of ability in the school and the profession.

We have a right, then, to ask why such action is not taken at once by the faculties of our medical schools. The answer is, that it has not been done for two reasons: first, that the students if required to finish a course in the liberal arts would be so old in beginning their long course of medical study that they could not qualify for practice before the age of twenty-seven or twenty-eight, and, second, that the medical schools are dependent on the tuition fees for their actual running expenses, and could not therefore afford to take action which would reduce the size of their classes.

With regard to the first objection, we can only say that if hard, earnest work were made a requisite for graduation at our colleges and preparatory schools, and their standards were not lowered so as to allow men to pass whose degree represents only a minimum of work, and means nothing to any one except to their parents — proud in the liberal education of their progeny — the degree in the liberal arts could be easily secured at an average age at least two years younger. Many of the brighter men in our colleges do two years' work in one, and secure early graduation. And that, we notice, without seriously injuring their health. It is keeping the brighter men back to the pace of the loafers and dunces which makes the average age at graduation so high.

With regard to the second objection, namely, poverty of the schools, we can only say the more true the greater pity. That our best medical schools should be forced to sacrifice the best interest of the profession they educate in order to maintain their own existence is truly a shameful compromise. The need of endowments for our schools is a crying one. If some of the money spent in founding new medical schools were put in the form of endowments for old ones, it were far better spent.

If the rich men of to-day could be made to realize the great importance of this matter, and to understand that unless they endow the medical schools their descendants will be likely to fall into the hands of inferior physicians, our schools might be placed above this shameful necessity.

## MEDICAL NOTES.

APPOINTMENTS AT JOHNS HOPKINS UNIVERSITY.— At the Johns Hopkins University Dr. Simon Flexner has been advanced to Associate Professor of Pathology and Dr. William S. Thayer to Associate in Medicine.

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA. — A Section on Gynecology has been organized in the College of Physicians of Philadelphia. Dr. Charles B. Penrose was elected Chairman, and Dr. John B. Shober, Clerk for the ensuing year.

UNIVERSITY OF PENNSYLVANIA. — The one hundred and twenty-ninth annual session of the Medical Department of the University of Pennsylvania, the seventeenth annual session of the Dental Department, and the eleventh annual session of the Department of Veterinary Medicine having just come to an end, the Annual Commencement was held at the Academy of Music, June 13th. The valedictorian was Prof. H. C. Wood. A class of 250 was graduated in medicine. A portrait of the late Prof. William Goodell, a bust of Prof. Joseph Leidy and a portrait of Prof. Horatio C. Wood were presented, and were duly accepted by the Board of Trustees. The new Provost, C. C. Harrison, Esq., was installed into office by the Governor of Pennsylvania and the Board of Trustees. The first official act of the Provost was the presentation of a permanent fund of half a million dollars, to be known as the "George Leit Harrison Fund."

THE CLIMATIC ADVANTAGES OF CAPE MAY. — The Government weather reports show that the mean relative humidity of Cape May is but 77, as compared with 80 for Atlantic City. The average temperature for the year is a little over one degree higher for Cape May, the difference between the temperature of the two places being slightly greater in the winter than in the summer months.

A DECISION AS TO A PHYSICIAN'S LIABILITY.— The *Cincinnati Lancet-Clinic* is authority for the statement that a late Iowa Supreme Court decision makes a physician liable for damages accruing from his having dismissed a case too soon.

PROFESSOR ESMARCH, of Kiel, was on May 28th elected correspondent of the Academy of Medicine of Paris.

A PROFESSOR OF PATHOLOGY FOR DUBLIN. — The Board of Trinity College, Dublin, have given notice that on June 22d they will elect a Professor of Pathology in Dublin University for the first time.

CONGRESS OF THE FRENCH SURGICAL ASSOCIATION. — The Ninth Congress of the French Surgical Association will be held at Paris, at the Faculty of Medicine, on Monday, October 21st, under the presidency of Dr. Eugene Boeckel. The subjects for discussion will be "The Surgery of the Lung," M. Reclus; "On Surgical Interference Early or Late in Solutions of Continuity of the Skull," M. Heydenreich.

THE INTERNATIONAL CONGRESS OF GYNECOLOGY AND OBSTETRICS. — The second session of the International Congress of Gynecology and Obstetrics will be held at Geneva during the first two weeks in September, 1896, and not as has been announced in some journals in 1895. The subjects for discussion in Obstetrics are "The Relative Frequency and Varieties of Pubic Deformity Peculiar to Different Countries," and "The Treatment of Eclampsia." The subjects in Gynecology are "The Operative Treatment of Retrodeviations of the Uterus," "Pelvic Suppuration and its Treatment," and "Methods of Suturing the Abdominal Walls, with the Object of avoiding Abscess, Hernia, etc."

STRYCHNINE POISONING THROUGH THE MEDIUM OF CIGARETTES. — The *Medical Press and Circular* quotes from a Russian journal an account of a chemist who carried loose in his pocket two capsules containing five grammes of strychnia, and six cigarettes. A severe convulsion, with cyanosis, trismus opisthotonus, which nearly proved fatal, was the result. When the chemist felt the earlier symptoms, restlessness and agitation coming on, he examined the capsules, and found that one of them had burst, and its contents were adhering to the card-board mouth-piece of the cigarettes. This is an excellent story; but a chemist who could not taste strychnia when placed in his mouth in quantity sufficient to poison him, and who under the circumstances did not throw the cigarettes away, must have been possessed of a palate which would enable him to smoke a very poor quality of tobacco.

### BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, June 19, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 70, scarlet fever 27, measles 96, typhoid fever 11.

ADDRESS AT YALE UNIVERSITY. — Dr. T. Mitchell Prudden delivers the Annual Address in Medicine before the medical faculty and medical students of Yale University on Tuesday, June 25th.

### NEW YORK.

REORGANIZATION OF THE ANTI-VACCINATION SOCIETY. — At a meeting of about fifty persons held at the Fifth Avenue Hotel on June 5th the "Anti-Vaccination Society of America" was revived and reorganized.

A WEDDING IN AN HISTORIC CHURCH. — On June 4th Dr. William L. Vroom was married in the historic old Paramus Church, near Ridgewood, New Jersey. This is said to be the first wedding ceremony held in the church since Aaron Burr and Theodosia Prevost were married there on July 2, 1782.

DIVISION OF THE DEPARTMENT OF CHARITIES AND CORRECTION. — On June 5th the Governor signed the bill dividing the Department of Charities and

Correction of New York City into two separate departments, and providing for them Commissioners of Charities and one Commissioner of Correction, each removable at the Mayor's pleasure. This is a reform measure which has long been desired, as it draws a sharp line between those public institutions which are of a penal character and those which are charitable. The new commissioners are to be appointed for a term of six years each and the formal separation of the two departments is to take place on January 1, 1896.

## Miscellany.

### MILK-BORNE THROAT ILLNESS: PHENOMENAL EPIDEMIC.

DR. KENWOOD records a somewhat unique outbreak of throat illness in Finchley in November last, followed by what was undoubtedly a prevalence of true diphtheria. The throat illness was of short duration, thanks to Dr. Kenwood's efforts to trace the cause so soon as cases began to be notified, he having concurred in the conclusion already arrived at by the private medical attendant of many of the patients that the malady was not diphtheria. Acute symptoms set in rapidly, and the cases tended to group themselves in one particular neighborhood, houses being in several instances invaded by multiple attacks, and houses of all classes and sanitary conditions being affected, the one community of this condition being, as Dr. Kenwood soon discovered, their milk-supply. His suspicions were strong by the fourth day of the outbreak, and twenty-four hours after the issue of a handbill warning all persons to boil their milk, the epidemic was stayed as suddenly as it had started. Not only could Dr. Kenwood exclude all other known causes of diphtheritic disease, but it was seen that better class houses, those using most milk, were most largely attacked — though children were not mainly sufferers — adults over twenty years of age being in the proportion of two to each child patient. Nothing was discovered amiss with the throats of the milkers of the cows supplying the implicated milk, but three of the cows were found to have diseased teats, and one had a chronic abscess on her udder. Of the 17 per cent. of total houses supplied by the milk, there were as many as 94 per cent. invaded in the period November 8th to 18th. Dr. Kenwood comes to the conclusion that climatic conditions preceding the outbreak, together with the cold, damp soil and the season of the year, sufficed to give rise to throat ailment, which, by reason of the milk infection, acquired an aggravated property and marked infectiousness — one of its prominent features throughout. Meanwhile, and while the throat illness was in progress of development, there began on November 13th a series of true diphtheria cases, which increased to 38 by the 25th, there being 28 houses invaded, and 25 of the patients being persons who had a few days previously suffered from the minor throat malady. Secondary infection seemed in every case improbable, and a progressive development of diphtheria from the former illness appeared most probable, bacteriological investigation with material from the cases of throat trouble having satisfied Dr. Kenwood that the milk throats were not those of diphtheria. Whence the diphtheria came Dr. Kenwood feels unable to say, but he opines that the milk-caused throat trouble laid the foundation for the subsequent diphtheria by rendering the throat incapable of resisting the graver malady. The case is one of exceptional interest to sanitary workers, and certainly deserves a place among milk outbreaks. The mildness of the disease — whatever its true nomenclature — may be gathered from the fact that only one death was registered from diphtheria in Finchley in the whole of the fourth quarter. Incidentally, Dr. Kenwood raises the question of the desirability of frequent skilled inspection of animals in dairies and cowsheds by some competent body, and we commend the suggestion to the central authorities.— *British Medical Journal.*

## Correspondence.

### BICYCLE SADDLES.

BOSTON, 76 MARLBOROUGH ST.,
June 18, 1895.

MR. EDITOR: — I have had some experiments made with bicycle saddles such as Dr. Chadwick refers to in his paper in the last number of the JOURNAL.

I have found that the saddle without the anterior projection, although theoretically desirable is impracticable. It does not give a secure seat.

Yours, etc.,
CHARLES W. TOWNSEND, M.D.

### RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JUNE 8, 1895.

## OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 8, 1895, TO JUNE 14, 1895.

CAPTAIN JAMES E. PILCHER, assistant surgeon, will be relieved from duty at Fort Niagara, N. Y., upon the expiration of his present sick leave, and will report in person to the Commanding Officer, Columbus Barracks, Ohio, for duty at that station.

CAPTAIN LOUIS BRECHEMIN, assistant surgeon, will be relieved from duty at Columbus Barracks, Ohio, upon the return from leave of absence of MAJOR WILLIAM E. WATERS, surgeon, and will proceed to, and take station at Baltimore, Maryland, as attending surgeon.

CAPTAIN HARRY O. PERLEY, assistant surgeon, upon the completion of his examination, for promotion, will proceed to Hot Springs, Arkansas, and take charge as Commanding Officer of the Army and Navy General Hospital, relieving LIEUT.-COLONEL ALFRED A. WOODHULL, deputy surgeon-general.

LIEUT.-COLONEL WOODHULL on being thus relieved will report in person to the Commanding General Department of the Colorado, for duty as medical director of that department relieving LIEUT.-COL. DAVID L. HUNTINGTON, deputy surgeon-general. LIEUT.-COL. HUNTINGTON on being thus relieved, will report in person to the surgeon-general for duty in charge of the Museum and Library Division of the Surgeon-General's Office, relieving LIEUT.-COL. JNO. S. BILLINGS, deputy surgeon-general.

CAPT. JOSEPH T. CLARKE, assistant surgeon, is relieved from duty at Fort Omaha, Nebraska, and ordered to Fort Washakie, Wyoming, for duty, relieving CAPTAIN HENRY I. RAYMOND, assistant surgeon.

CAPT. RAYMOND on being thus relieved, is ordered to Fort Niagara, N. Y., for duty at that post.

CAPTAIN PHILIP G. WALES, assistant surgeon, now on temporary duty at Fort Niagara, N. Y., upon the arrival of CAPT. RAYMOND at that post, will return to his proper station.

CAPTAIN WILLIAM J. WAKEMAN, assistant surgeon, will be relieved from duty at Fort Thomas, Ky., upon the arrival there of CAPT. ROBERT J. GIBSON, assistant surgeon, and will upon the expiration of the leave of absence granted him, report for duty at Fort Huachuca, Arizona.

### PROMOTIONS.

To be assistant surgeons with the rank of captain after five years' service, June 6, 1895:

FIRST LIEUTENANT FRANK R. KEEFER, assistant surgeon.
FIRST LIEUTENANT THOMAS U. RAYMOND, assistant surgeon.
FIRST LIEUTENANT HENRY D. SNYDER, assistant surgeon.
FIRST LIEUTENANT ALLEN M. SMITH, assistant surgeon.
FIRST LIEUTENANT ASHTON B. HEYL, assistant surgeon.
FIRST LIEUTENANT JOSEPH T. CLARKE, assistant surgeon.

CAPTAIN CHARLES RICHARD, assistant surgeon, is relieved from duty at the U. S. Military Prison, Fort Leavenworth, Kansas, to take effect June 30, 1895, and will proceed to comply with the order for him to take station at St. Louis, Missouri.

Leave of absence for two months, to take effect about July 1, 1895, is granted COLONEL FRANCIS L. TOWN, assistant surgeon-general.

CAPTAIN HARRY O. PERLEY, assistant surgeon, will report in person to COLONEL CHARLES H. ALDEN, assistant surgeon-general, president of the examining board appointed to meet in this city, at such time as he may be required by the board for examination as to his fitness for promotion, and upon the conclusion of his examination to return to his proper station.

Leave of absence for one month and twenty days, to take effect on or about August 10, 1895, is granted MAJOR LOUIS M. MAUS, surgeon.

CAPTAIN EDWIN F. GARDNER, assistant surgeon, is relieved from duty as attending surgeon and examiner of recruits in Boston, Massachusetts, and will report in person to COLONEL CHARLES H. ALDEN, assistant surgeon-general, president of the examining board appointed to meet in this city, for examination by the board as to his fitness for promotion, and upon conclusion of his examination, will report for duty at Fort Grant, Arizona.

Leave of absence for three months to take effect when he shall be relieved from his present duties, on or about June 30, 1895, is granted CAPTAIN CHARLES RICHARD, assistant surgeon.

## OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SIXTEEN DAYS ENDING MAY 31, 1895.

J. B. HAMILTON, surgeon, granted leave of absence for five days, May 15, 1895.

G. W. STOVER, surgeon, granted leave of absence for one day, May 22, 1895.

F. W. MEAD, surgeon, to proceed to Portland, Maine, and assume command of service, May 18, 1895.

J. J. KINYOUN, passed assistant surgeon, granted leave of absence for seven days, May 30, 1895.

R. M. WOODWARD, passed assistant surgeon, granted leave of absence for thirty days, May 23, 1895.

G. B. YOUNG, passed assistant surgeon, detailed to make physical examination officer Revenue Cutter Service, May 24, 1895.

M. J. ROSENAU, passed assistant surgeon, to proceed to Staunton, Va., for special temporary duty, May 17, 1895.

NORMAN SEATON, assistant surgeon, to rejoin station at Baltimore, Md., May 25, 1895.

EMIL PROCHAZKA, assistant surgeon, to proceed to Cleveland, O., for temporary duty May 25, 1895.

## APPOINTMENTS.

DR. M. H. RICHARDSON has been appointed Assistant Professor of Clinical Surgery in the Harvard Medical School, and DR. FRANKLIN DEXTER, Assistant Professor of Anatomy.

## RESIGNATION.

DR. A. M. SUMNER has resigned his position as visiting physician at the Boston City Hospital.

## RECENT DEATH.

H. W. WILLIAMS, M.D., M.M.S.S., died in Boston, June 14, aged seventy-three.

## BOOKS AND PAMPHLETS RECEIVED.

Diseases of the Nervous System. By W. R. Gowers. Reprint. 1895.

Thirty-fourth Annual Report of the Cincinnati Hospital for the Fiscal Year Ending December 31, 1894.

Some Impressions of Gynecology in Europe. By Hunter Robb, M.D., Professor of Gynecolgy, Western Reserve University. Reprint. 1895.

## Original Articles.

### THE IMMUNIZING EFFECTS OF ANTITOXIN.[1]

BY F. GORDON MORRILL, M.D.,
*Visiting Physician to the Children's Hospital, Boston.*

BEFORE describing the results obtained from 438 immunizing injections of antitoxin at the Children's Hospital, I will briefly explain the reasons which have rendered such an extensive use of the serum necessary.

The policy of the institution has always been to decline to admit cases of such diseases as are generally regarded as infectious; and the building originally included but two small rooms for the isolation of such cases as might appear among the patients in the house. After a time (as might be naturally expected in any large congregation of children), endemics occurred, and larger, but (in the light of recently acquired experience) insufficient quarters were provided.

During the year 1894, cases of diphtheria occurred so frequently as to necessitate the closing of the hospital, and disinfection of the wards, on three separate occasions; to the great inconvenience of all concerned, and with serious detriment to the usefulness of the institution.

It was thought at first, that the infection was introduced by the parents or friends of the patients; and blouses and disinfectant washes for the faces and hands of all visitors were prescribed. But in spite of these precautions, fresh outbreaks occurred, and we were reluctantly forced to the conclusion that the Klebs-Löffler bacillus had installed itself as a permanent and most unwelcome guest within our walls, and stood in no need of an introduction.

Furthermore we convinced ourselves that the chief source of trouble was confined to one ward, where grave defects of ventilation were discovered. Some time elapsed before this last conclusion was reached; for while cases of diphtheria were more frequent in this ward than elsewhere, the fact that the majority of the children were in the habit of meeting in the play-room, had led to such a distribution of the infection as to give rise to cases in all parts of the hospital. The type which the disease assumed was seldom frank; children with coryza or slight tonsillitis and scarcely any constitutional symptoms, would perhaps fatally infect others, and in many instances repeated bacteriological examinations of the secretions alone showed when the trouble began and ended — no membrane or other clinical evidence of diphtheria being present at any time.

January 13, 1895, there were nine cases in the infectious wards, four or five of which had been transferred from the house within forty-eight hours.

The question of closing the hospital for the fourth time was discussed, and it was decided to first try immunization with antitoxin, in the hope that this course might enable us to maintain open doors and go on with our work. The staff was so kind as to give me *carte blanche*, so far as the diphtheria was concerned, and within thirty-six hours, thirty-nine patients who remained in the house, and three nurses who were on duty in the contagious wards, received each an injection of five cubic centimetres of the serum prepared at the Pasteur Institute of New York, according to the formula of Roux.

The apparent result of this first attempt was to instantly arrest any further spread of the disease. Patients in the contagious wards were disinfected and returned to the house as soon as negative reports of the cultures of two specimens taken forty-eight hours apart, were received from the bacteriological laboratory of the Harvard Medical School. No patients were admitted with any suspicious symptoms in their noses or throats; and all new-comers received an injection of five cubic centimetres on entrance. Specimens were obtained frequently from all patients, and reports of the cultures were all negative until January 29th, when a boy who had reacted perfectly well to an immunizing dose, was found guilty of harboring the Klebs-Löffler bacillus, and was at once transferred to the contagious wards. The specimen from which this positive culture was obtained, was taken sixteen days after immunization; and while there was no certainty that the bacillus had not been present for an indefinite time in this particular case (through an oversight, no previous culture having been made) it was thought best to inject antitoxin again in all cases which had not been immunized within ten days. Cultures were now made at the bacteriological laboratory of the Harvard Medical School, of specimens from every nose and throat in the house, and negative reports obtained in every case but one — that of a boy who had been returned to the house from the infectious wards after two favorable bacteriological examinations.

A rule was now made that all new patients should be injected in the bath-room before being allowed to enter the wards for the first time, and the dose of antitoxin was increased to ten cubic centimetres for children ten years of age or over. I do not believe that the injections have been omitted or deferred a dozen times on account of the condition of any child's health, and I have seen but one instance in which danger was suggested by the use of the serum — a case which I shall refer to later on. The mere inspection of noses and throats was soon found to be a very slight safeguard against the introduction of the bacillus, for children with apparently normal mucous membranes were frequently discovered to have bacteriological diphtheria a day or two after entering the hospital, and emergency cases were often found to be in the same plight. One of the latter developed diphtheritic membrane; and while all this went to prove the reliability of antitoxin as an immunizing agent, bitter experience had rendered us timid, and the rules for admission were amended so far as to exclude all applicants until they had been reported as free from the bacillus, excepting cases of the greatest urgency. Meanwhile, all patients found guilty of secreting (and perhaps excreting) the Klebs-Löffler were transferred to the infectious wards, there to remain until negative reports of their cultures should set them free.

No signs of the enemy were present again in any patient whose mucous membranes were free at the start, until February 15th, when a boy who had been twice immunized — the second time on January 29th — and whose cultures had always given negative results, was found to be infected. Injections were at once given in all cases which had not been immunized within two weeks, and the rule established, to repeat them every fortnight.

[1] Read before the American Pediatric Society, Hot Springs of Virginia, May 27, 1895.

March 12th, a patient who through an oversight had been given no antitoxin since February 16th, was found to have the bacillus; but we had now become quite accustomed to its presence, and so long as it had not been detected in any child who had begun with a clean record, in a shorter space of time than seventeen days after immunization, we felt pretty safe so long as the injections were regularly given every two weeks. The next day, however, a positive culture was obtained in the case of a patient who had been injected February 28th. This eclipsed any previous records, and showed that fourteen days could not be surely counted on, so the period allowed to intervene between the immunizations was shortened to thirteen days. Meanwhile an estimate of the applicants for admission whose cultures were positive, showed that over 20 per cent. had the bacillus in their throats or noses. Emergency cases came thick and fast (emergency is an elastic term from a surgical standpoint) and when the observation rooms in which such cases were kept (pending reports from the bacteriological laboratory) happened to be full, they went into the common wards. Some of these proved to have bacteriological diphtheria, and one developed clinical evidence of the disease. There is not the slightest doubt that many patients in the house were thoroughly exposed, aside from the infection present in the building itself. Our contagious wards were now full, and the question of continuing to admit patients, and allowing such patients as might present bacteriological but no clinical evidence of the disease to remain in the open wards (or even to be transfered to them from the contagious quarters) was discussed. I thought at the time, and I still think that this could have been done with safety so long as immunization was regularly kept up. There had been but few days during the past month when the wards had been free from the bacillus either alone, or as a companion to membrane. A large majority of the staff agreed with me; but we refrained from pursuing a course which might injure the hospital by giving rise to distorted rumors.

So a vote was passed to the effect that every patient with the bacillus present, whose culture had not been tested by injecting a guinea-pig, should remain in the infectious wards, and admissions to the hospital suspended; for if measles or scarlet fever broke out among the children we should find ourselves badly crippled. Everything considered, I am sure that the staff is entitled to the credit of showing a considerable degree of deference to the somewhat freely expressed opinion of outsiders, who know but little about the actual situation. Fortunately the bacilliary tide began to ebb at this time, and we were spared the guinea-pig test, which often consumes a fortnight's time, and may lead to no really definite conclusion in the end.

Things now went along smoothly until March 25th, when an unmistakable break-down occurred in a child who had been antitoxined on the 10th, and again (by mistake) on the 16th. Negative cultures had been obtained on the 4th and 19th, but the girl had perfectly well-marked clinical diphtheria, and the diagnosis was confirmed by bacteriological examination. Within twenty-four hours bacilli, but no membrane, were found in two other cases which had been immunized on the 16th. But in spite of these exceptional cases (occurring as they did nine and ten days respectively after being injected) it was not thought best to shorten the interval between the immunizations, as I had good reasons for doubting the reliability of the serum used in these instances. April 4th, but two patients remained in the infectious wards, and as the service was becoming less active we no longer made surgical patients wait for bacteriological examinations before admitting them to the house. Two or three proved to be infected (inasmuch as the bacillus was present in their throats and such cases must be regarded as infectious no matter how robust their general health may be until their cultures have been proved benign by the guinea-pig test) and were allowed to remain in an open ward; the epidemic was on the wane, the infectious wards were quite empty, and we did not care to reopen them. In short, we did now what we might have safely done weeks before, and for better reasons. No bad results followed this course, and I am sorry it was not pursued at an earlier date. Children who had the bacillus but no symptoms requiring special care, might far better have remained in the house and passed their time in being cured of the affections they entered the hospital for originally, than have gone to the infectious wards and increased the work of the staff and nurses. Certainly nobody who is familiar with the conduct of children in hospitals — their close intimacies, the manner in which toys are used by all — can believe that the risk of infection would have been materially increased over what already existed if they had been allowed to remain.

An analysis of all the cases, shows that of a total of 438 immunizing injections given between January 13th and May 13th, 109 were of Gibier's serum; 104 of Behring's; 74 of Aronson's; and 151 of the antitoxin prepared by the Massachusetts State Board of Health. The largest number administered to one child was seven. Many of these patients were under treatment for acute diseases at the time of injection: croupous and broncho-pneumonia, grippe, tubercular peritonitis, empyema, typhoid, or such surgical troubles as naturally find their way to a children's hospital. No special symptoms were noted as produced by the serum with regard to the existent diseases at the time of injection excepting in one or two suppurative hip cases, in which there was a temporary improvement in the appetite and general condition. In a few cases of desperate illness the antitoxin was omitted, or postponed until the patient's condition improved; but as a rule, all fared alike. I have failed to observe any dangerous symptoms arise from immunization excepting one case—a boy, aged two, with leucocytosis and a large spleen, upon whom two preceding doses had produced no ill effect, had a temperature of 105.4° F. and considerable edema about the point of injection (given in the abdominal wall in this instance), and certainly appeared very sick. Cold baths and brandy soon made him better, however, much to my relief. Of course, the results of an analysis of our cases are by no means claimed to be conclusive. They are, however, sufficiently well based to permit their being regarded as suggestive. As a rule, the temperature goes up less than a degree a few hours after immunization, and in 75 per cent. of all cases this is all there is to be seen. Erythema around the point of injection occurred in 23 cases. In four it was very extensive, and closely resembled erysipelas — in one instance the child was isolated. The average duration of this symptom is three days; in some cases it lasts only a few hours. It usually appears on the first day after antitoxin, and

never later than the eighth. Urticaria occurred 28 times. The frequency, severity, time of appearance, and duration of this symptom varies greatly with the brand of serum employed. That of Gibier (Pasteur Institute of New York), produced it in 22 per cent. on the (average) seventh day, and lasting (an average of) two and a half days. Behring's caused it in but one case, appearing on the eighth day and lasting three days. Aronson's gave rise to no urticaria. The serum of the Massachusetts State Board of Health produced in about four and a half per cent. an eruption, appearing on the (average) second day, and disappearing in a day and a half. This serum at present very rarely gives rise to anything cutaneous, although at first urticaria was of pretty common occurrence. In three instances the erythema was papular, and very closely resembled measles. In two instances an eruption like scarlet fever was present. Occasionally a child whose skin remained clear after the first or second or third immunization, broke out with an erythema, or an urticaria after a subsequent injection. The same brand of serum may produce an urticaria, an erythema, or no skin eruption whatever in the same subject, as proved in more than one instance where repeated injections were given. Pain (at times intense) was noticed about the point of injection in sixteen; edema in seven; axillary or inguinal glands enlarged in three; general malaise (in one instance a mild delirium) in three. Pain in the articulations in less than one per cent. Nausea, with or without vomiting, in two per cent. Diarrhea (ephemeral) in less than three per cent. Increased frequency of micturition was noted in rare instances. The urine of 82 children was very carefully examined with reference to the effects of antitoxin on the kidneys, and the result of 540 examinations may be briefly stated as follows: In 20 per cent. no change whatever was detected. Of the remaining 80 per cent., those which had been free from albumin previous to immunization, showed a slight trace — in most instances the slightest possible amount, which could be detected only when placed in front of a dark back-ground. This within twenty-four or forty-eight hours after injection. In cases where albumin had been present before the use of antitoxin, there was a very slight increase of the amount. In no case was there any diminution in the amount passed, or any evidence of failure to eliminate properly. Repeated microscopic examinations revealed nothing more than an insignificant amount of renal irritation in any case; and when the albuminuria was produced by antitoxin, it disappeared in a period varying from two or three days to a fortnight.

With regard to the protection afforded by antitoxin, our experience has tended to show that the serum, when fresh, can be relied upon to immunize against anything resembling clinical diphtheria thirteen days, and very probably for a longer space of time. Moreover, in no instance was the bacillus detected in the nose or throat of any child who started with a clear record in a shorter space of time than that just mentioned. This last point (if eventually established) is of practical importance as showing that an immunized child is not only safe from diphtheria, but is also safe as concerns others for a definite length of time. I am by no means sure that daily examinations of cultures from every case might not have shown the fallacy of the theory; but the fact that quite numerous examinations were made, with the results described, certainly deserves mention. In the cases which broke down in eight and ten days after being immunized, the serum used had become decomposed. The color differed from that usually presented, but so slightly at the time of injection that it was used without hesitation. Forty-eight hours later it was of the color of milk.

Regarding the use of antitoxin for curative purposes, our experience, while decidedly favorable, has been too slight to warrant the expression of an opinion. Statistics at the Children's Hospital, if made up from the standpoint that the mere presence of the bacillus in the nose or throat constitutes diphtheria, would justify the extremely favorable and entirely fallacious statement, that our mortality has been less than three per cent. For of 34 patients who have been inmates of the infectious wards, only one died; and all of them received antitoxin — the great majority, however, never more than one small injection, for the purpose of immunization upon entrance, before the reports of their cultures had been obtained. Assuredly one might as well claim, that the existence of the pneumococcus in the saliva implies the presence of pneumonia, as to call all cases which have the Klebs-Löffler bacillus, diphtheria. Equally absurd is it to treat such cases with antitoxin, unless some clinical evidence of the disease is present. I have convinced myself that full doses of the serum has no influence on the mere presence of the bacillus after it has once obtained a foothold. The more ardent supporters of the treatment, will greatly endanger its reputation if they present claims based on statistics such as I have described. On the other hand, I do not doubt that equally enthusiastic opponents of antitoxin will bring forward abundant proof that it does no good whatever. I can well remember something of the kind being done in the case of salicylic acid, and kindred preparations, by conscientious men, who showed by apparently flawless statistics, that cases of acute rheumatism did better under the old treatment by alkalies; but the remedies whose merits they denied, have stood the test of time wonderfully well, and if taken away from us to-day would be badly missed.

Results of the serum treatment, if they are to inspire confidence, must be based upon such cases as are clinically diphtheria, and the diagnosis of which is confirmed by bacteriological examination. Care must be taken to exclude all cases in which a membrane, which to all appearances is identical with that of diphtheria is present, but which is due to the work of other germs. Instances of this sort are far commoner than was formerly suspected — I have observed four (two at the hospital and two in private practice) during the past six months.

In the present state of our knowledge, the Klebs-Löffler bacillus may be said to resemble an idle but extremely competent workman, who under certain unknown conditions may suddenly accomplish a wonderful task. He gives no warning of his intentions, and does not trouble himself to put on working clothes — at least none of a sort which can be recognized under the microscope.

Even such cultures as have every appearance of virulence may prove to be benign when tested, and when they look doubtful may promptly kill the injected guinea-pig. Every active diphtheritic germ is undoubtedly a Klebs-Löffler, but every Klebs-Löffler is by no means an active diphtheritic germ. On the

contrary, it does not, as a rule, harm those who afford it shelter. Of 34 patients who have passed through our infectious wards at the Children's Hospital during the past six months, but seven have had anything resembling what used to be called diphtheria before the birth of the bacillus was announced in the journals, and two of these cases were caused by other germs. But I cannot doubt, that the bacteriologists who have given us so much of inestimable value during the past few years, will before long extricate us from the dilemma caused by our uncertainty of the sanitary status of a person who has only bacteriological diphtheria. Until this knowledge is vouchsafed us, we must continue to regard such a one as a dangerously indefinite quantity; and in an institution like the Children's Hospital, this implies the absolute rejection of a large number of cases, and the disaffection of many others, who cannot be admitted until reports of their cultures have been obtained; for after such alterations shall have been effected during the coming summer as will render the building safe, and immunization is no longer a routine, no case can be permitted to enter which is open to suspicion of harboring the bacillus.

Another thing: Are we justified in admitting a child on the strength of a single negative report? As to the reliability of these reports, there are defects in the present method of obtaining specimens for bacteriological examination (and very probably in any possible method) which render occasional errors unavoidable. I do not wish to be understood as questioning the skill and accuracy of the gentleman at the bacteriological laboratory who make the cultures. If there are no bacilli in the specimens handed in to them, we cannot reasonably expect positive reports; and I merely state an obvious fact when I say, that the wires used for obtaining specimens, may be justly compared with a hook which is lowered into a dark pool in the hope of jigging fish. If the fish are plenty, there is a strong probability of success — if scarce, the chances are fewer. And whether they are plenty or scarce, the element of luck must be taken into account. Of course, if membrane is present and the wire pushed under the outer edge, there is but little probability of failure.

To arrive at an estimate of the frequency of errors due to the uncertainty of bringing away bacilli on the wire when they are present, I have taken the bacteriological reports concerning patients in the infectious wards, from whom specimens were examined at short intervals, and called such negative reports erroneous as are immediately preceded and followed by positive cultures. Of 253 reports 26 were incorrect — a little more than 10 per cent. Under these circumstances I think two negative reports of specimens taken twenty-four hours apart should be obtained — nor can we then feel absolutely safe.

Some of the patients in the infectious wards were very slow in getting rid of their bacilli. One case was lodged and fed at the expense of the hospital for two months, for the sole reason that we failed to obtain two negative reports in succession. He was in robust health, and a particularly noisy and troublesome boy. Finally he was discharged, much to the relief of all concerned.

Various means were tried in cases of that kind to hasten the departure of the bacillus. Good results were finally obtained by atomizing strained lemon juice into the noses and throats six times per diem. Cases which had resisted equally frequent applications of peroxide of hydrogen yielded promptly to this treatment. It is not a pleasant procedure. Children do not like it — but neither does the bacillus. At first it occasions considerable irritation about the nostrils and upper lip; but tolerance is soon established, and the end justifies the means. Since finishing this paper (May 13th) a sufficient number of injections of antitoxin have been given at the Children's Hospital, to bring the total close to five hundred, and with no fresh evidence to alter the views which I have expressed. I think that the fact that we have not had a single abscess resulting from so many injections, speaks well for the careful attention to cleanliness on the part of the internes of the hospital, Messrs. Hall, Wylie and Washburn, whose good and painstaking work deserves mention.

In conclusion, I wish to express my thanks to Drs. Ernst and McCollom for the unvarying courtesy with which they have borne the severe strain upon their patience which the many hundred cultures made at my request must have caused them.

## INTRAVENOUS, MEDICATED INJECTIONS ACCORDING TO PROF. GUIDO BACCELLI'S METHOD.[1]

BY RICH. HOGNER, M.D., BOSTON.

AT the Medical Congress held at Rome in 1894, Professor Baccelli delivered a lecture[2] on intravenous — or as it is also called, endovenous — corrosive-sublimate injections, about which, among other things, he says that the method has been adopted widely in Italy, and that all who have had experience with it agree that it is "harmless, rapid and searching in its effects."

After Baccelli had reminded his hearers that it was he who "originated the idea of injecting medicament directly into the veins for malaria," he continued:

"Professor Nothnagel considers intravenous injections especially needless, inasmuch as one can treat subcutaneously with the same effect and without inconvenience, but Professor Nothnagel speaks without having had experimental acquaintance with the subject, while the tests up to this time, with their results, plainly show his *a priori* views."

Baccelli began with intravenous, medicated injections on animals; and when he found them not only harmless but to be "the most energetic, safe and rapidly working therapeutic agent against malignant diseases," he began in his clinic to apply them, in doubtful cases, to human beings, and with "fine results"; a success, moreover, which has been confirmed in the Italian clinics and in those of private practitioners in Italy. As there are only a very few reports of the use of the method in other lands, the following trial thereof may justly be described.

The intravenous medicated injections have been used by Baccelli, so far, only for malaria and syphilis — neutral solutions (ten per cent.) of quinine hydrochlorate, also corrosive-sublimate solutions (one to two per cent.); but Baccelli believes that the breach is opened, and that his method will spread widely, so much the more, as besides what has already been said

[1] Read before the Clinical Section of the Suffolk District Medical Society, March 20, 1895.

[2] Guido Baccelli: Ueber intravenöse Injectionen mit Sublimat. Berliner klin. Woch., 26 März, 1894.

about the method, "it should not be ignored," he says, "that all pharmaceutic remedies finally are distributed — no matter how first applied — only by means of the circulating fluid in the body's organs."[3]

In favor of the intravenous corrosive-sublimate treatment for syphilis, may be mentioned:

(1) The small quantity of Hg used.

(2) The possibility of rapidly fighting the syphilitic symptoms which point to direct blood-poisoning.

(3) The prompt and searching effect on the walls of the vessels, which are the specially favorite place for syphilitic changes.

The technique of the method consists in choosing a vein, in the arm-pit fold, the hand, the leg or the foot — wherever, in fact, it is desired to make the injection. Bind the limb, centripetally, with a convenient bandage or rubber band, so that the vein will swell as much as possible. Make the fingers and the skin aseptic as for an operation, also inject, with a convenient syringe, the medicament solution chosen. From the beginning to the end, aseptic! "If the injection is made," says Baccelli, "after this manner, then no local phenomenon will appear." If one has injected corrosive-sublimate solution, the patient will get the taste of mercury in the mouth after a few seconds or minutes, and the salivation will result from a small quantity after five or six minutes.

The corrosive-sublimate solution used, is:

| | | |
|---|---|---|
| ℞ | Hydrarg. chlor. corros. . . . . | 1.00 or 2.00 |
| | Sodii chloridi . . . . . | 3.00 or 6.00 |
| | Aq. destill. . . . . | 1,000.00 |

Of the weaker solution (one per cent.) one cubic centimetre, or one milligramme corrosive sublimate, is first injected; and then the doses are increased in strength — two, three, four, up to eight milligrammes corrosive sublimate at a time and in a day. With four milligrammes the strong solution is used, so as to avoid injecting too great a quantity of fluid. Of the stronger solution (two per cent.) one cubic centimetre contains two milligrammes corrosive sublimate, wherefore eight milligrammes — *dosis maxima!* — contain four cubic centimetres of the two-per-cent. solution.

Baccelli used immediately, in urgent cases, four to five milligrammes in his corrosive-sublimate treatment. With my experiments bandages were sometimes used after the injection, sometimes not; however, it is better always to use a little bandage afterwards.

The sign that the lumen of the vein has been reached, is, according to Baccelli, the cessation of pain from the injection and the absence of subcutaneous swelling.

A perivascular corrosive-sublimate injection is, moreover, so painful to the patient, that one would not willingly undertake so severe a treatment.

I have just used Baccelli's intravenous corrosive-sublimate injections in the case of a woman living in East Boston. She is twenty-seven years old, thin but rather strong, and the wife of a working-man. She has been married seven years; has had two children, who are six and four years old; also has had a miscarriage at the seventh month, in September, 1893, as she said, without apparent cause. In the beginning of pregnancy, brown "rosy spots" broke out all over her body, but disappeared in time, before the miscarriage, after which the body was said to be "white" again. At the time of delivery she was attended by an "old woman." The husband and the rest of the family showed no signs of syphilis. A month after the miscarriage another eruption appeared on the forearms, face, neck and legs — the chest was comparatively free — in size from a half-dime to a twenty-five-cent piece, in color reddish-brown on the skin, which here and there became confluent in still larger pigmentary spots, varying greatly in form and located on both the flexor and extensor sides of the arms and legs. The skin was not scaly, was without increased secretion, and did not itch. No other disease symptoms, except some swollen glands, were apparent. No sore on the genitalia or anus. Two months later a dimness appeared before the eyes. On examination, on the 24th of January, 1894, besides the above-named symptoms, numerous synechiæ on the capsula lentis. Ordered hydrargyri iodidum rubrum .01+ gm., and potassi iodidum .50 gm., three times a day; and after the patient had continued a while with this without the eruption growing paler, ordered daily inunctions of two grammes Hg in four grammes lanoline per day. The iritis had besides been treated with atropia and tepid wet dressings.

The patient was not seen for several months, not till the 15th of June, when she said she had used 60 packages (120 grammes) Hg, during several interruptions, necessary for mercurial stomatitis. The condition on the above-named day was as follows: Almost unbearable pains in the legs, especially at night. The parts of the body before named were covered for the most part with irregular, more or less pale, brownish pigment spots. On the forehead, under the roots of the hair, and under the outer corner of the right eye, besides an increased brownish-red, somewhat scaly, papulous eruption; also on the outer side of the right forearm. On the outer side of the right lower leg was found a somewhat excavated granulated sore the size of a half-dime, and on the front of the left leg a similar one about the size of a fifty-cent piece, also, immediately under it, a sore of the size of a cent, resembling an ulcer, which had undergone a deep scraping a few days before. There was a greater or less reaction of all sores, but they showed slight tendency to heal. Aside from a slight stomatitis and a lack of appetite, there was nothing further noticeable in the patient's condition.

As the case in question showed great obstinancy in yielding to the anti-syphilitic treatment so far employed, then, following Baccelli's advice, to "use the intravenous injections of corrosive sublimate in such forms of syphilis as showed themselves passive towards the usual specific treatment," and gaining the patient's consent, we decided to begin with injecting corrosive sublimate directly into the blood and ambulatorially.

June 15th. After making my hands aseptic with lysol solution, the patient's left elbow (upon which a vein shone forth through the skin) was cleansed with lysol, then with corrosive-sublimate solution (two per cent). An elastic band, cleansed in lysol, and as thick as a quill, was placed so tightly around the arm that the cubital veins swelled to their greatest extent. A common Pravatz syringe was then cleansed in lysol solution and in Baccelli's weaker corrosive-sublimate solution, very carefully; after which the syringe (one cubic centimetre) was filled with the same solution (one milligramme corrosive sublimate). The needle was then inserted in the vein, and a few drops of blood escaped around the needle; then the liquid was in-

[3] Not "all," not the insoluble ones; for example, bismuth for gastritis, etc.

jected very slowly but continuously. After one-half of it had been injected, the patient complained of numbness in the arm. The band was removed, after which the numbness disappeared and the rest of the liquid in the syringe was injected. No attendant subcutaneous swelling appeared. The injection was painless. The liquid injected was at summer heat (+ 30° to + 32° C.). No taste of mercury in the mouth; no salivation. When the needle was withdrawn, another drop of blood followed. No bandage was placed on the arm. It may be added the patient's subcutaneous veins were unusually small and were with difficulty caused to swell.

June 16th. No reaction from yesterday's treatment. After the same preparation as then, an injection of three cubic centimetres (of three milligrammes corrosive sublimate) was made in a right cubital vein, with a ten-cubic-centimetre graduated syringe, armed with a fine morphine needle. The needle was not withdrawn immediately after the injection, but was left in the vein some seconds, while the patient was questioned as to how she felt; for the intention was, if possible, to inject a few more milligrammes of sublimate. In the mean time, a bloody liquid forced its way into the syringe. Consequently, the injection was not continued, but the needle withdrawn.

June 18th. Injected three milligrammes corrosive sublimate. In all respects the same as yesterday, including the penetration of blood into the syringe at the close of the injection.

June 19th. Injected four cubic centimetres of the weaker solution, that is, four milligrammes corrosive sublimate. As soon as two cubic centimetres had been injected a little pause was made, in order to change the direction of the needle, upon which blood forced itself into the syringe; it seemed to coagulate into the minutest particles, not instantly, but after several seconds. Was somewhat undecided as to continuing the injection; but as in Italy the method was proven harmless, and as it seemed to me at the moment probable that the injected corrosive-sublimate liquid had, though being very slowly injected, a similar effect on the blood in the walls of the vein with which it came in contact, two cubic centimetres more corrosive-sublimate solution were injected, on which a cloudy precipitate followed, also some uncoagulated blood. The corrosive-sublimate solution entered more quickly than the blood. All of the blood from the vein (about one-third of a cubic centimetre) followed the lower wall of the syringe; and although the syringe was held inclined from below upwards, it was impossible not to inject some of it as the operation continued. There was no disadvantageous results from the injection.

June 20th. The symptoms have not altered. The pains at night are particularly severe. The dose was increased to six milligrammes corrosive sublimate, or three cubic centimetres of the strong solution. Six hours after the treatment yesterday, the patient had slight chills and perspired freely, also felt weak. (The heat has been oppressive, and nearly every one has been affected by it.) Patient slept unusually well during the night.

June 21st. Injected three cubic centimetres two-per-cent. solution, or six milligrammes corrosive sublimate. The instant the needle entered the vein, blood appeared in the syringe. Before it was visibly coagulated it was injected together with the named quantity of the solution. She had again felt pain in the legs during the night, but felt well otherwise. As the syphilis did not appear to be especially affected by this treatment, ordered simultaneously potassii iodidum, per os.

June 22d. So far the injections had been made into different veins in the elbow folds, and twice in precisely the same spot with intervals of times between. Injected now four cubic centimetres strong solution (eight milligrammes corrosive sublimate) into a vein in the right wrist, volar side. The needle appeared to be in the vein, yet, though the syringe was held inclined from below upwards, and the solution was not instantly injected, no blood was seen, as happened so often before, to enter the syringe. Accompanying the injection was a swelling alongside the vein, for about two centimetres, and the patient complained of pain. As it was evident the needle had come perivascularly, the injection was suspended after half a cubic centimetre, (one milligramme corrosive sublimate) had been used.

June 23d. After yesterday's treatment an appreciable swelling appeared on and around the spot pierced, also the skin was "black and blue." Injected to-day nine milligrammes corrosive sublimate in a vein in the left wrist. No inconvenience from it, more than a "queer taste" in the mouth about half an hour later, which lasted several hours.

June 25th. Complained of pain in the right elbow, where one of the veins, which had received two injections into almost the same point, felt rather hard for the distance of one centimetre with the ligature around the upper arm, scarcely any swelling of the vessels where a former injection was made is noticeable. An unused vein on the back of the left hand, swelled enough, however, and here an injection of five cubic centimetres strong solution (ten milligrammes or one centigramme corrosive sublimate) was made. Stronger metallic taste in the mouth than formerly; otherwise about the same as yesterday.

June 26th. No tenderness in the teeth. The gums redder, without being swelled, however. No diarrhea. General condition good. Syphilitic symptoms show a good tendency to disappear, although one cannot call the condition satisfactory in consideration of the strong treatment. The patient, who has been for some time taking one and a half grammes potassii iodidum per day, has to increase the dose to two grammes per day.

June 27th. Injection of five cubic centimetres (one centigramme corrosive sublimate) in the right foot's dorsal vein. Some drops of the fluid came, in the beginning, perivascular.

June 28th. Patient says her foot was very painful after treatment yesterday. Foot was very swollen and red on her arrival home. She felt later creeping and cramp in her body, and wanted to sink down every time she rose; had nausea; felt numbness in her body; had something like trembling in her face, hands and legs. Teeth tender (but not loose). Has stomatitis to-day; feels weak, but only the symptoms of the foot and mouth — of those already named — remain, the former of which is red, swollen on the back and tender up to the tibio-tarsal joint and above, precisely as during an acute, mild phlegmon. Ordered no corrosive-sublimate injection, no potassii iodidum. Lying still. Lead water compress.

June 29th. All symptoms decreasing. Patient takes potassii iodidum again, but in small doses, because she appears not to tolerate large ones.

July 6th. Foot no longer red; some swelling and tenderness in the tibio-tarsal joint. The pain in the left leg, which disappeared a while, has returned since. The potassii iodidum mixture was exhausted four days ago. The old papulous eruption seems to have disappeared, but new eruptions appear to be coming. Ordered hydrargyri iodidum rubrum and potassii iodidum in pills.

July 16th. Has not taken any pills for three days, because diarrhea set in. The more recent syphilids are worse than two weeks ago, and, besides, small balls and holes appear in the right leg. The right foot is perfectly free from tenderness or swelling. Began again with intravenous corrosive-sublimate injections, without accompanying iodine treatment. Injected five milligrammes corrosive sublimate into the left-arm fold. Immediately following the insertion of the needle, blood appeared in the syringe. By holding the instrument much inclined downwards, the solution (which was at once injected and hindered the entrance of more blood to the syringe) could be injected without the blood — which kept to the lower side of the syringe — entering the vein again; antiseptic bandage afterwards.

July 17th. On the middle of the left forearm injected four cubic centimetres, strong solution (eight milligrammes corrosive sublimate), of which nearly half came perivascularly; followed by swelling. Massage; bandage.

July 18th. Upper half of the left forearm swollen, red and with increasing local temperature. The facial papulæ were cauterized with solution corrosive sublimate in alcohol (one to five); besides this no other treatment than cold compresses on the forearm.

July 21st. Patient, who has had to remain for three days on account of the swollen arm, and so did not have any syphilitic treatment, was found better in the left arm, but new eruptions had appeared on the right cubital region. After putting the band round the right upper arm, a vein on the middle of the under arm appeared somewhat swelled. On attempting to penetrate the vessel, a little blood entered the syringe through the needle; but when the liquid was injected, perivascular swelling appeared, for which reason the needle was instantly withdrawn and a new attempt was made with a vein on the back of the left hand, with the result that five cubic centimetres (ten milligrammes, that is one centigramme corrosive sublimate), could be injected without pain and which expanded the vessel nearest above the needle to considerable extent, but which disappeared after some seconds. The swelling, therefore, was not perivascular or subcutaneous, but depended on the injecting fluid not being carried away quickly enough, hindered by the band which strangled the upper arm and which was not removed till the injection was entirely finished. Bandage applied. Patient said afterwards that she got the metal taste in her mouth immediately after leaving office. After a few hours, headache and diarrhea, which latter continued the following day a little. After coming home (making it an hour after the treatment) the patient noticed that her *right* forearm was swollen, but no pain was felt. The left hand and arm seemed to be normal.

July 23d. The right arm very slightly swollen, and several ecchymoses in the skin where the band sat, also for some distance down.

As all veins suitable for injection seemed to have disappeared the intravenous treatment had to be given up entirely. Some improvement, though very slight, has taken place in all respects. Ordered potassii iodidum.

August 19th. The sore on the left leg is half healed, but new eruptions of small gummata have appeared on the right leg. Ordered syrup Giberti in increasing doses, as large doses as possible.

September 3d. Patient improving very little.

It cannot be denied that Baccelli's treatment of syphilis with intravenous corrosive-sublimate injections showed itself harmless, even in this case. The maximum dose should not exceed eight milligrammes.

The patient received, however, one centigramme three times; twice without any injury at all, but once when one centigramme corrosive sublimate was injected on two following days, the latter injection of one centigramme was accompanied with alarming symptoms of mercurial poisoning. The symptoms, however, decreasing very soon.

Several times, in spite of all attentions, the injections became perivascular instead of intravascular, with the consequent pain and swelling, which sometimes compelled the suspension of the treatment; but finally the marvellous fact appeared that the veins became smaller and at last were not large enough or available for injections, which perhaps shows, as Baccelli says, "the prompt and searching effect on walls of the blood-vessels," although in this case almost too strong.

In the case before us, the intravenous treatment did not act so "quickly" or "powerfully," but the patient seemed to be able to bear very much, almost one centigramme corrosive sublimate intravenously. She did not get salivation or stomatitis after nine milligrammes, only a taste of mineral in the mouth, which quickly disappeared, which, however, is so much the more remarkable, as she got diarrhea after comparatively small doses of mercury and potassii iodidum per os. We have clearly a case of very rebellous syphilis, rather refractory against mercury; but the intravenous treatment showed itself, however, to be of use, and, finally, although slowly, caused a change in the disease for the better.

There is do doubt but the intravenous, medicated treatment of diseases is a step forward, and to be resorted to in some cases, when other methods fail.

Dr. Kezmarsky [4] has recently published two cases of venous sepsis, treated with intravenous injections of corrosive sublimate, one to eight milligrammes, *pro dosi*, and, as it seems, with good results.

Last November I had a similar case:

Mrs. A., forty years of age, delivered by a midwife from her fifth child, took ill the following day with fever and very great pains in the *articulationes ileo-sacrales*. She was given a pelvic girth and (per os) some phosphorus, and was getting along better every day, when on the sixth day she got chills and (suddenly) increase of fever. When I saw her at this time she had all the symptoms of venous sepsis, with almost no local symptoms by palpation and touch of the pelvic organs. Lochia were normal or perhaps a little fetid. The tenderness in the joints was gone. The condition of the patient was half soporous, and so bad that I found it hopeless and too dangerous to curette. She was given an intra-uterine washing of lysol solution, one per cent., and an intravenous in-

[4] Centralbl. f. Gynäk., 1894, No. 33.

jection of corrosive sublimate (three milligrammes *à la Baccelli*).[5]

The seventh day of the disease no washing, because the lochia were not fetid at all, intravenous injection of five milligrammes corrosive sublimate; the eighth and ninth day of eight milligrammes. The eleventh and twelfth days diarrhea. No corrosive-sublimate injections; quinine, ergot, opium. The thirteenth day eight milligrammes corrosive sublimate intravenously, and an intra-uterine washing, because of a little fetid lochia. During all these days the temperature was very irregular, from + 38.5° to + 40.5° C. Pulse 124–130; very weak. The patient sometimes had chills. She was weaker for every day, but somewhat less soporous.

The fifteenth day, no injection. The temperature at 6 P. M. + 38.6° C. Following morning + 40.6° C. When I could not find any especially good result from the intravenous corrosive-sublimate injections, I omitted them, especially as they could be made only in the dorsal veins of the hands, which swelled in the case more than the cubital veins, and it was very difficult always to prick on the same vessels.

As the very poor patient had no nurse and no help in her home, she was on the seventeenth day sent, although much weakened, to the hospital, where she died after four days. The autopsy gave "grayish" endometrium with numerous colonies of staphylococcus and some other bacilli therein and in the liver, the blood, etc., also in the infarctions of the kidneys, spleen and valvulæ cordis.

The result might perhaps have been different if the intravenous corrosive-sublimate injections had been given earlier and from the beginning stronger. It cannot be denied, however, that the idea may in some degree be a rational one, that to sterilize the blood, or rather to somewhat weaken the bacilli as to the organism itself, is more easily to overcome the infection; and it seems to me that the scraping and antisepsis of the endometrium combined with intravenous corrosive-sublimate injections, perhaps may at present be the most rational treatment of puerperal fever; so much the more as the intravenous injections do not seem to destroy the antibacillar or antitoxic power of the blood, but only co-operate to overcome the infection.

As we know, Baccelli first employed intravenous injections, namely, neutral quinine hydrochlorate solution, for malaria, with very good results; and when cases of febris intermittens perniciosa, defying the usual treatment, are found, as talked of in our Section last spring, then this treatment may be vouchsafed for in some words.

In a letter to me, dated Rome, July 5, 1894, Baccelli gives the following formula:

| | | |
|---|---|---|
| ℞ | Quininæ hydrochloratī, . . . . . | 10.00 |
| | Sodii chloridi . . . . . | 0.75 |
| | Aquæ distillatæ . . . . . | 100.00 |

Adding that the solution should be warmed to boiling point, then cooled to + 37° or + 38° C.;[6] also be injected to the amount of five grammes of liquid (0.50 grammes quinine hydrochlorate). The injection is performed as above described.

Baccelli's closing words about the subject, "Attenzione alla antisepsi," are to be remembered.

[5] All the following injections were made without inconvenience with a solution of chamber temperature, that is, of about + 18° C.

[6] A little under this temperature the quinine is mainly precipitated.

## THE CAUSES OF SUDDEN DEATH.[1]

BY THOS. M. DURELL, M.D.,
*Medical Examiner, Lecturer on Legal Medicine in Tufts Medical School.*

IN the discharge of his official duties the medical examiner is called upon to view the bodies and to examine into the cause and manner of the death of such persons as are supposed to have come to their death by violence. A large proportion of the number of cases that are investigated each year by the examiners are cases in which a simple view of the body is made, without autopsy. This is an unfortunate state of affairs; still it is the law, and we must abide by it. On this account the matter of post-mortem diagnosis is of vital importance to us; and it is for this reason that I have presumed to bring to the notice of this Society a matter which has been discussed and written upon until one may fairly ask, What new can be said upon it? For all this, one can never be called upon to view a dead body without being confronted by the same difficulties that have annoyed the medical expert for all time.

The saying of Dr. Holmes upon the subject of phrenology is often suggested to me in this connection; you will remember that he said "that one could tell about as much about what was inside a skull by feeling of the outside, as one could by feeling of the outside of a bottle without smelling of the cork."

We have all felt for a long time the almost uselessness of views without autopsy; but under the existing laws we are obliged to do the best we can; and I think that experience has shown that the examiners have become wonderfully expert in this direction with the limited means at their disposal.

The language of the statutes is very wise, and has suggested a means of solving a part, at least, of this difficulty. I refer to that part which I have already quoted, namely, "to examine into the cause and manner of the death."

A careful inquiry into the manner of the death is of the utmost importance; for this manner of death is the real clinical history of the case, if I may be permitted to use that term as applied to a death history. By these means we have been enabled to learn some few things, and I trust that I may in this paper add my mite to the grand total.

It is a popular belief, not only among the laity but among the profession as well, that the cause of sudden death is either a disease of the heart or an apoplexy; but we certainly know now that there are very many other causes than these, and we also know that persons do not die very suddenly from a cerebral hemorrhage, and that in these cases there is always a period, longer or shorter, of unconsciousness with stertorous breathing.

The causes of sudden death as given by Tidy, are as follows:

(1) Disease of the heart (especially fatty and brown degeneration), aortic regurgitation, interstitial abscess, rupture of the heart or of its valves, diseases of the pericardium.

(2) Diseases of the blood-vessels (especially aneurism and thrombosis), large effusions of blood into the brain or its membranes (cerebral and meningeal apoplexy).

(4) Pulmonary apoplexy and hematothorax.

[1] Read before the Middlesex South District Society.

(5) Sudden bursting of visceral abscesses.

(6) Ulcers of the stomach, duodenum or other parts of the alimentary canal.

(7) Extra-uterine pregnancy, peri- and retro-uterine hematocele, rupture of the uterus.

(8) Rupture of the urinary bladder or of the gall-bladder.

(9) Cholera and certain zymotic diseases.

(10) Large draughts of cold water taken when heated.

(11) Mental emotions.

(12) Accidental swallowing of foreign bodies.

In regard to death from diseases of the heart I shall say nothing except to call attention to the very able paper read before the Massachusetts Medico-Legal Society on October 4, 1893, by Dr. William T. Councilman, in which the writer calls attention to the very important part which the coronary arteries play in causing disease of the heart. He says that "the coronary arteries stand in casual relation with the pathological conditions known as fibrous or chronic myocarditis"; and further on he says "that the only condition of the heart not connected with disease of the coronary arteries which may be followed by rupture is fatty infiltration."

It is not my purpose to attempt to deal with the vast majority of the causes of sudden death; but I shall simply confine myself to some few that have been of great interest to me personally and which are not dealt with much in the text-books. One of these causes is pneumonia; and the more I look into the matter the more I am convinced that a large number of deaths occur — sudden deaths within the meaning of this paper — each year from this cause, which are not recognized as such, and in which other causes are given in the death-certificate. We all know that it is not an uncommon thing to find upon examination of the chest, of persons who do not appear very sick and who are walking about and attending to their business, large patches of consolidation at the base of the lungs. Now in a large percentage of the cases with which we have to deal we have added to this the elements of alcoholic excesses and consequent exposure to wet and cold — elements in themselves very conducive to the growth of the germ of pneumonia. These cases present a history which is very characteristic and which is as follows:

A man is brought into a police-station and locked up for drunkenness. He may or may not complain of feeling sick; but at any rate there will be nothing about his appearance that would lead one to think that he had any serious illness. In the morning he is found dead in his cell. Or again, a person may come home and complain of slight illness, go to bed, and be found dead in the morning. In either event autopsy is very liable to show that death was due to pneumonia, the probable explanation being that during the night, with the combined favorable elements of alcohol and exposure, the process spreads upwards rapidly from the base, involves the apex, shuts off the supply of air, and causes death.

The following cases illustrate this matter; the first I was permitted to see by the kindness of Dr. F. A. Harris, of Boston.

Woman had been a hard drinker, and had been to the Island. On January 9th, she came home, and complained of not feeling well. She was helped up to her room in the attic, threw herself on the bed, and, after a gasp or two, died. Upon autopsy it was found that the whole right lung was in a state of gray hepatization, and that the left lung was engorged with blood. This was all that was found.

J. K., age twenty-four years. Taken to the station-house and locked up for drunkenness. Had a slight cough, and complained of not feeling well. Was found dead in the morning. Autopsy showed complete consolidation of the left lung, with commencing trouble at the base of the right.

H. R. After a mild spree returned home; complained of feeling cold, and went to bed. Was found dead in the morning. Autopsy showed pneumonia.

Mrs. Ann F., age fifty years. Was apparently well on going to bed on the night of December 5th. Was found dead in bed in the morning. Autopsy showed complete consolidation of both apices, and an older process at the base and throughout the right lung.

Another and quite common cause of sudden death in the same class of persons is edema of the brain from alcoholic poison.

And just here let me say that it is a very unwise and unsafe thing to make a diagnosis of alcoholism without an autopsy. A case which I saw a good many years ago illustrates this. A man was found in an outhouse apparently asleep. He was roused with difficulty, and was finally taken to the police-station. Here there was a question of opinion as to whether his condition was due to alcohol or opium; at any rate he was sent home, and died. At the autopsy, there was found an occlusion of the middle menigeal artery, and no evidence of alcohol or opium. And in this connection let me say that the odor which is found in alcoholic cases is not the odor of alcohol, but resembles that of molasses.

Several cases of my own illustrates this condition of death from edema of the brain.

John C. S., age thirty-five years. July 9th was found dead in bed, with blood on his face and on the bed-clothes. His wife was in the bed with a cut on her head, and so drunk that nothing could be learned from her. Two men who were in the house the night before said that S. had been drinking heavily, but that he appeared all right at 10 P. M. Autopsy showed no evidence of violence, but showed the most marked condition of edema of the brain. The blood evidently came from the cut on the wife's head.

Edward S., age thirty-one years. Found dead in the loft of a barn. Had been drinking heavily for some time, but was apparently no drunker than usual at 10 P. M., when he was last seen. He was found dead at 6 A. M. Autopsy showed edema of the brain and no other cause of death.

J. H., age twenty-eight years. Arrested for drunkenness, and taken to police-station. Died during the night. Autopsy showed extensive edema of the brain.

P. McM., age twenty-six years. Had been drinking hard for some days. The night before his death he ate his supper at about 7 P. M., and went out. He was not seen after this. In the morning he was found dead on the floor of the front entry. Autopsy showed edema of the brain, and nothing else.

The following cases show several rather unusual causes of sudden death.

Ellen D., age forty-seven years. Had been as well as usual up to April 23d. On this day, while at work, she was taken with hemorrhage from the mouth, and died in a few minutes. The amount of blood lost was enormous. Upon autopsy the stomach was found full of blood, and the cause of this was found to be cirrhosis of the liver.

John M., age forty years. On his way home from a drinking-bout he fell down and vomited into a slight depression in the ground, and was literally drowned in his own vomit.

Chas. D., age twenty years. Came out on a horse-car from Boston between eleven and twelve o'clock. Had evidently been drinking, but could walk unaided. After he left the car he was seen to lean against a fence and then fall to the ground. When he was found he was dead. Autopsy showed the presence of a large piece of meat in the trachea. He had evidently attempted to vomit, and in the process this piece of meat had lodged in the trachea.

Andrew D., aged fifty years. Had been drinking, and became unconscious. His wife, who had also been drinking, attempted to bring him to consciousness by placing a cloth wet in strong ammonia-water over his mouth and nose. He died from the effects of the ammonia; and upon autopsy his larynx and trachea looked as if the mucous membrane had been scarified.

P. V., aged fifty years. Had been well up to Saturday night. In a quarrel with his wife she is said to have thrown a shoe at him which struck him in the abdomen. No attention was paid to the matter, but on the following night he died suddenly. Autopsy showed no marks of violence externally. Then was found a single ulceration of the descending colon, with perforation; fecal matter in the cavity of the abdomen; peritoneum not opaque but with injection of the vessels.

L. B., aged fifty years. History, during previous ten years, of abdominal pain. After a severe attack of pain he suddenly died. Autopsy showed perforation of gall-bladder, and escape of numerous stones into the peritoneal cavity.

G. R., age twenty eight years. Robust health. Was being treated for a common sore throat; suddenly he grasped his throat, ran around the room, and expired in two or three minutes. Autopsy showed absolutely nothing, with the exception of edema of the larynx and the cardiac and pulmonary appearances of asphyxia.

One might go on almost indefinitely relating curious histories of sudden death; and the one lesson that can be learned from a connection with these cases is the absolute necessity of making an autopsy in all cases of sudden death.

## Medical Progress.

### REPORT ON MENTAL DISEASES.

BY HENRY R. STEDMAN, M.D., BOSTON.

#### GENERAL PARALYSIS.

*General Paresis a Toxine Disease.* — Bannister contributes to the April number of the *American Journal of Insanity* an excellent article on the present theories of the etiology of general paresis. Three views are held by authorities as to the relations of syphilis and paresis: (1) That syphilis has no part in the etiology of the disorder. This was the prevailing one in the early history of the affection, but statistics of late years have rather given place to another view. (2) That syphilis constitutes a predisposing cause in a large number of cases, but that paresis could not itself be considered as syphilitic. This is probably the dominant view at the present time. There is considerable range of opinion among authorities of this group as to the etiological importance of syphilis, the general opinion being that the specific infection simply prepares the way for the causal factors, mental strain, worry, traumatism, intemperance, etc., to bring on the disorder. (3) That paresis is almost invariably or always of syphilitic origin, and in its extreme form that it is in itself only a late manifestation of syphilis — an effect of the syphilitic poison.

Bannister believes, from the present trend of opinion, that the view that paresis is in almost every instance, if not in all, a result of syphilis, will become before long the prevailing one. A review of statistics and data of a dozen authorities mentioned in this article show syphilis in from 75 to 95 per cent., of cases. The fact that paresis can be indisputably caused from comparatively recent syphilis and that this is in all respects undistinguishable from the usual type is now generally recognized, which fact supports the view of the generally syphilitic character of the disease.

Other facts supporting the specific origin of paresis are those of conjugal paresis, as lately reported by Dr. Dewey and others, in which husbands seem to communicate the disease to their wives; also cases of precocious paresis in which it appears at puberty in subjects of hereditary syphilis. The relative influence of profession or occupation is also significant in this connection. Members of certain trades and professions seem to have an especial liability to paresis, as military men, railroad men, and commercial travellers. That this is not simply due to the hardship and hazards of the life they follow, is indicated by the fact that 70 per cent. of the female paretics at Kankakee were wives of men of these classes.

After successfully answering the objections offered against this view of relation of syphilis to paresis, Bannister presents his theory that paresis is the result of the action of a poison on the nervous system, and that poison is a specific toxine, needing only certain conditions to prepare the way for its activity. We have, therefore, in paresis a disease that in its typical form may unquestionably follow syphilis; that according to the last statistics is preceded in from 70 to 90 per cent. of all cases by syphilis; which seems to be communicable from husband to wife; that abounds in great cities and is rare in rural districts; that occurs early in persons of hereditary syphilis; and that is especially frequent in classes of men and women in whom syphilis is common.

*The Etiology of General Paralysis.* — Houghberg[1] has made an important contribution to the question whether general paralysis is caused by syphilis. One group of psychatric physicians, including most of the French, do not give any high importance to syphilis as a cause of paralytic dementia, laying more stress upon the abuse of alcohol, excess in venery, and injuries to the head.

Those who support this view do not take sufficient pains to make sure whether their patients really have had syphilis or not. On the other hand, the psychiatric physicians of Scandinavia and Finland hold that general paralysis is a disease entirely caused by an earlier infection of syphilis. The German alienists, with Mendel, for the most part take a middle position. Although they admit that syphilis is an important factor in the production of so-called paralytic dementia, they do not consider it to be the sole cause.

Houghberg's own observations, which are, by the way, confirmatory of Bannister's opinions, were made upon 107 patients, 98 of whom were males and nine females. The details are given at length in a paper of 82 pages. He found syphilis to have been undoubtedly present in 81 per cent. of his cases, and probably so in 11.2 per cent., thus raising the proportion

[1] Allgem. Zeitschrift für Psych., 1 Band, 3 and 4 Heft.

to 92.2 per cent. This is the highest ratio recorded by any observer save Dengler, who found syphilis in 28 out of 30 cases, equal to 90 per cent.

Houghberg arrived at the following conclusions:

(1) General paralysis is a disease which especially affects the town population of Finland. It does not affect women of the better classes.

(2) The importance of syphilis as a factor in progressive paralysis seems to be very great, especially when we consider that venereal disease plays no longer part in the causation of other forms of insanity.

(3) General paralysis, which comes on most frequently between the ages of thirty and forty-five years, makes its appearance from four to five years after the syphilitic infection.

(4) The symptoms of constitutional syphilis which precede general paralysis are of a mild character.

(5) Compared with syphilis, the other assigned causes, such as hereditary predisposition, affections of the mind, abuse of alcohol, and excess in venery, play but a subordinate part.

(6) In paralytic dementia known to have followed syphilis, there were no distinctive symptoms from the cases in which syphilis was presumed to be absent. No benefit was derived from antisyphilitic treatment, nor were any alterations of a specially syphilitic character found on examination post-mortem.

*Pathogeny of General Paralysis.* — Kowalevsky [3] has a toxic theory of general paralysis: It is well known that progressive general paralysis is believed by some authorities to be the result of an interstitial and by others of a parenchymatous encepalitis. He believes both to be equally well-founded opinions, but gives as the fundamental cause of this initial alteration of the neuroglia in certain cases and of the nervous elements in the others, an intoxication of internal or external origin.

Whenever cerebral function is exaggerated, there is an internal or external toxic influence at work. The products of non-assimilation which accumulate then in the nerve cells of the brain greatly alters and finally destroys them. Then follows irritation of the neighboring vessels by this toxic material, and also proliferation of the neuroglia. At the same time he does not hold that cerebral hyperactivity or intellectual overstrain can by itself alone exercise a destructive action upon the nervous elements unless the soil be prepared by other conditions, such as hereditary syphilis or hereditary instability of the nervous system.

Toxic influences of external origin which may produce general paralysis are quite numerous. First and foremost comes the syphilitic virus, then a number of toxic substances such as alcohol, lead, mercury, etc. Each of these agents may give rise to a different clinical variety of general paralysis. General paralyses of traumatic origin have in equal degree auto-intoxication for the cause. However, we must admit that traumatism by determining a circulatory disturbance of the brain modifies cell-nutrition and makes room for the production of compounds of pathological origin, which play the rôle of veritable toxines. To some of these cases an intoxication of external origin is superadded to this auto-intoxication, when the subject of the traumatism is a syphilitic, an alcoholic, etc. In these cases the trauma, by modifying the resistance of the brain, favors the injurious action of the alcohol, the syphilitic toxine, etc.

[3] Bull. de la Soc. de Med. Ment de Belgique, 1894, No. 74.

*Syphilis of the Nervous System and General Paralysis.* Raymond [2] gives histories of three cases which he believes to throw light on the relations of general paresis to syphilis.

The first, a woman with history of syphilis, presented the symptoms of general paresis (with the exception of extravagant delusions), combined with those of tabes. Death in a series of epileptiform seizures. At the autopsy were found meningeal hemorrhage, multiple foci of cerebral edema, and syphilitic meningomyelitis of the spinal cord and brain.

In the second, in a man with history of chancre, but not of secondary symptoms, there was rapid development of symptoms, both of tabes and general paresis. At the autopsy, lesions of diffuse syphilitic meningoencephalitis, and typical posterior sclerosis of the spinal cord. Evidence of former gummata of the kidneys.

The third, a man, contracted syphilis at the age of twenty-five, and two years later developed paraplegia, which improved under specific treatment to such a degree that he was able to walk; anesthesia disappeared, but a spastic condition persisted. Two years later he had three transitory attacks of aphasia, which left no mental impairment. Death at the age of thirty-two, of pulmonary tuberculosis. At the autopsy there were found a focus of sclerotic myelitis in the upper part of the dorsal regions of the spinal cord, with ascending and descending degeneration of the ordinary character; slight arteritis obliterans of the internal carotids and the left middle meningeal artery; and a general diffused inflammatory condition of the capillaries of the cortex.

From these cases he thinks the conclusion justified, that in general paresis of syphilitic origin the lesion is primarily vascular, affecting especially the arterioles and capillaries. If, as in his last case, the lesion does not progress to such an extent as to impair the nutrition of the nerve cells, no cerebral symptoms may be noticed, but when they degenerate, symptoms of general paresis make their appearance.

He gives account of two other cases, in which subjects of syphilis have shown symptoms calculated to excite suspicion of general paresis, in one case for six, in the other for fifteen years, without progress of the malady.

### PSYCHOPATHIC FAMILIES.

From observations in this direction Perugia [4] deduces the following conclusions:

(1) The morbid types are not transmitted in psychopathic families in identical forms, but become aggravated in their transmission through the generations.

(2) Suicidal insanity only is constantly transmitted to descendants in the same form.

(3) Among the various insane types the periodical form is relatively frequent.

(4) The somatic signs of degeneracy are much more frequent than in non-hereditary lunatics, but are not aggravated proportionately to the psychic degeneracy.

(5) Very often sexual abuses, alcoholism, morphinism, and onanism are concomitant causes aggravating the heredity in these families.

(6) Bodily diseases attack the hereditarily insane with more than ordinary frequency.

[2] American Journal of Insanity, October, 1895.
[4] Rivista Sperimentale, xx, p. 68.

(7) Maternal heredity is propagated to the greater number of descendants.

(8) Psychopathic families have a fatal tendency to intermix and fuse among themselves, thus reinforcing the heredity.

(9) The psychopathic heredity affects both sexes equally.

(10) Psychopathic families, especially those in whom the heredity is bilateral, are doomed to extinction, as much by their great mortality in infancy as the sterility of their marriages.

### TREMORS IN THE INSANE.

Cristiani[5] concludes from experimental researches that in insanity generally of all the various forms we may meet with tremors, independently of other factors, due solely to the altered functions of the psychic sphere. These tremors are of the "intention" kind, ceasing during repose. They cannot be referred to any single form of mental disorder, but are solely connected with the two fundamental symptoms of excitement and depression. In excitement the tremor is vibratory, more frequent, arythmic and unequal; in depression it is undulatory, slower and more rhythmic. The tremors of the insane have a pathogenic mechanism and a semiotic significance that may be stated to depend on a functional dissolution of the nerve centre; and a weakness, incoördination and dissipation of the psychomotor energy was presumed to be absent. No benefit was derived from antisyphilitic treatment, nor were any alterations of a specially syphilitic character found on examination post-mortem.

### LOCAL ASPHYXIAS IN THE INSANE.

Kiernan[6] calls attention to the coexistence of the phenomena of Raynaud's disease with insanity, and recalls a former article of his own in which he pointed out its association with certain special types of mental disorder.

Sixteen years ago in an exceedingly brief discussion of trophoneuroses in the insane, in an article (*Journal of Mental and Nervous Disease*, April, 1878) intended to bring psychiatry into more intimate relation with neurology, he pointed out that all these phenomena occurred in hebephrenial stupor, in stuporous insanity, in melancholia attonita, in katatonia, and in certain cases of paretic dementia. He called attention to a marbling of the extremities and to a gangrenous condition of the same, as a result of paretic dementia.

In nearly all the stuporous states, whether the stupor be that of stuporous insanity or resulting from absorption in a delusion, as in paranoia or melancholia, or occurring in hebephrenia, or katatonia, or stuporous epilepsy, or paretic dementia, manifestations of the Raynaud disease type occur. The pain, due to the disease, felt by melancholic, paranoiac, hebephreniac, paretic dement or epileptic, forms the basis of a persecutory (electric, witchcraft) element in a delusion. The disease is exceedingly frequent in the stupor which sometimes succeeds cases of acute mania. In four of such cases which came under his observation in the Cook County Insane Hospital, and in ten he observed at the New York City Asylum for the Insane, the condition in the feet proceeded to gangrene, and when the patients recovered, as they all did, one or more toes were injured. In such cases, amyl nitrite by the nose, and quebracho hypodermatic injections have been of service. The condition disappears on recovery, but in certain cases may lead to blood-poisoning and secondary gangrene.

In his discussion of the mechanics of these conditions, together with that of the edemas, etc., observed in the insane, Dr. Kiernan adopts the term "vasomotor ataxia" given by Dr. Solis Cohen, as the expression of its underlying condition. Between the typical constrictive variety, as shown in Raynaud's disease, and "local asphyxias" common in the insane, which include both local relaxation and contraction, there are numberless varieties, including demographism, which in its less pronounced phases, is a very slight removal from the normal.

## Reports of Societies.

### MASSACHUSETTS MEDICAL SOCIETY.

#### COUNCILLORS' MEETING.

THE annual meeting was held at the Medical Library, Boston, on Tuesday, June 11, 1895.

The meeting was called to order at seven P. M. by the President, DR. FRANK K. PADDOCK. One hundred and thirty-seven Councillors indicated their presence by signing the roll.

The Secretary read the names of 137 Fellows admitted since the last annual meeting, and of 36 whose deaths had been recorded.

The Treasurer, DR. FORSTER, presented his report, which was accepted, showing the receipts of the Society for the year ending April 15, 1895, with the balance on hand at the beginning of the year, to have been $13,659.96, and the expenditures $9,103.53, leaving a balance of $4,556.43.

DR. DRAPER, for the Committee on Membership and Finances, reported the names of seven Fellows whom the Committee recommended to become retired members; of four to be allowed to resign; and of thirteen to be dropped for non-payment of assessments.

The report of the Committee was adopted.

It was also voted, on recommendation of this Committee, that $2,500 of the surplus in the treasury be distributed among the district societies.

The Committee on Publications reported that DR. W. W. KEEN, of Philadelphia, has been appointed to deliver the Shattuck Lecture at the annual meeting of the Society in 1896.

The Librarian, DR. BRIGHAM, presented his report.

The Committee on Nominations reported, and the following were chosen officers of the Society for the ensuing year: President, Dr. Franklin K. Paddock, of Pittsfield; Vice-President, Dr. A. Martin Pierce, of New Bedford; Treasurer, Dr. Edward J. Forster, of Boston; Corresponding Secretary, Dr. Charles W. Swan, of Boston; Recording Secretary, Dr. Francis W. Goss, of Roxbury; Librarian, Dr. Edwin H. Brigham, of Boston. Dr. Henry P. Bowditch, of Boston, was chosen Orator for the annual meeting of the Society in 1896.

*Voted*, That the next annual meeting of the Society be held in Boston on the second Wednesday in June, 1896.

Standing Committees were appointed as follows:

Of Arrangements: Drs. A. Thorndike, A. K. Stone,

J. G. Mumford, M. V. Pierce, P. Thorndike, J. E. Goldthwait.

On Publications: Drs. B. E. Cotting, O. F. Wadsworth, G. B. Shattuck.

On Membership and Finances: Drs. F. W. Draper, J. Stedman, E. G. Cutler, L. R. Stone, A. H. Johnson.

To Procure Scientific Papers: Drs. H. P. Bowditch, F. H. Zabriskie, H. L. Burrell, S. B. Woodward, L. Wheeler, C. W. Townsend.

On Ethics and Discipline: Drs. G. E. Francis, F. C. Shattuck, C. G. Carleton, E. Cowles, J. F. A. Adams.

On Medical Diplomas: Drs. E. J. Forster, H. E. Marion, E. N. Whittier.

On State and National Legislation: Drs. F. K. Paddock, H. P. Walcott, H. P. Bowditch, T. H. Gage, S. D. Presbrey.

## ASSOCIATION OF AMERICAN PHYSICIANS.

TENTH ANNUAL MEETING, WASHINGTON, MAY 30 AND 31, 1895.

(Continued from No. 25, p. 627.)

FRIDAY. — MORNING SESSION.

### DISCUSSION ON DIPHTHERIA ANTITOXIN.

W. H. WELCH: The decision as to the efficiency of the diphtheria antitoxin is in the hands of the clinician and not of the pathologist.

The soundness of the experimental basis for the antitoxin treatment of diphtheria has been attacked, particularly by Hanseman. It is impossible to take this position unless one denies absolutely, as Hanseman does, that the Klebs-Löffler bacillus is the cause of diphtheria. His position is not justified by the facts; and all of his arguments are equally applicable to the cholera bacillus, and even to the tubercle bacillus and to most of the specific bacteria of infectious diseases. The results of these experiments upon animals are among the most striking ever performed in the laboratory. Nevertheless, we have even more striking results, probably, in the application of the tetanus antitoxin in the treatment of animals inoculated with the tetanus bacillus; although in the application of the tetanus antitoxin to the treatment of human cases the results are distinctly disappointing, so disappointing that it is doubtful whether it has a future in its present form. One cannot argue altogether from the effects upon animals as to the benefit to be derived in the human being. The reason the tetanus antitoxin is inefficacious in the human being is because doubtless the toxine of tetanus is accumulated to such an extent before recognized that the antitoxin comes in too late.

There are two prominent theories as to the mode of action of the antitoxin: the one can be called the chemical, and the other the vital theory. The chemical theory is that the antitoxin directly, in a chemical sense, neutralizes the toxine. The vital theory is that each acts through the agency of cells, that the antitoxin does not in a chemical sense neutralize the toxine but acts upon the cells so as to render them tolerant of the toxine. It seems to me that there are certain points which come out as the result of the application of the antitoxin in diphtheria which speak strongly in favor of the vital theory. One fact is that this method of treatment does not prevent the post-diphtheritic paralyses. They are apparently as common, if not more common, with the antitoxin treatment than without it. The contention of some is that a larger number of severe cases survive, and therefore there will be naturally a larger number of post-diphtheritic paralyses. These paralyses, as all evidence goes to show, depend upon the action of the toxine; and it seems to me that we have here an argument opposed to the view that the antitoxin in a direct chemical sense, is an antidote to the toxine. It speaks to my mind that they act antagonistically upon cells, and that the toxine is not kept from exerting an injurious action upon a certain class of cells. Another point to be borne in mind is the quantitative relation between the antitoxin and the toxine. In a given case of diphtheria, we have no means of knowing with any precision, how much toxine is in the blood, and therefore we do not know how much antitoxin to give. It doubtless happens often that we give an insufficient quantity. We must bear this in mind in considering discrepancies of different observers.

The question is not decided as to whether the antitoxin exerts a specific influence on the pseudo-membrane. Does it tend to become sharply demarked and roll up from the mucous membrane? Many say it does; others say not. Such discrepancies may readily be explained by the fact that in one class of cases or in one instance the dosage is correct, the amount of antitoxin given is sufficient to antagonize the toxine, while in another it is not.

Another point to be borne in mind is one that has been emphasized by Behring, namely, that the benefits of this treatment are very doubtful when the antitoxin has been introduced after the third day of the disease. That has been borne out by experiments on animals. It is very difficult indeed to obtain any positive results twenty-four hours after the injection of the diphtheria culture or the diphtheria toxine, so that we are not to expect brilliant results if the treatment is not begun early.

There are certain points which pertain to diphtheria itself, as it occurs in human beings, which are worth calling attention to. Bacteriologists at present are in favor of calling all cases of sore throat diphtheria, where the Klebs-Löffler bacillus is demonstrable. That means that a considerable number of cases which clinicians have not regarded as diphtheria are now classed by bacteriologists in this group. The diphtheria bacillus occurs in healthy throats occasionally, and in the mildest forms of anginas as well as in the more severe pseudo-membranous inflammations. Now if we see very mild cases put down as diphtheria, cases with very favorable prognosis, of course, the statistics will turn out far more favorably than otherwise. On the other hand, there are certain other cases of pseudo-membranous inflammation which the clinician cannot in any way distinguish from diphtheria and which bacteriological examinations show are due to some other micro-organism, usually to the streptococcus. Now, if no bacteriological examination is made, and these cases are included in the statistics of diphtheria, they result unfavorably to the antitoxin treatment, because the healing serum neutralizes nothing but the toxine of Löffler's bacillus. As to the proportion of these cases, which have all the appearances, clinically, of diphtheria and which are not genuine diphtheria, statistics differ. We must regard such statements as that 30 or 40 per cent. of the pseudo-membranous

anginas which the physician would regard as diphtheria are not true diphtheria, with a good deal of scepticism. In my opinion perhaps not 10 per cent. of the cases are not genuine diphtheria.

Then, of course, the diphtheria of the human being differs from experimental diphtheria. In the experimental diphtheria, we have pure uncomplicated infection due to one organism. In people we often have a complication. The human cases are often complicated with streptococcus septicemia, with pneumonia, and with great mechanical obstruction in the larynx and lower air-passages. Such cases are very unfavorable for the operation of the healing serum treatment.

As regards the statements as to the direct effect of the healing serum, they are very various; but those who favor the treatment are of the opinion that there is a direct and specific effect manifested, but in no instance are these effects different from those which may occur as the result of the natural course of the disease. Thus, you have not any such direct specific manifestation of the action of the diphtheria antitoxin which forces you to believe that something has happened which would not necessarily have happened in the course of nature. The cure is a natural cure; and why should it not be? The natural cure is a cure by antitoxin. This is only a hastening of a natural process.

What conclusion can now be drawn from the elaborate statistics which we have now before us of cases treated with the serum? There are three classes of opinions based upon these statistics. According to one class they prove nothing. According to another, they leave the matter in doubt; they speak neither for nor against the efficacy of the treatment. Others believe that they decide the question, that they cannot be interpreted otherwise than as supporting the claims of Behring. The objections urged against the statistics are, in the first place, that statistics in general prove nothing, that nothing can be demonstrated as regards the efficacy of treatment in such diseases as diphtheria simply by statistics. Then it is urged that these statistics include a very large number of light cases of the disease; that the bacteriologists, call these very mild cases of angina, diphtheria, and if they appear in any large number in the statistics, the result is much more favorable than previously when the diagnosis was purely clinical. It is said that the agitation of this subject in the public press leads the parents of children having mild sore throats to take them to places where the healing serum is administered, and the treatment is begun at an earlier stage than it would have been before this agitation.

As against this argument, it can be urged that these statistics are many of them classified so that you can tell the number of cases, for instance, with laryngeal stenosis, the condition of the throat with reference to false membrane, and so on. There are definite statements that the group of cases does not include a particularly large number of mild cases, etc. It seems to me that the results, which are recorded to the effect that when the treatment is begun before the exudate had extended to the larynx, before there are any symptoms of croup, there is no subsequent involvement of the larynx or only in a very small proportion of cases, are very significant, and furnish a very strong argument in favor of the efficacy of the treatment.

It is also urged that the epidemics of diphtheria at the present time are of a mild character, that the mortality of cases which are not subjected to this treatment is lower than in ordinary seasons. That is not in accordance with the statistics which have been collected with very great pains by a student of Bollinger, showing that in some cities, especially in Vienna, there has been a constant increase year by year of the death-rate from diphtheria.

It is contended that cases which have been treated strictly according to the directions of Behring, the treatment commenced on the first, second or third day of the disease, have continuously progressed in the spread of the membrane and the development of severe symptoms, and terminated fatally. If there were many of such cases, they would be a strong argument against the efficacy of the treatment. A comparatively small number of such observations would outweigh enormous statistical figures; but I fail to find any considerable number of such cases. There seem to be some well-authenticated cases of that character; and it seems to me possible to explain such cases, if we assume that the action of the antitoxin is not that of a chemical antidote but is upon cells. If the antitoxin acts through the agency of cells, we can understand how there may be individual difference and circumstances under which the cells would fail to respond altogether, through idiosyncrasy to the action of the treatment. Then we must consider the possibility that the serum is not of the right quality in these cases.

I think some importance is to be laid upon the clinical impression, quite aside from the statistics, of such men as Baginsky, Widerhofer and Ranke, who have had large experience. They are personally impressed by the observations at the bedside. When one reads the reports of these men, one cannot fail to see, as far as this particular point is concerned, that the impression they receive at the bedside is distinctly favorable to the treatment.

There is a new kind of argument recently introduced, based upon the result of autopsy, particularly upon the work of Ballisto (?) and Klebs (?). They have made autopsies in a number of cases treated with the healing serum. They state that of those cases of diphtheria which were treated without the healing serum, one-quarter of the autopsies presented lesions of fresh diphtheria, whereas only a hundredth of the cases treated with the healing serum gave the lesions of a fresh diphtheria, They conclude from their autopsy-material that Widerhofer (?) is perfectly correct in his conclusion as to the effect of the treatment in Vienna.

Behring was mistaken in saying that the antitoxin was as harmless as common salt solution. There is evidence that it does cause some albuminuria. The discussion of this treatment has called attention to the necessity of a careful examination in diphtheria, and it would appear that albuminuria is present in diphtheria in the vast majority of cases, according to some statistics 67 to 68 per cent., according to others 100 per cent. The arguments for the injurious effects of the blood-serum should be based upon the distinction between the subcutaneous introduction and its intravenous introduction, as Dr. Meltzer has pointed out. The skin eruptions, the affections of the joints, general prostration and cases of diarrhea, which occasionally follow the use of the serum, but which are not permanantly injurious, should lead to discretion in the use of the serum; but they do not, of course, outweigh the benefits of it.

I shall say nothing about immunization. I will simply say, in conclusion, that it seems to me there is a sound experimental basis for the use of the treatment; that the natural interpretation of the statistical results is in favor of the efficacy of the treatment; that it does undoubtedly exert a specific effect upon diphtheria; that it reduces the mortality from one-third to one-half; that when the treatment is begun during the first two days of the disease, the mortality is very low indeed; that it is the duty of the physician to make use of the treatment; that the injurious effects of the treatment are unquestionable in certain instances, but that they are not of the nature of permanent injury so far as we are at present informed, and while they should lead to care in the use of the remedy and care in the dosage, they do not outweigh the benefit which results from its specific action.

Dr. Mason: Dr. Welch has stated so clearly and fully the arguments for and against the antitoxin treatment that I will not dwell upon those points. I will simply present facts in relation to the series of cases which we have had under treatment in the diphtheria department of the Boston City Hospital, where we began to use serum December last. This department is a large one. It receives annually one-third to one-fourth of the diphtheria cases which are reported to the Board of Health in Boston. The material is large, and includes a large proportion of the worst cases, cases which are sent to us, often as a last resort, for tracheotomy, intubation or other treatment. The series of cases we have had to judge from the past year have been severe cases. About one third of all these have come for intubation or tracheotomy. Each of the hospital staff takes his turn of a period of one or two months as it may be. The cases I mention have been under the care of several physicians. I speak therefore for my colleagues.

The mortality for a series of years was from 40 to 50 per cent. or thereabout, one year amounting to 52 per cent. From December 12, 1894 to May 14th of the current year, 306 patients were admitted. There were 81 deaths, or a mortality of 26.4 per cent., which is a reduction of one-half in the mortality. The operative cases numbered 31, with a mortality of 19, or 61 per cent., which was a reduction of about one-third in the mortality of previous years from tracheotomy and intubation. Comparing that series of cases with the cases for a like period in the year previous, from December 12, 1893, to May 12, 1894, the mortality for this series was 44 per cent. This gives a reduction of about 20 per cent. in the mortality between this year and last year.

There is another way in which, perhaps, the efficacy of this serum may be approximately tested, and that is the results upon the death-rate of the city at large. Of course, that could perhaps be open to more fallacies than the hospital figures; but in the city of Boston, the mortality during the last four months (January 1st to May 1st), has been 14 per cent. of diphtheria as against 41 per cent. in the previous year. Still, allowing for these sources of fallacy, I think the showing appears to be very favorable.

Not only are we impressed with the special effect of the treatment upon individual patients, but also by the general appearance of the diphtheria ward, the appearance of comfort and contentment upon the part of the children. Instead of going into a ward with dread as we have done in former years, to find a large number of pallid, strangling and moribund children, we now go into a ward presenting a very different appearance; and I dare say that all of our physicians undertake this service now with much greater confidence and satisfaction than they ever had before. The effect on membrane is certainly noticeable in many cases. The membrane does not curl up, but it does become more effectually limited. I think the suggestion that this mode of cure does not differ from the course of nature will hardly be borne out by the observation of cases. They do pursue a much more rapid course than in the natural progress of the disease, that is, in the severe forms. The patients get rid of the membrane sooner, are able to sit up in bed, perhaps the next day; they lose their pallor; the fetor disappears; and their convalescence ensues very promptly.

With regard to the number of light cases, upon which statistics are based, I think this criticism hardly applies to our hospitals. The cases are bad, and the average severity of the cases is great, as is shown by the number which require intubation or tracheotomy at the outset. Under this mode of treatment, the proportion of tracheotomies and intubations has diminished materially, and the result of these operations has been more favorable to the extent of perhaps one-third. Of course, a much more favorable result can be expected where the serum is administered on the first, second or third day. We seldom see our cases before the third day.

Paralyses have occurred, but I think in a smaller proportion of cases than before. We know nothing as to the cause of the paralysis in diphtheria.

The nature of epidemics, as Dr. Welch states, varies. Cases may be more severe in one year perhaps than in a previous year; but if we consider the fact that for ten or twelve years there has been a very large mortality and the type in Boston has been a very severe type, I think that this year we cannot consider that as an important element.

As far as my own opinion goes and that of my colleagues, this treatment is most valuable. The ultimate test, of course, must be the result of clinical experience.

Dr. Jacobi: I am certainly favorably impressed with the effects of the treatment; but, as Dr. Welch has pointed out, small numbers of cases, even the number that we have now, are not sufficient to allow us to come to any final conclusion about it. We do not want hundreds, but thousands of cases, in different years and different seasons, in order to get to a final conclusion. There have been seasons in which other treatments have been just as successful. I know of 40 cases of diphtheria in which the bacillus was found, 39 of which got well one after another without antitoxin. I know of years where a dozen cases would get well under other treatment. When I offered antitoxin to a number of my younger medical friends in New York, some of them took it and some of them refused it. They said they were perfectly satisfied with the results of mercurial treatment such as had been in vogue in New York since 1848, where fairly large doses of bichloride are given, largely diluted, at short intervals.

We must not forget that there are almost none of those who have published large numbers of cases but have added something to the antitoxin treatment. One of the most enthusiastic men is Baginsky. In all of his 525 cases he combines the antitoxin with his old local treatment — frequent mild disinfectant washes

to the nose and throat — and insists in not giving them up. My advice to those in New York, who have asked it, has been not only to use the antitoxin treatment but to continue the mercurial treatment as well. I am a practical man. As such, I want to save my patients; and knowing how much I have succeeded in doing in the course of a long number of years with careful mercurial and other treatment, I have deemed it unwise to discontinue such treatment. Is it due to this or to the antitoxin alone, that in all the cases that I have used antitoxin recovery has taken place. I would rather have double treatment than insufficient treatment.

Regarding the existence of albuminuria in diphtheria, we ought not to forget that albuminuria is a very common symptom, as has been known these thirty years past. In Baginsky's cases (525) he directly makes the point that he had less albuminuria in the antitoxin cases than he had in those treated in previous years. He also proved by his statistics that the nephritis was less frequent in the cases treated by antitoxin.

There is one point, particularly, in Baginsky's cases that struck me very forcibly. He says that in the last five years he has seen 2,000 cases. In these there were 523 laryngeal operations; so certainly they were not favorable cases. He states that a large number of his intubations would require tracheotomy following the intubation, and these were mostly fatal cases. Now he states that since the antitoxin treatment, not only is the number of operations very much less, but the results of intubations and tracheotomy are exactly contrary to what they were formerly. While formerly they intubated reluctantly only, they now prefer intubation to tracheotomy; and in a large number of cases intubation has taken the place of tracheotomy; and where they did intubate, only in a small number of cases was tracheotomy required afterwards. This proves to my mind that the claim that membranes limit themselves very soon and are thrown off very soon is sustained by facts, and that therefore intubation is so favorable because these cases have to wait but a short time before the membrane is thrown off.

I want to place myself on record here as a heretic. I do not repeat Hansman's opinion, but I simply state the opinion that I had before and after Hansman — that we have been too much in the hands of our friends the bacteriologists. It is well known that the diphtheria pseudo membrane is the same morphologically; when you have the bacillus or the coccus present you have the same sort of exudation, the fibrin, a few blood-cells, leucocytes, and epithelium changed in the characteristic way. Now, then, if that be so, then I should say that the characteristic of diphtheria is the pseudo-membrane. We should be very poorly off if we should have to rely always on a culture to be made before making a diagnosis. I am not prepared as yet to accept the postulate, for it is nothing else but a postulate, that the diagnosis of diphtheria must necessarily include the presence of a bacillus. The bacteriologists claim that you must call diphtheria those pseudo-membranous processes in which you find the bacillus. That has been accepted, and the result is that nowadays everybody speaks either of a diphtheria or a pseudo-diphtheria.

I am prepared to say that it is only the bacillus cases that are amenable to the antitoxin treatment; therefore, I do not say that in every case a culture should not be made in order to justify the antitoxin treatment. I say that every doubtful case should be treated with the antitoxin. I cannot accept that we have to deal with diphtheria only when we find the bacillus.

DR. J. S. BILLINGS: It is only by statistical methods that the efficacy of any remedy can be settled. The experimental methods in the laboratory will first suggest the treatment and then we must get the evidence by statistical methods prepared over a long time and through various seasons. At present the figures given for the treatment by antitoxin are not sufficient to give absolute and positive results. If you apply the chances of error to these death-rates, you will find that their importance vanishes. Two hundred cases with forty deaths, and three hundred cases with ninety deaths, come within the limits of each other.

As has been pointed out by Dr. Welch, it is difficult to compare the recent carefully observed cases with those which were observed prior to the introduction of bacteriological methods. To compare the mortality in the lump is something like trying to compare the mortality of typhoid fever at this time of accurate knowledge with the mortality of low fevers in 1810, when typhoid, typhus and relapsing fevers were all mixed up together. Now, however, we are in a fair way to get definite information and definite statistics.

It would be very bad for public hygiene if the antitoxin treatment is to be relied upon alone. One of the difficulties that I have in dealing with many of the statistics that are furnished is that there is no statement as to what has been done in the way of local treatment. Dr. Jacobi says he uses both methods. Baginsky also uses the two. Where that is done, such statistics should be put apart by themselves, and the cases where the reliance is solely on the antitoxin should be put out by themselves, and the results compared.

We have not solved, by any means, bacteriologically or otherwise the problems as to the spread of diphtheria or its difference in mortality in different epidemics. Twelve years ago diphtheria was rife throughout the Northwest. It swept away 60 to 70 per cent. of the children under five years of age. The mortality, collected by the very imperfect statistical methods in the year ending June 1, 1880, was simply enormous. Now, using the same methods, ten years afterwards, we find that the mortality from diphtheria is extremely small in all that region. It has increased very greatly in the East, and markedly so in the cities. For instance, it is more prevalent in the cities and towns in Massachusetts than it was ten years ago. The reason for this we know nothing about as yet.

DR. MASON: Of course, local treatment is not abandoned in our hospitals; and general treatment, as stimulants and tonics, is also continued. It may have some bearing upon that if I state that since the use of the antitoxin treatment, the expenses of the hospital for local agents, such as peroxide of hydrogen, have diminished $700.

DR. A. C. ABBOTT: With regard to Dr. Jacobi's complaint that the clinicians have allowed themselves to be too much in the hands of bacteriologists in the study of diphtheria, it seems to me that their reasons for allowing themselves to occupy this position are very good. It is very well known to those who have followed the subject closely, that until the bacteriologist made his appearance the knowledge of diphtheria from a clinical standpoint was in a very chaotic condi-

tion. The reliance that was placed upon differentiating diphtheria from other pseudo-membranous inflammations of the throat on pathological and anatomical grounds was very uncertain. Thus, as Dr. Jacobi has said, there are conditions in the throat that on anatomical grounds cannot be recognized. Fortunately the bacteriologist made his appearance, and found factors concerned in the production of these processes that not only differed one from the other biologically, but also in the more important point, in the production of disease. The secondary occurrences in diphtheria are definite pathological manifestations; secondary occurrences that are found in the few fatal cases of pseudo-membranous inflammation of the throat due to streptococci, are of a totally different nature and are associated with the immediate presence of bacteria at the points of secondary deposit. Of course, it is too well known to require dwelling upon that the cases which bacteriologists recognize as non-diphtheritic are not by any means as fatal as those recognized by them as diphtheria. If we are to have statistics of any value on the subject, we must have some fixed point to go on, and the standpoint taken by the bacteriologists is the only one that supplies that want.

Dr. G. M. Sternberg: A word in reference to the nature of the experimental evidence upon the lower animals. The experimental evidence in regard to tuberculin on the lower animals was very unsatisfactory, and is still unsatisfactory. But in the cases of the diphtheria infection, it is demonstrated beyond peradventure that susceptible animals are cured by the timely administration of doses of the serum. The thing has been tested in laboratories all over the world, and in this laboratory by Dr. Reed. Two guinea-pigs, for example, are inoculated with a fatal dose of the diphtheria cultures. One of them gets a dose of antitoxin, the other does not. The one that does not get it dies, the other recovers. That has been done over and over again; and, as you know, that is the way it is tested before it is sent out. The results are almost as definite as a chemical experiment in a test-tube. In a healthy animal of a given weight, a given dose of antitoxin will neutralize a given dose of toxine.

Very interesting experiments have been made by various men on the presence of antitoxin in the milk of an immune animal. A goat is immunized and has the antitoxin in considerable quantity in its milk, although not in so large a proportion as in the blood, perhaps one-fifteenth as much in the milk. It is given off constantly as in the blood. This, of course, raises the question as to whether there is any continuous production of the antitoxin. From the milk it may be obtained in the form of a dry powder.

Dr. F. H. Williams: I began using antitoxin last September, and soon noted the very marked improvement in many severe cases in which it was used early, within twenty-four or forty-eight hours. Sometimes one can see the membrane loose in the pharynx twelve hours or so subsequent to the administration of the antitoxin. In some cases it seems to me the convalescence is less rapid and less satisfactory than without it. I have noticed in a few cases some swelling of the joints, which persisted on one case for more then two months. Doses of half a grain of morphia were hardly sufficient to overcome the pain which the patient suffered.

As has already been stated other means of treatment should not be overlooked. In some cases local treatment may be serviceable, although in many cases it is not required.

I want to show here a syringe for injecting antitoxin, which is a modification of the syringe which I got up some years ago for another purpose. This syringe is made of glass and is packed with asbestos. To sterilize it it is only necessary to boil it in water. To prevent the breaking off of the needle, I have put a piece of rubber tubing, between the needle and the syringe, which allows of considerable motion without breaking the needle. This syringe is less expensive than the ordinary syringe, and can be kept perfectly clean.

One word regarding the bacteriological test. Other things being equal, the prognosis is decidedly more favorable in cases where we do not find the bacillus than where we do. As regards the prevention of diphtheria, it seems to me, that we have in the bacteriological test, a very valuable agent. For some time past I have been in the habit of having the throats of all the members of the household in which there was a case of diphtheria, tested in this way, and I have not infrequently found, where there were several children, that there was one or two and in some cases three other persons in the family infected, where by simply looking into the throat nothing was to be seen. These people would develop all the general and local symptoms of diphtheria, sometimes within one or two days, sometimes not for several days after the discovery of the bacillus.

Dr. Osler presented a statement of the cases from the wards of the Johns Hopkins Hospital.

*(To be continued.)*

## Recent Literature.

*Memoranda and Tables of Human Anatomy.* Vol. I, with a preface by Prof. James E. Garretson, Muscles and Ligaments, by Justin Harold, A.M., M.D., and Sebastian J. Wimmer, M.A., M.D., A.M., M.D. Philadelphia: The Medical Publishing Co. 1894.

A very prettily got up compendium.

*Dissections Illustrated.* By C. Gordon Brodie, F.R.C.S., In four parts. Part IV, The Abdomen. London: Whitaker & Co. New York: MacMillan & Co., 1895.

This is the fourth and last part of this series of colored plates, with very short descriptions of them. Enough has been said of the preceding ones to show that we find much to praise, though the treatment is limited.

*Travaux d'Electrotherapie Gynécologique.* By Dr. G. Apostoli. Paris, 1894.

This is the first half-yearly volume of a series founded and published by Apostoli, the object of which is to collect and translate into French all the most important articles on gynecological electro-therapy which have appeared and are appearing. The present volume of over seven hundred pages contains translations of English, American, Russian, Italian, German, Hungarian, Canadian, Belgian, Danish, Polish and Austrian articles. The importance and convenience of such a series of papers is certainly very great, and their value is increased by foot-notes and annotations by the editor.

## THE TREATMENT OF TETANY BY THYROID EXTRACT.

IN view of the continued interest associated with the subject of the diseased thyroid gland, any new information from trustworthy sources should be heartily welcomed. Dr. Byrom Bramwell writes, in a recent number of the *British Medical Journal*, of the relationship of tetany to removal of the thyroid gland, and draws therefrom interesting and important conclusions as to the employment of thyroid feeding in the former condition.

He refers first to a case seen in consultation, in which tetany had supervened upon removal of the thyroid. To this patient small doses of thyroid extract had been given without appreciable effect. By largely increasing the amount, however, a speedy improvement followed by ultimate cure resulted.

The fact of tetany occurring after complete removal of the thyroid has been established by a large number of observations. Gowers, for example, says: — "when the whole thyroid is removed tetany supervenes in about one-sixth of the cases. The symptoms of tetany set in during the first ten days after the operation. It does not follow partial extirpation. It had been observed in association with atrophy of the thyroid and myxedema."

Dr. Bramwell's view of this operative tetany is that it is merely one manifestation of acute myxedema, and that it is the result of the arrested thyroid secretion. That such otherwise fatal tetany may be cured, as in the above case, by thyroid extract tend to the confirmation of this view; the acute myxedema, however, of which the tetany is but a symptom, is more properly to be regarded as the cause of death, than the tetany itself.

From a consideration of the striking dependence of tetany upon the integrity of the thyroid gland, as shown by operative removal of the gland, Dr. Bramwell arrives at the conclusion that ordinary, so-called idiopathic tetany may be due simply to deficient thyroid secretion and therefore might be cured by the administration of thyroid extract.

An opportunity soon offered itself of testing his theory clinically, with a result, which seems certainly to justify his position. The details of his case are of such interest that we shall give them at some length.

The patient was a boy of eight who had been suffering from tetany for more than a year, with slight and merely temporary relief from bromide of potash and chloral hydrate. The case was a perfectly typical one, characterized by frequent and severe spasms, affecting the muscles of the hands, feet, arms, legs, chest and larynx. Pain was at times extreme; the temperature subnormal. The patient was worse in cold weather, as is usually the case, a fact again which points toward the relationship between tetany and myxedema, since myxedema is also aggravated and even induced by cold. Regarding this case, which had passed out of Dr. Bramwell's personal care, he advised, in consultation, a thyroid treatment for the following reasons:

(1) Total extirpation of the thyroid gland is followed in a considerable proportion of cases by the development of tetany. This form of tetany is often fatal.

(2) In some cases, at all events, this operative tetany can be promptly arrested and cured by the internal administration of thyroid extract.

(3) Operative tetany is in all probability merely a manifestation (symptom) of acute myxedema and due to arrested thyroid secretion.

(4) Idiopathic tetany, like idiopathic myxedema, seems to be induced and aggravated by cold.

(5) It is not improbable, therefore, that idiopathic tetany may be the result of defective thyroid secretion.

(6) If this is so it is probable that idiopathic tetany can, like idiopathic myxedema, be cured by the administration of thyroid extract.

The treatment was carried out with the result that improvement began immediately, and went on to almost complete cure. The annoying symptoms of spasm, pain, headache, and palpitation, passed off. Two months after beginning treatment there had been no return of the spasms, and the mental condition was decidedly better. The patient was able to go to school and take an interest in his tasks.

Although one case under ordinary circumstances, could hardly serve as the basis of a generalization, Dr. Bramwell thinks, since the remedy was given with a definite therapeutic object in view, based on a clear line of reasoning, that certain just deductions may be drawn. It seems to him reasonable, as it certainly does to us, that in some cases, at least, idiopathic, like operative tetany, is due to defective thyroid secretion and may be arrested and cured by the administration of thyroid extract.

His final conclusions are as follows:

It is highly probable that the thyroid extract will be found to be a valuable remedy in some other cases of tetany. I do not say in all cases, for it is possible that the clinical condition which we term tetany may, like the clinical condition which we term an epileptiform convulsion for example, be due to a variety of different causes; hence it does not follow that because thyroid extract can cure operative tetany and some cases of idiopathic tetany, that it will cure all cases of idiopathic tetany.

Idiopathic tetany is a comparatively common condition in

young children, but is rare in older children and in adults. It is possible that the infantile and the older cases may be due to different conditions, and that thyroid extract may cure the older cases but may be useless in the infantile cases. Whether this is so or not can only be determined by direct observation and therapeutic research.

Infantile tetany is in the vast majority of cases associated with rickets. Like laryngismus stridulus, it is merely a manifestation of rickets, and it is important to remember that it is usually very amenable to treatment, easily cured by appropriate feeding, milk, fresh air, tonics, cod-liver oil, the syrup of phosphates, lacto-phosphate of lime, bromide of potassium, and chloral hydrate. Further, in many cases it tends to get well itself. These facts must be kept in mind in drawing conclusions as to the effects of the thyroid extract in the treatment of this, the ordinary infantile form of tetany.

I am anxious then to know whether (*a*) the ordinary infantile form and (*b*) the rarer adult form of tetany can be arrested and cured by the administration of thyroid extract.

If it should prove to be the case that the ordinary form of infantile tetany is arrested by the administration of thyroid extract, it will, I think, be reasonable to conclude that it, like operative tetany, is due to deficiency of the thyroid secretion. But, further, if the ordinary form of infantile tetany, which seems merely to be a manifestation of rickets, can be cured and arrested by the administration of thyroid extract, it will be very interesting and important to note the effect which thyroid extract (or, preferably, perhaps, thymus extract) has in cases of rickets and laryngismus stridulus.

Dr. Bramwell hopes that his preliminary consideration of the etiology of tetany in its possible relation to the thyroid gland may lead others, whose clinical opportunities may be greater than his own, to investigate the matter further. His case and its outcome under thyroid feeding, would most certainly justify any to whom the opportunity offers, in faithfully employing thyroid extract in cases of primary tetany as well as in those supervening upon complete thyroidectomy.

## THE BACTERIOLOGY OF WATER-SUPPLIES.

In response to the call of the American Public Health Association through Surgeon Charles Smart, U. S. A., its chairman, about forty bacteriologists met at the New York Academy of Medicine, June 21st and 22d, for the purpose of establishing some common plan for systematic work in bacteriology, and especially the bacteriology of water-supplies. The papers on the programme were listened to with attention, and discussed in a most free and informal manner. The convention was presided over by Prof. W. H. Welch, of Baltimore; and much of the success of meetings was due to his skill, tact and suggestiveness in directing the discussion.

In one way the meetings proved to be a great success, showing clearly, as they did, the inside workings of many of the best-known laboratories of the country. And this knowledge, together with the opportunities of personal acquaintance and estimation, made every one feel that the time had been well spent. Throughout the discussions the impression made was the absolute honesty of the speakers, and their perfect willingness to expose their defeats as well as their successes. It was most interesting and encouraging to find out how universal was the dissatisfaction with the existing methods of definitely differentiating bacteria. At the same time one could not help having a feeling of disappointment that there were not more positive suggestions from the readers; for, with the exception of the work of the gentlemen connected with the Massachusetts Board of Health, there was little that was new, positive and constructive presented to the convention. However, it cannot result otherwise than that so many men coming together and freely recognizing their limitations must be productive of much good in the near future.

A committee was appointed to consider both the papers presented and the discussion that followed, and to make a report to the American Health Association as to the most desirable methods to be observed to secure the greatest uniformity in the results of the bacteriological examination of water. The names of this committee are sufficient to give surety that this important work will be well done. They are Prof. W. H. Welch, M.D., Chairman; Prof. W. Sedgwick, Ph.D.; Prof. Theobald Smith, M.D.; Prof. T. M. Prudden, M.D.; Prof. J. G. Adami, M.D.; George W. Fuller, S.B.; Prof. A. C. Abbott, M.D.; Prof. V. A. Moore, B.A., M.D.

A further suggestion was made which was of the greatest importance. Realizing that the chief result which the convention had arrived at was the recognition of a large number of unsolved problems in what may be called fundamental bacteriology, the committee were instructed to formulate a number of these questions and refer them to the various laboratories for work, possible solution and future report. If this is carried out, it will mean an association of the best laboratories of America, all working under practically the same methods, and whose results, when given to the public, will be in terms that can be interpreted by every one conversant with the subject. Having the utmost confidence that the difficult task imposed upon the committee will be well done, and from the *esprit du corps* created by the meetings, the convention may be said to have been a great success.

## MEDICAL NOTES.

A MEETING OF THE AMERICAN ACADEMY OF RAILWAY SURGEONS will be held in Chicago on September 25th, 26th and 27th, 1895.

THE BRITISH MEDICAL JOURNAL. — The receipts of the *British Medical Journal* last year were $176,000; the expenses were over $150,000. The total assets over liabilities exceed $279,000.

MEDICINE IN TOKYO. — In Tokyo a recent census has shown that the city contains 2,315 medical men, 70 dentists, 69 veterinary surgeons, 371 pharmaceutical chemists, two city hospitals, three government hospitals, and 41 private hospitals.

A KINDERGARTEN FOR DEAF AND DUMB CHILDREN. — A kindergarten for deaf and dumb children was opened in Berlin in April, in 1894. The first annual report which has lately been issued, shows

that excellent results have been accomplished with the fourteen children who have attended the school during its first year.

GOITRE IN THE HIGH ALPS. — Leon Jacques is of opinion that endemic goitre is an infectious disease, the germ of which is not yet isolated, but which exists in the water, soil, air and fruits of the infected area. The inhabitants are predisposed by certain secondary influences — poor water, vitiated air, unhealthy dwellings, poor food and, above all else as a determining cause, the influence of extreme temperatures, that is, excessive cold and heat acting alternately. Removal of these causes will nearly exterminate the disease; and the author demands the establishment of cisterns in the infected villages, the construction of roads and better homes, and the suppression of marriages between goitrous subjects. In its incipiency goitre is best combated by iodine; at a more advanced stage it is amenable to surgical measures. — *Journal of the American Medical Association.*

"LES SONNETS DU DOCTEUR." — Noir, in *Le Progrès Médical*, gives the following extract from "Les Sonnets du Docteur," by Camuset, descriptive of the self-congratulatory feelings of an aged physician on returning from a visit to the labyrinths of the Marquis de Rambuteau.

Moi, j'en sors souriant, car j'eus des mœurs austères.
Mes organes sont purs comme ceux des agneaux.
L'âge les rend peut-être un peu moins génitaux,
Mais ils sont demeurés largement urinaires.

THE POWER OF IMAGINATION. — A man was recently admitted to the Bootle Hospital suffering from all the symptoms of opium-poisoning, and he confessed to having swallowed three-pennyworth of the drug. On inquiry, however, from the chemist who was stated to have supplied the laudanum, it transpired that the chemist, being suspicious of the intention of the customer, did not supply him with the laudanum undiluted, but with a mixture of twenty drops in a small quantity of colored water. The victim naturally recovered, but not till he had undergone the agonies, physical and mental, of opium-poisoning.

RESULTS OF THE TREATMENT OF CANCER BY STREPTOCOCCUS TOXINES. — In *La Médecine Moderne*, June 1, 1895, are given some rather discouraging reports on the treatment of cancer by this method. Bruns announces that in six cases of cancer he has seen no improvement under this treatment; and Petersen remarks with regard to the six cases reported by Emmerich and Scholl, it is only necessary to read their accounts of the cases to see that they are as little "cured" as possible. Angerer has just given the medical society of Munich a further report on one of the cases treated by Emmerich in his service. The woman in question died of cancerous cachexia at her home just one month before the publication of Emmerich and Scholl's memoir, in which she was presented as a permanent, or at least temporary, cure. The cure seems to have been temporary in the extreme sense of the word.

A CASE OF HYPERPYREXIA. — Alfred Stanley in the *British Medical Journal* of May 25th, reports a case of pleurisy and pneumonia, in which the temperature twice reached the extraordinary level of 114°. How much higher it may have gone is not known, as the writer states that the thermometer was marked as high as 110°, but that there was space for four degrees above this mark, and the mercury filled that space to the top. This reading was checked by two other thermometers, which registered the same. During these extraordinary excursions of temperature, which only lasted from two to four hours, the pulse remained between 84 and 96, and there was no pain nor delirium, but the patient complained of loss of sensation in the hands and feet. The case recovered, and the doctor had his thermometer tested at Kew Observatory, and found it practically correct.

## BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — During the week ending at noon, June 26, 1895, there were reported to the Board of Health, of Boston, the following numbers of cases of acute infectious disease: diphtheria 88, scarlet fever 23, measles 88, typhoid fever 15.

ACADEMIC HONORS TO PROFESSOR PARK AND PROFESSOR DOCK. — Harvard College has conferred the A.M. degree *honoris causa* upon Prof. Roswell Park, M.D., of Buffalo, N. Y., and upon Prof. George Dock, M.D., of Ann Arbor, Mich.

MEDICAL REGISTRATION. — As a result of the examination held by the Massachusetts Board of Registration in Medicine on June 4th, twenty of the twenty-eight applicants examined were accepted.

THE HARVARD DENTAL ALUMNI ASSOCIATION. — The annual reunion and dinner of the Harvard Dental Alumni Association was held at the Hotel Thorndike last Monday evening. Dr. D. M. Clapp presided, and the speakers were M. C. Ayres, editor of the *Advertiser*, Rev. A. E. Winship, editor of the *Journal of Education*, Hon. C. F. Adams, Hon. Sherman Hoar, Prof. V. B. Loring, Dr. W. M. Conant and others. Professor Fillebrown of the Dental School gave some information of interest concerning the school, referring to the fact that the faculty has just raised the standard of the institution by stiffening the requirements for entrance, proficiency in either Latin or French being henceforth obligatory. Recent improvements in material facilities at the school, have perhaps, said the speaker, postponed the erection of the expected new building. A letter was read from Dr. C. A. Brackett, of Newport, expressive of the sympathy felt by the members of the Association for Dr. T. H. Chandler, who has been connected with the Harvard Dental School almost from its inception. Dean Chandler has been quite ill for a considerable time. At the business meeting Dr. Potter read a report concerning the Dental School, which stated the building fund to be in good condition. These officers were elected: President, James Shephard; Vice-

President, Frank Perrin; Secretary, W. S. Boardman; Treasurer, W. E. Page; Executive Committee, W. E. Boardman, W. P. Cooke, D. W. Moriarty.

Trustees of the Massachusetts Hospital for Epileptics. — Governor Greenhalge has appointed as trustees of the Massachusetts Hospital for Epileptics: Dr. William N. Bullard, of Boston, five years; Mabel W. Stedman, Boston, four years; Charles A. Clough, Boston, four years; Dr. Albert C. Getchell, Worcester, three years; Adelaide A. Calkins, Springfield, two years; Dr. Roswell B. Benner, Lowell, two years; Francis L. Higginson, Boston, one year.

Officers of the New Hampshire Medical Society. — At the Annual Meeting of the New Hampshire Medical Society at Concord, N. H., on June 4th, the following officers were elected for the ensuing year: President, E. F. McQuesten, Nashua. Vice-President, A. P. Richardson, Walpole. Treasurer, M. H. Felt, Hillsboro Bridge. Secretary, Granville P. Conn, Concord. Executive Committee, Charles R. Walker, Concord; George D. Towne, Manchester; F. A. Stillings, Concord; W. T. Smith, Hanover; F. E. Kittredge, Nashua. Officers of the Board to Issue Licenses: President D. C. Adams, Manchester; Secretary, T. Hiland, Concord; Associate; J. W. Parsons, Portsmouth. Delegates to the various societies were also elected. After the adjournment the anniversary dinner was served at the new Eagle Hotel.

NEW YORK.

Commencement at the College of Physicians and Surgeons. — The commencement of the College of Physicians and Surgeons was held, in connection with that of Columbia University, at Carnegie Hall on the evening of June 12th. A class of 192 was graduated, and before the candidates received their diplomas the Hippocratic oath was administered to them by Prof. John G. Curtis. Among the degrees conferred by the University was that of LL.D. upon Thomas Messinger Brown, M.D., President-elect of Lehigh University. The Cartwright biennial prize of $500, for the best medical essay submitted, was awarded to Dr. James Ewing, whose subject was antitoxin treatment.

Successful Treatment of a Broken Neck. — A lady whose neck was recently broken by a fall from a hammock, and whose case was treated by Drs. Reginald Sayre and H. W. Frauenthal, is reported as doing well and in a fair way of recovery.

Changes in the Staff of the Harlem Hospital. — The Commissioners of Charities and Correction have removed the entire medical board of Harlem Hospital, owing to certain complaints as to neglect of patients and other changes, and decided to appoint a new board of eight physicians and surgeons. The selection of this new visiting staff is to be made by the governing faculties of the College of Physicians and Surgeons, the Medical Department of the University of the City of New York, and Bellevue Hospital Medical College. Considerable dissatisfaction with this arrangement is expressed by medical men not connected with either of the three schools named, and especially by those interested in the Polyclinic and Post-Graduate Schools.

Veto of the Bill for the Transfer of the Dependent Insane. — Governor Morton has finally decided not to approve the Conkling bill, providing for the transfer of the New York City dependent insane to the care of the State, which was returned to the governor by Mayor Strong without taking action thereon. The governor filed a memorandum on the bill giving his reasons for the decision, in which he discusses at length his power under the new Constitution when a bill has been rejected or approved by the mayor. In conclusion, he says: "I deeply regret the condition produced by the failure of the mayor to approve this bill, but I cannot, in a conscientious performance of my constitutional duty, add to the unfortunate result of the mayor's want of action, a plain violation of the Constitution." Much influence was brought to bear upon Governor Morton to induce him to sign this bill, especially by the State Commission in Lunacy, who urged that the measure was in accordance with the will and desire of the people, in both State and County, as expressed by a unanimous vote in both Houses of the Legislature. The unsatisfactory and over-crowded condition of the insane asylums under city management was also dwelt upon with much emphasis.

A Bill for the Study of the Effects of Alcohol and Narcotics. — The governor has signed the Ainsworth bill providing for a broader study of the nature and effects of alcoholic drinks and narcotics in connection with physiology and hygiene in the public schools. With the bill he filed the following memorandum: "The fact that the Legislatures of forty-one States, including our own, and the Congress of the United States, have already passed laws providing for instruction in the subjects indicated in this bill, shows that it is supported by a widespread public sentiment; and inasmuch as this bill seeks to simplify and reduce to a more systematic method the study of the effects of alcoholic drinks and narcotics upon the human system, without necessarily decreasing the amount of study required by the present law, I think it should receive executive approval."

A Recovery from a Tremendous Electrical Shock. — On June 21st the foreman of the Rochester gas and electricity was accidentally exposed for some seconds to an electric current said to have been of a strength of 2,899 volts. Life was apparently destroyed by the shock, but efforts at resuscitation were at once commenced, and after 45 minutes' employment of artificial respiration and other measures the first sign of life was noticed. Then natural breathing began and in half an hour more he opened his eyes and recognized those about him. His body was considerably

burned, but otherwise the patient is now said to be quite well.

BEQUESTS TO ST. LUKE'S HOSPITAL. — By the will of the late Rufus Waterhouse the bulk of his estate, amounting to about $200,000, is left to St. Luke's Hospital for the purpose of establishing and maintaining the "Mary S. Waterhouse Memorial Ward" for consumptive sewing women or consumptives dependent upon sewing women. Mr. Waterhouse was a large manufacturer of men's furnishing goods. His wife, whose name the ward will bear, died of phthisis, and he saw many of the young women whom he employed stricken with the disease and unable to support themselves. He died a widower and childless. The will of Percy H. Pyne, who died at Rome, Italy, on February 11th, also leaves $20,000 to St. Luke's Hospital.

DEATH OF DR. SALTONSTALL. — Dr. Gilbert Saltonstall, Health Inspector of Jersey City, died suddenly at his home in that city on June 15th. He was sixty-six years of age, and had served as Health Inspector since 1880.

DEATH OF DR. MEEKS.— Dr. Meeks, of Stamford, Conn., died recently at the Presbyterian Hospital, of typhoid fever. Since April 21st there have been considerably over four hundred cases and about thirty deaths from the outbreak of typhoid in Stamford which was traced to a contaminated well on a milkman's premises. A full account of the epidemic was given in the JOURNAL of May 9th.

## Miscellany.

### A NOVEL FORM OF OBSTACLE RACE.[1]

SOME years ago a favorite comic song at suburban evening parties recorded the adventures of a man with a "cork leg," which, if we remember right, ran away with its owner. If races of the kind which recently took place at Nogent-sur-Marne become fashionable, a modern Pindar will be required to celebrate the swiftness of wooden legs. The "events" were arranged for runners who had had the lower limb amputated above the knee (*cuissards*), and for those who had lost a leg below the knee (*jambards*). The distance in each case was 200 metres. In the final heat for the "grand championship" the prize among the "thigh-ers" fell to M. Roulin, who did the distance in excellent style in 30 seconds. Among the "leggers" the victor was M. Florant, who travelled over the same course in 36 seconds. It is worthy of note that the "thigh-ers" on the whole, showed better form than the "leggers," two others — MM. Blangy and Jhienne — having in earlier heats done their 200 metres in 30 and 33 seconds respectively, while the fastest time among the "leggers" was 36. The longest time among runners who were "placed" was 55 seconds. Several of the runners were over fifty years of age. The champion, Roulin, who belongs to Orleans, is thirty years of age, and lost his leg as the result of an accident when he was twenty-two. This interesting athletic contest may possibly lead to boxing matches for men who have lost an arm, but it is hoped that we shall be spared a singing competition among persons with artificial larynxes.

## OBITUARY.

### HENRY WILLARD WILLIAMS, A.M., M.D.

IN speaking of Dr. Henry W. Williams we shall confine ourselves to his professional career. It is just to do so; for he, more than others, has impressed his strong personality on his medical brethren, as he lived and worked largely for them. He was, all in all, a doctor first, and other things afterwards.

Of large stature and strong character, he was a conspicuous figure on all medical occasions. He was familiar to all as a frequent and forcible, but persuasive speaker; and an excellent presiding officer.

He always had the welfare of the Massachusetts Medical Society at heart.

Conservative to a fault, he yet was kindly and thoughtful of his medical brothers. He was one of the founders of the Massachusetts Medical Benevolent Society, and long its president.

His own life was a marked instance of success achieved by untiring patience, punctuality and conscientious discharge of public duty, as well as by much ability as a hospital surgeon and teacher. Three times a week, for twenty-six years, his carriage entered the hospital gate at nine o'clock, every morning; and he devoted two or three hours to a laborious eye clinic.

Unlike some specialists, he broadened his mind by being first a general practitioner.

The writer recalls well the evenings in his little office in Essex Street, where eye cases were gathered in from a poor neighborhood, to instruct a small class of medical students. So, too, one remembers toiling with him and with his able colleague, Dr. Charles E. Buckingham, at the sparsely attended clinics of the City Hospital in its early days, when the labor was great and the reward small.

As an operator on the eye, few equalled him. He was ambidexterous: and to see him extract a double cataract, first with the right hand and then with the left, with equal precision and grace, was a surgical *coup* never to be forgotten.

He did not grow old, but retained his enthusiasm to a remarkable degree; and in middle age he went abroad to master the ophthalmoscope, and the application of the laws of optics to astigmatism.

He was a consistent and steady opponent of the admission of women to the medical profession. But he was as sturdy and honest in suppressing quackery, as in favoring his weaker medical brothers with professional advice and with substantial aid.

Occupying with success a chair of ophthalmology in the Harvard Medical School, he marked his appreciation of its worth, by endowing it from his private earnings.

His mind was virile, set, consistent, naturally meeting with and contending with opposition.

He left his mark on his times and on our community.

And to how few is it permitted, in the course of Nature, to live to see six sons grown up, three of them in one's own profession, and to have one's remains borne to the funeral altar on their shoulders!

D. W. C.

Ophthalmic Surgeon, Boston City Hospital, 1864 to 1891.
Professor of Ophthalmology, Harvard Medical School, 1868 to 1890.
Honorary Master of Arts, 1868.
Honorary Member Phi Beta Kappa, 1871.
Boylston Prize Essayist, 1868.
Founder Massachusetts Medical Benevolent Society, 1869.
President Massachusetts Medical Society, 1880 to 1882.
President and Founder of the American Ophthalmological Society.
Fellow of the American Academy of Arts and Sciences.
Author of numerous monographs, and of two distinct treatises on the eye.

## Correspondence.

### MASSACHUSETTS REGISTRATION REPORT.

SPRINGFIELD, MASS., June, 1895.

MR. EDITOR: — Having been engaged in preparing a paper upon certain phases of the divorce question for a club in this city, I was referred to the Massachusetts Registration Report for certain information which I desired. I find, however, on consulting the last report for 1893, that it is extremely untrustworthy, so far as any correct information can be had. I desired to know how long divorced people live together before obtaining divorce, and find a table on page 132 which pretends to answer this question; but the compiler has in this table contented himself with a defective method of dividing the sum of five averages by five to obtain a five-year mean, without noticing that the factors from which his averages are obtained are not uniform, hence the footing of each of his ten columns is incorrect, and this vitiates most of the figures on the following page. For example, 9.19 should read 9.93; 10.96 should read 10.34; 7.03 should read 6.87, etc. These figures may be verified by consulting the reports of the previous years.

On turning to other pages I find that a similar defective method has been employed in other instances; and what makes the matter worse is the fact that the compiler states in a somewhat boasting manner, for a public document, that these figures "have been made with the greatest care, and that they have been reviewed by an able and experienced statistician wholly familiar with vital statistics."

On examining this report more carefully, and comparing it with some early reports previous to 1860 which I obtained at a second-hand bookstore, I find it to be utterly defective and untrustworthy, and by compared with the excellent work of those worthy men, Dr. A. Gould, Mr. Shattuck and others which made our State a shining example in this respect, this report shows a lamentable falling off.

Now a careful examination of one or two of these reports shows that they are the result of the compilation of the work, mainly of the physicians and clergy of the State, who make their returns directly to the city and town authorities, and these authorities in turn send them to the Secretary of State. It certainly is an injustice to these gentlemen that their work is not fairly represented.

If there is any reason why the official who has this work in charge should thus depreciate its value, it is time that his reason should be known. I asked one of the local physicians about the matter, and he informed me that, for the past few years the entire medical profession has given up all confidence in this report, in consequence of its inaccuracy and its disregard of the general opinion of the profession, which demands better and more useful work. On asking him whether any paper or journal had taken special interest in this matter, he kindly referred me to your journal, and hence this letter. Yours very truly,

SPRINGFIELD PARSON.

### BICYCLE SADDLES.

BALTIMORE, 11 MT. VERNON PLACE,
June 22, 1895.

MR. EDITOR: — I have found an unusually long saddle, with but little dip to the seat and almost no elevation of the anterior projection which meets in some instances the objection urged by Dr. Chadwick. It is also in my opinion the safest saddle for men.

Such an one was formerly manufactured and known as the "Sager Saddle"; but is now, I believe, out of style, and can only be procured second-hand.

By proper tilting, a most secure seat is obtained directly upon the tuberosities of the ischia, without noticeable pressure anteriorly. Yours, etc., H. B. J.

### METEOROLOGICAL RECORD.

For the week ending June 15th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

| Date. | Barometer | Thermometer. | | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | We'th'r. * | | Rainfall in inches. |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Daily mean. | Daily mean. | Maximum. | Minimum. | 8.00 A. M. | 8.00 P. M. | Daily mean. | 8.00 A. M. | 8.00 P. M. | 8.00 A. M. | 8.00 P. M. | 8.00 A. M. | 8.00 P. M. | |

| Quincy | 19,642 | 8 | 3 | — | — | — | — | — |
| Pittsfield | 18,892 | 9 | 2 | 11.11 | — | — | — | — |
| Everett | 16,585 | 3 | 0 | — | 66.66 | — | — | — |
| Northampton | 16,331 | 1 | 0 | — | — | — | — | — |
| Newburyport | 14,073 | — | — | — | — | — | — | — |
| Amesbury | 10,920 | 3 | 0 | — | 33.33 | — | — | — |

Deaths reported 2,157; under five years of age 750; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrheal diseases, whooping-cough, erysipelas and fevers) 321, acute lung diseases 200, consumption 321, diphtheria and croup 109, diarrheal diseases 69, measles 63, scarlet fever 20, whooping-cough 21, typhoid fever 26, cerebro-spinal meningitis 6, erysipelas 3.

From typhoid fever Philadelphia 11, New York 5, Boston, and Washington 2 each. Brooklyn, Cleveland, Providence, Worcester, Cambridge and New Bedford 1 each. From whooping-cough New York 9, Brooklyn 4, Philadelphia 3, Boston, Cincinnati, Cleveland, Cambridge and Haverhill 1 each. From scarlet fever New York 8, Boston 3, Cleveland 2, Philadelphia, Brooklyn, Providence, Cambridge, Salem, Haverhill and Everett 1 each. From cerebro-spinal meningitis New York 3, Bos-

ton, Cleveland and Worcester 1 each. From erysipelas New York 2, Philadelphia and Pittsburg 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,591,530 for the week ending June 1st, the death-rate was 17.2. ## THE THIRD INTERNATIONAL CONGRESS OF PHYSIOLOGISTS.

The Third International Congress of Physiologists will be held in September, 1895, from the 10th to the 14th of the month, at Bern, Switzerland. Professor Kronecker, Director of the Physiological Institute of the University of Bern, has kindly expressed his readiness to afford to Members of the Congress all facilities for demonstration and experiment, as well as for the exhibition of scientific apparatus. It is particularly desirable that those intending to avail themselves of Professor Kronecker's assistance should let him know what their requirements are not later than June 30th.

In connection with the Congress, an Exhibition of Physiological Apparatus will be held. Exhibits may be contributed by all Members of the Congress, by the Directors of Physiological Laboratories, and by makers recommended by any Member of the Congress, or by the Director of a Physiological Laboratory. The exhibition of apparatus will open two days before the Congress, and will close two days after the Congress.

Those intending to be present and to make communications are requested to notify Professor Kronecker, of Bern, or the Secretary for the English Language, before August 1st, giving, if possible, the title of their communications.

Each member of the Congress is required to contribute the sum of ten francs toward defraying the expenses of the Meetings; he will obtain in receipt from the President, Professor Kronecker, a card of membership of the Congress.

C. S. SHERRINGTON,
*General Secretary for the English Language.*

## APPOINTMENT.

DR. EDWIN W. DWIGHT has been appointed by Governor Greenhalge, Assistant to the Commissioners of Public Institutions.
